Honored Life Member
John B. Glude

John Glude was born August 2, 1918 to William and Florence Glud of Silverdale, Washington. William Glud worked at the Bremerton Naval Shipyard and Florence worked as an elementary school teacher. Growing up in the Silverdale area with his brother Clarence, John got his first taste of aquaculture when his father had two ponds on the property where trout were raised. The fact that he was able to be involved with raising trout got him interested in aquaculture, which he continued to pursue and later became known for.

Along with his skills related to farming, building, and raising fish, he helped his father create an innovative system for generating electricity by taking advantage of the changing elevation of the stream entering their property. A wooden sluice carried water from the stream to the pond. There the water was released, falling into cups on the paddle wheel they had constructed. Through a series of axles and gears, enough force was created to generate all the electricity they needed. They were the first in the area to have electric lights.

John attended grade school and high school in Silverdale from which he graduated in 1935 as class salutatorian at the age of 16. He then entered the University of Washington received his Bachelor of Science degree in Fisheries in 1939, with a major in Fisheries and a minor in Engineering. He then got his first job with the Washington Department of Fisheries (WDF), but left briefly during World War II. He put his education in engineering to work by taking a job as a naval architect draftsman at the Tacoma Naval Shipyard. His work was considered vital to the war effort. After the war was over, he returned to his position as a Fishery Biologist with the WDF. He was then involved with research to determine the effects of polluted waters from pulp mills on oysters. This work formed the basis for regulatory actions to reduce sulfite liquor waste from pulp mills, which set the stage for assisting in the preservation of the valuable oyster resources in the state of Washington.

After the war, John was sent to Japan to inspect sea oysters for export to the United States to prevent contamination and/or introduction of undesirable organisms to the west coast oyster growing areas. Cedric Lindsay was a colleague of John's with the WDF who also went along with him on some of the early trips to Japan to inspect seed oysters for importation to the United States. These trips ultimately led to major seed importation to the Pacific coast of the United States and thus maintained the major oyster fisheries until recent years when seed shipment from Japan was no longer necessary. There John learned a great deal about the various Japanese methods for culturing oysters and other species which he brought back to the United States to share with growers.

In 1948, John was offered a position at the Woods Hole Oceanographic Institute in Woods Hole, Massachusetts. The main emphasis during that time was research on the abundance and survival of soft shell clams throughout the entire U.S. east coast. The research project was moved the following year to a former fish hatchery at Boothbay Harbor, Maine. He continued his research on softshell clam populations and other species found in the region. During this time, he became lab director of the Boothbay Harbor facility and instituted further research on artificial propagation of clams and other species. Some of the earlier efforts were relative to wild catches of soft shell clams, but were also concerned with hatchery setting. He also studied the effects of green crab predation and their control. The research during those years on the soft shell clam was ground-breaking and is still referred to extensively.

John continued his career in the federal government with the U.S. Fish and Wildlife Service and the subsequent National Marine Fisheries Services (NMFS) under the National Oceanographic and Atmospheric Administration (NOAA). He later became director of the NMFS Laboratory in Annapolis, Maryland where he moved in 1956 with his wife Jean, daughter Nancy and son Terry. This laboratory was primarily engaged in research to develop methods for farming shellfish (main emphasis on oysters). With the lab's closure, John was offered a position in the national headquarters of NMFS in Washington, D.C. While there, he was in charge of the shellfish research branch of the NMFS and responsible for seven regional laboratories. At that time, he developed the first National Aquaculture Plan through NOAA.

During President Kennedy's Administration, John was appointed to lead a team of fisheries experts to assist Ireland in improving their fisheries resources. He spent one year on this project and recommended many changes to the Irish Department of Fisheries which were implemented to improve the economic situation.

Yearning to return to the northwest and the state of Washington, John accepted a position of Assistant Regional Director of the Northwest Region of the National Marine Fisheries Service, which was headquartered in Seattle, Washington. His family moved back to the state where John not only oversaw federal fisheries research in the area but also pushed to promote and implement the NOAA National Aquaculture Plan.

Upon retirement in Seattle, John started the Glude Aquaculture Consultants. Much of his work involved aquaculture, and he was a primary consultant for numerous aquaculture projects in various countries. He continued to encourage aquaculture enterprises and eventually organized a program in Puerto Rico to test the applicability of known culture methods for fresh water prawns. John also acted as a consultant for the United Nations Food and Agriculture Organization where he headed a team of scientists to determine how to increase fishery resources and revenues in a number of developing countries. One project was entitled "The South Pacific Fisheries Investigation" through which recommendations were provided for best approaches to increase fisheries activities for the regions.

John has been a life member of several professional organizations. He served as Vice President and President of the World Aquaculture Society in 1977 and 1978, respectively. He also served for two years as president of the National Shellfisheries Association in 1963–65. Along with this service to the societies, he has published over 100 scientific papers related to his many areas of shellfish research. John is retired now, but he is most certainly a pioneer in the fields of aquaculture and fisheries, best known for his research on clam and oyster culture. An avid sportsman, his love for fly-fishing and duck hunting is well recognized. I have been on many duck hunting trips with John and his brother-in-law Dick Steele in Dabob Bay, Hood canal in Washington State and know of his obsession with bird hunting. John now resides at 6101 River Crescent Drive, Annapolis, MD 21401.

GROWTH OF THE NORTHERN QUAHOG, *MERCENARIA MERCENARIA*, IN AN EXPERIMENTAL-SCALE UPWELLER

CRAIG L. APPLEYARD AND JOSEPH T. DEALTERIS

Department of Fisheries, Animal and Veterinary Science, University of Rhode Island,
Kingston, Rhode Island 02881

ABSTRACT Upwellers have proven to be extremely effective as bivalve nursery units and their use is steadily increasing in North America. The re-analysis of previous work by others suggests an asymptotic relationship between growth (% volume increase per day) and chlorophyll-*a* effective flow rate (the amount food flowing past a unit biomass of northern quahogs, μg per minute per liter of northern quahog volume). An experiment field study was conducted to define the relationship between food flow and bivalve stocking density. Furthermore, this study was designed to investigate other significant environmental parameters influencing bivalve growth in an experimental-scale upweller system.

Northern quahog, *Mercenaria mercenaria* (Linné), seed were grown from ~2 (longest axis) to ~13 mm in an experimental-scale floating upweller from June 21 to August 19, 1999 (four separate experimental periods) in Point Judith Pond, Wakefield, Rhode Island. Flow rates and stocking densities were varied in order to produce a chlorophyll-*a* effective flow rate range of 360 to 1,500 $\mu g \cdot min^{-1} \cdot l^{-1}$, and growth and environmental parameters were measured semiweekly. During the first two-week experiment (June 21 to July 7) an asymptotic relationship was observed between growth (% increase/day) and chlorophyll-*a* effective flow rate. A significant difference in growth was found between the treatments. The difference in the functional relationship between experiments 1 and 3 was possibly related to lower DO values, which reduced differential growth in experiment 3. In experiment 1, the low-biomass treatments grew faster than the high-biomass treatments. A significant difference in growth between treatments was also observed in experiment 3, although the asymptotic relationship was less pronounced. In experiment 3, the high-biomass replicates grew faster than the low-biomass replicates. Experiments 1 and 3 both experienced similar environmental conditions; however, experiment 1 encountered higher morning dissolved oxygen (DO) levels. In addition, the within experiment variability in experiment 3 was much less than the variability in experiment 1; therefore, accentuating growth differences in experiment 3. In both experiments 1 and 3 maximum growth occurred near treatment 2 in a range of chlorophyll-*a* effective flow rates of 550 to 650 $\mu g \cdot min^{-1} \cdot l^{-1}$. In experiments, 2 and 4 there were no significant differences in growth between treatments.

Growth appeared to be limited by low oxygen. In order to eliminate the effect of food limitation on growth, the upper third of the replicates (the fastest growing animals) were used to calculate the relative growth rate (RGR) during the two-month experiment. Growth was linearly correlated with morning-dissolved oxygen ($R^2 = 0.42$) and with chlorophyll-*a* ($R^2 = 0.35$). The critical DO threshold for growth in upwellers appears to be 5 ppm, below which growth is adversely affected. During this study, morning DO levels were less than 50 % saturated, indicating the potential for DO levels to be increased. Future research should investigate methods for elevating DO levels in upwellers.

KEY WORDS: northern quahog, *Mercenaria mercenaria*, upweller, growth

INTRODUCTION

Over the last decade, the use of upwellers as bivalve nursery units has increased dramatically in North America (Manzi & Castagna 1989). A number of studies have explored the relationships between flow rate, stocking density, and growth in upwellers (Hadley et al. 1999; Baldwin et al. 1995; Malinowski & Siddall 1989; Malinowski 1988; Manzi & Hadley 1988; Manzi et al. 1986; Manzi 1985; Hadley & Manzi 1984; Manzi et al. 1984; Bayes 1981; Claus 1981; Manzi & Whetstone 1981; Rodhouse & O'Kelly 1981). The majority of research on upwellers has focused on the northern quahog, *Mercenaria mercenaria*, because of its significant aquaculture potential. In particular, the northern quahog grows well at high densities, has adapted to a variety of geographic sites along the northeast coast, and has a lucrative market.

Manzi et al. (1986) described a qualitative relationship between flow rate, stocking density, and growth in an experimental-scale upweller. In their experiment, stocking densities were varied while flow rates were held constant. The flow rate was converted to an effective flow rate by multiplying the amount of food (μg/l of chlorophyll-*a*) by the flow rate (l/min). The amount of food passing by a unit biomass of clams was defined as the chlorophyll-*a* effective flow rate ($\mu g \cdot min^{-1} \cdot kg^{-1}$). During a period of optimal northern quahog growth in the fall 1982 the authors found that a maximum biomass increase of 267% (over 30 days) occurred at the highest chlorophyll-*a* effective flow rate of 1,929 $\mu g \cdot min^{-1} \cdot kg^{-1}$ and the most efficient growth (213%) occurred at an intermediate chlorophyll-*a* effective flow rate of 476 $\mu g \cdot min^{-1} \cdot kg^{-1}$. If growth (% increase/day) is plotted as a function of chlorophyll-*a* effective flow rate, the data is represented by an asymptotic relationship; in particular, as the chlorophyll-*a* effective flow rate increases, growth increases steeply and then levels off with increasing chlorophyll-*a* effective flow rates (Fig. 1). Efficiency in this upweller system refers to economically optimizing both upweller space (density) and pumping capacity (flow). Theoretically, growth will be optimized at some percentage of the maximum growth rate; as indicated in Figure 1, 80 to 90% of the maximum growth rate equates to a chlorophyll-*a* effective flow rate range of 470 to 700 $\mu g \cdot min^{-1} \cdot kg^{-1}$.

Manzi et al. (1986) concluded that food supply was the primary limitation in their upweller system. Their data suggests that to obtain unlimited growth, northern quahog seed needed to remove approximately 150 $\mu g \cdot min^{-1} \cdot kg^{-1}$. The investigators deduce that northern quahog growth was reduced if more than 20% of the ambient chlorophyll-*a* concentration (μg/l) was removed as water passed by the bivalves. Consequently, to supply the necessary ration of 150 $\mu g \cdot min^{-1} \cdot kg^{-1}$ without exceeding 20% removal, food must be supplied to the bivalves at a rate of 750 $\mu g \cdot min^{-1} \cdot kg^{-1}$. Malinowski and Siddall (1989) confirmed that ambient chlorophyll-*a* concentrations were reduced by ~20% through an initial

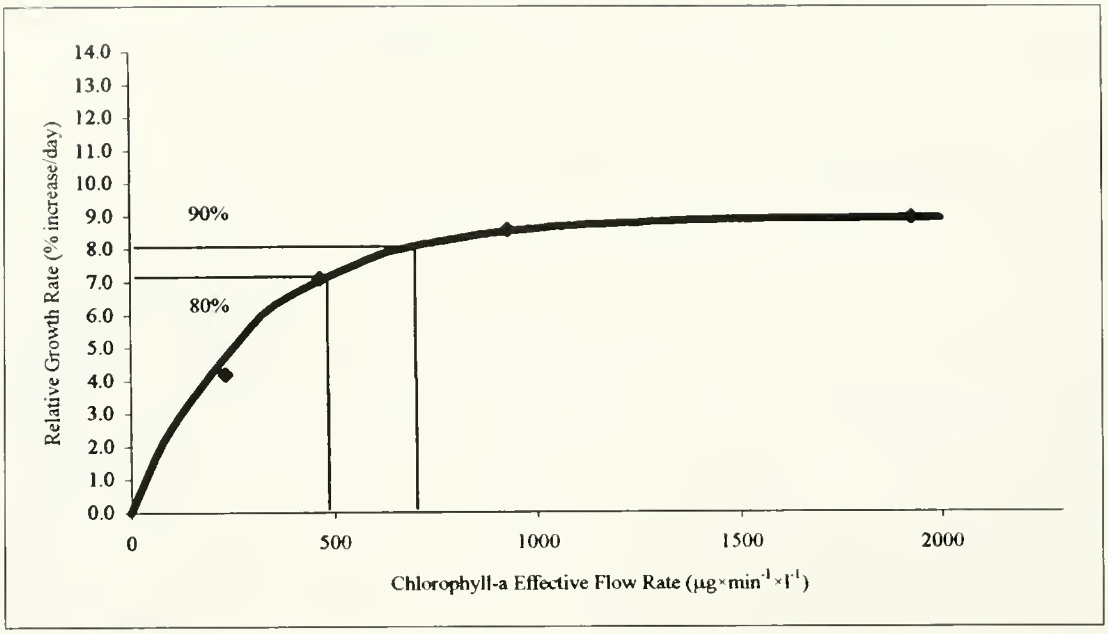

Figure 1. Growth (% increase/day) of northern quahogs as a function of chlorophyll-*a* effective flow rate re-plotted from Manzi et al. (1986).

silo of northern quahogs at similar stocking densities. However, they found that after water passed through an initial group of northern quahogs it could then support an additional equivalent biomass of northern quahogs at the same growth rate. They conclude that to achieve maximum growth of northern quahogs in an upweller it is necessary to pass more water through the animals than can actually be filtered; therefore, the low rate of chlorophyll-*a* removal reported by Manzi et al. (1986) may reflect a large amount of unused water through the system. The authors hypothesize that this surplus water may be a physical requirement of the system where minimum flow rates are required to create uniform flows through the seedbed, remove waste products, maintain water quality, and maintain a minimum concentration of chlorophyll-*a*.

Manzi et al. (1986) found that food was the primary limitation in their upweller system, while Malinowski and Siddall (1989) concluded that flow rate was the primary limitation. Malinowski and Siddall (1989) also speculate on the importance of environmental conditions, specifically water quality, but they fail to characterize these parameters in their system. Growth and survival of the northern quahog is clearly influenced by the surrounding environment. Northern quahog adults and juveniles can survive in water temperatures from 1 to 33°C, but grow optimally at 23°C (Stanley 1985; Stanley & Dewitt 1983). Northern quahogs can tolerate salinities between 10 and 35‰ (Stanley & Dewitt 1983) for short periods, but prefer to inhabit waters greater than 20‰ (Castagna & Kraeuter 1981). Northern quahogs have been known to endure oxygen concentrations below 1 mg O_2/l (Stanley & Dewitt 1983) for more than three weeks; however, growth is significantly reduced and an oxygen debt is incurred when oxygen concentrations fall below 5 mg O_2/l (Stanley & Dewitt 1983; Hamwi 1969).

Although there is a general disagreement as to the limiting parameter for growth in upwellers, in the literature growth is clearly related to both system operating parameters (flow rate and stocking density) and environmental conditions at the site (temperature and dissolved oxygen).

Given the environmental conditions in the study area, an experimental field study was conducted as to:

(1) Define a relationship between food flow, bivalve stocking density, and growth so as to determine the chlorophyll-*a* effective flow rate that optimizes growth; and
(2) Determine the most significant limiting parameter for bivalve growth in the upweller system.

The experiment monitored growth of northern quahog seed in an experimental-scale floating upweller at three ranges of nominal chlorophyll-*a* effective flow rates of 350, 600 and 1,400 $\mu g \cdot min^{-1} \cdot l^{-1}$. In addition, environmental conditions were monitored at the site.

MATERIALS AND METHODS

Experimental Design

Growth of northern quahog seed was studied over an 8-week period in an experimental-scale floating upweller system located in a nutrient-rich estuary. At the beginning of the experiment the ambient chlorophyll-*a* concentration (μg/l) was measured at the site, and flow rates and stocking densities were adjusted to achieve three nominal ranges of chlorophyll-*a* effective flow rates, including a low (~350 $\mu g \cdot min^{-1} \cdot l^{-1}$), medium (~600 $\mu g \cdot min^{-1} \cdot l^{-1}$), and high range (~1,200 $\mu g \cdot min^{-1} \cdot l^{-1}$). Each combination of effective flow rate (μg/min) and northern quahog biomass (l) or chlorophyll-*a* effective flow rate ($\mu g \cdot min^{-1} \cdot l^{-1}$) represents a treatment, as shown in Table 1. The average chlorophyll-*a* concentration during the time period was 11.70 ± 2.06 μg/l (S.E.) and the flow rates were set at 4 l/min, 6 l/min, and 8 l/min resulting in three effective flow rates of 38.36 μg/min, 57.84 μg/min, and 77.12 μg/min. The northern quahog seed were initially stocked at a biomass of 0.055 l (density of 0.3 l/cm^2) and 0.109 l (density of 0.6 l/cm^2) resulting in the desired range of chlorophyll-*a* effective flow rates. The experiment was a two (density) by three (effective flow rate) factorial design with six treatments of chlorophyll-*a* effective flow rates. Each treatment was replicated in triplicate resulting in 18 observations (silos).

TABLE 1.

Chlorophyll-*a* effective flow rates and their corresponding treatment.

Effective Flow Rate (μg/min)	Initial Stocking Biomass (liter)	
	Low	High
Low	Treatment 4	Treatment 1
Medium	Treatment 5	Treatment 2
High	Treatment 6	Treatment 3

Site Location

The experiment was conducted at Ram Point Marina, Inc., at the head of Point Judith Pond, Wakefield, Rhode Island (41°25.57′N; 71°29.87′W) (Fig. 2). Ram Point Marina, Inc. is located on a spit between Silver Spring Cove and the Upper Pond. The site was selected to take advantage of the relatively high and consistent phytoplankton biomass (chlorophyll-*a* concentrations >10 μg/l, Rheault 1995) during the summer months. The experimental-scale floating upweller was situated at the northernmost corner of the marina to ensure a water depth >1.4 meters at mean low tide.

Upweller System

An experimental-scale floating upweller was designed and constructed to ensure the control of flow through each silo. The upweller unit was 4.27-m long, 1.22-m wide, and 1.35 m deep. Two 25 cm inside diameter (ID) polyvinyl chloride (PVC) pipes were positioned at the base and ran the length of the unit forming a manifold. Ten 15-cm (ID) silos were plumbed into the top of each manifold. Flow was provided by a half horsepower axial flow

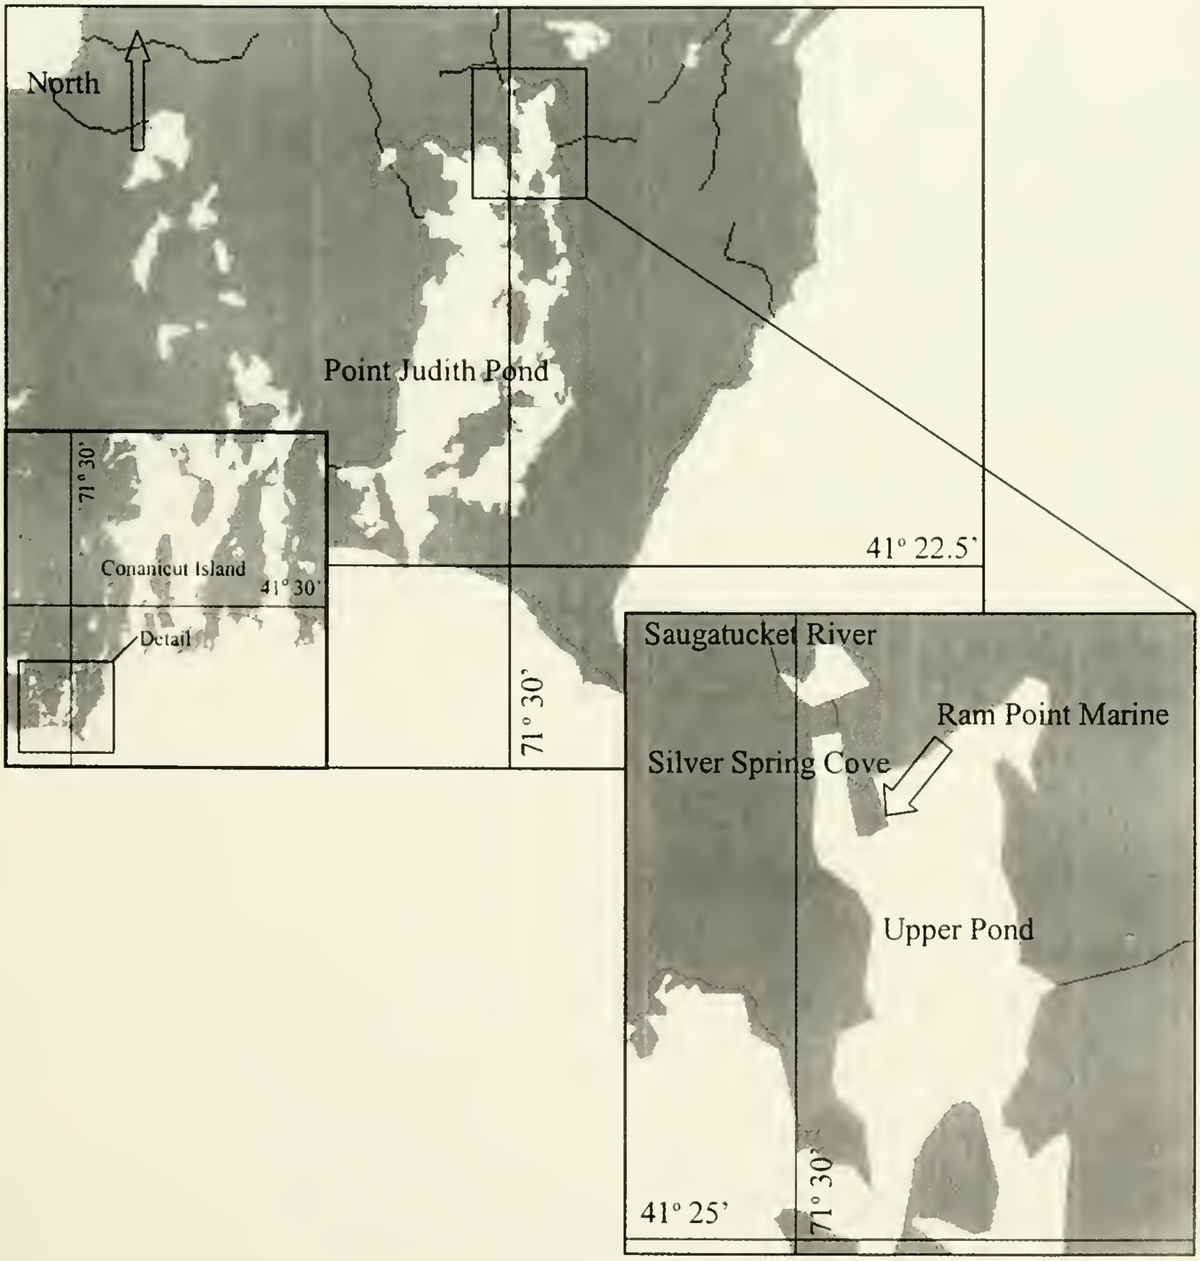

Figure 2. Location of the experimental-scale upweller at Ram Point Marina, Point Judith Pond, Wakefield, Rhode Island.

pump (Ice Eater, Power House) mounted in each manifold. Water was pumped along the manifold, flowed up each 15-cm silo, and exited through an 8-cm (ID) ball valve plumbed into the top of each silo. The seed were placed on a Nytex screen 0.5 m above the silo's base. When the unit was in operation, each ball valve lay approximately 8 cm above the water line. Flow through each silo was manipulated with the ball valve and was measured volumetrically with a graduated cylinder and a stopwatch.

Northern quahog seed (300,000 at 0.6 mm) were purchased from Bluepoints Company, Inc., West Sayville, New York. The seed were held in the upweller until they reached >2 mm (longest axis).

Data Collection

At the beginning of each experiment the seed were pulled from the unit, sieved, and randomly distributed throughout the 18 replicates at a biomass of 0.055 l (wet volume) and 0.109 l. In addition, the valve length of a random sample ($n = 75$) of seed was measured to the nearest 0.01 mm with vernier calipers. Five subsamples of northern quahogs were also taken to develop a relationship between wet volume (l) and wet weight (kg). Each experiment was terminated when the biomass in the slowest growing replicate doubled. This occurred approximately every two weeks during the summer. At the termination of each two-week experiment, the valve length of a random sample ($n = 25$) of northern quahogs from each replicate was determined. Four two-week experiments were completed during the summer 1999.

The change in volume of each silo was measured semiweekly resulting in 3- to 4-day growth intervals. Semiweekly flow rates to each silo were also measured in the morning or late at night to minimize wave activity. Care was taken to ensure that the upweller unit was not altered during measurements and flows were adjusted accordingly.

Chlorophyll-*a* (Chl-*a*), particulate organic matter (POM), temperature, salinity, and dissolved oxygen (DO) were measured semiweekly from an empty silo. With the start of the second two-week experiment (July 7) all environmental parameters were taken in the morning, midday, and evening to quantify daily fluctuations at the site. Discrete chlorophyll-*a* samples ($n = 3$) were taken with a syringe. Samples were pre-filtered with a 150 μm Nytex screen to remove particulates that bivalves are unable to filter (Defossez & Hawkins 1997). Samples (10 ml) were forced through a 25-mm diameter Whatman GF/F filter contained in a 25 mm Swinnex filter holder. The procedure for chlorophyll-*a* analysis is slightly modified from the standard procedure outlined in Strickland and Parsons (1972). Filters were dissolved in acetone for 24 hours and read on a Turner Designs fluorometer (Model 10-005R, Turner Designs, Inc., Sunnyvale, CA). All samples were corrected for phaeophytin-a. One-liter samples were also taken ($n = 2$) for POM analysis. The samples were pre-filtered on a 150 μm Nytex screen and later analyzed in the laboratory. In the laboratory, samples were vacuum pumped through a pre-ashed 47 mm Whatman GF/F filter (normal pore size 0.1 μm), rinsed with isotonic ammonium formate, and dried in an oven at 110°C for 24 to 48 hours. Filters were then ashed for >6 hours at 450°C in a muffle furnace. Filters were weighed on an Ohaus electronic balance (Model AS120) to the nearest 0.1 mg. Temperature, salinity were measured with an YSI (Model 30) probe and oxygen was measured with an YSI (Model 55) probe. The oxygen probe was calibrated prior to each measurement.

When measuring the change in volume of northern quahog seed, each silo and screen was cleaned with freshwater. Once a week the remainder of the upweller manifold was cleaned by a diver to ensure consistent flow through the system.

Data Analysis

The chlorophyll-*a* effective flow rate ($\mu g \cdot min^{-1} \cdot l^{-1}$) for each replicate was calculated as the product of the average chlorophyll-*a* concentration (μg/l) during the period and the flow rate (l/min) to the replicate all divided by the average biomass (l) of the replicate during the same period. This study characterized growth as the relative growth rate (RGR) and was calculated as:

$$RGR = \{[(Volume_{(final)} - Volume_{(initial)})/Volume_{(initial)}] \times 100\}/\#\text{ of days}$$

where volume is measured in liters. RGR is expressed as a percentage increase per day (% increase/day). POM (mg/l) was calculated as the difference between total suspended particulate matter (SPM) and particulate inorganic matter (PIM).

The Effect of Food Limitation on Growth

To elucidate differences in growth between treatments the total RGR (% volume increase) was divided by the longest period available, the length of each experiment. Since the RGR (% increase/day) measures the change in volume over each two-week experiment, the average chlorophyll-*a* concentration and average treatment biomass during the time was used to calculate treatment chlorophyll-*a* effective flow rates. Prior to ANOVA analysis, the RGR (% increase/day) was arcsine transformed (Sokal & Rohlf 1995). Within each experiment, one-way ANOVAs were performed for each two-week experiment with the average RGR (% increase/day) as the dependent variable and treatment as the independent variable. Differences between treatment means were elucidated with the Tukey Honestly Significant Difference (HSD) test. When the one-way ANOVA proved significant, a within experiment two-way ANOVA was performed to further investigate the effective flow rate and density as independent variables. Again, the Tukey HSD test was used to verify differences in means. The strength of the relationship was characterized by the standard omega-squared (ω^2), when appropriate. The ω^2 was calculated as

$$\omega^2 = [SS_{Effect} - df_{S/A}\,(MS_{S/A})]/SS_T + MS_{S/A}$$

where SS_{Effect} is the sum of squares of the effect, $df_{S/A}$ is the degrees of freedom for the error term, $MS_{S/A}$ is the mean squares for the error term, and SS_T is the sum of squares total.

A between experiment one-way ANOVA was performed to elucidate growth differences between the two-week experiments. The Tukey HSD test quantified differences between means.

The Effect of Environmental Characteristics on Growth

In order to illustrate the effect of environmental parameters on northern quahog growth, growth was characterized at the finest possible scale. In particular, RGR was calculated for each 3 to 4 day period (growth interval) between semiweekly volume determinations. The daily value of each environmental parameter was averaged over the concurrent growth interval.

To eliminate the effect of food limitation on growth, RGR of the upper third of the replicates (upper 1/3 RGR) was calculated. A linear regression analysis (SAS Institute, Inc.) of the upper one-third RGR was performed with temperature, salinity, chlorophyll-*a*, and dissolved oxygen to determine which independent variables were significant in determining growth. Dissolved oxygen concentrations were converted to percent saturation based on temperature and salinity measurements (Benson & Krause 1984). A step-wise linear regression analysis was also performed to elucidate the most significant parameter(s) for predicting growth in the experiment.

RESULTS

The Effect of Food Limitation on Growth

There was no observed mortality during the course of the two-month experiment. Calculated mortality was extremely variable in experiments 1 and 2 because counts per ml were not replicated. In addition, counts were not made before and after sieving. In experiments 3 and 4, counts per ml were replicated ($n = 3$) and counts were made before and after sieving. Mortality was calculated to be 111 ± 3% (S.E.) and 99 ± 2% (S.E.) respectively. The first experiment began on June 21 and ended on July 7, 1999 (16 days) and the northern quahogs grew from 3.11 ± 0.06 mm (S.E.) to 3.95 ± 0.05 mm (S.E.). The average chlorophyll-*a* concentration was 16.42 ± 2.25 μg/l (S.E.) and the average treatment biomass ranged from 165.8 to 85.5 ml. The chlorophyll-*a* effective flow rate ranged from 420 to 1,445 $\mu g \cdot min^{-1} \cdot l^{-1}$ roughly correlating with a RGR from 4.76 to 9.32% increase/day. As the chlorophyll-*a* effective flow rate increased, the RGR increased until ~650 $\mu g \cdot min^{-1} \cdot l^{-1}$ at which point growth leveled off (Fig. 3a). Growth, as measured by RGR, was subjected to a one-way ANOVA with six levels of treatment. This was found to be statistically significant ($F(5, 11) = 5.48$, $P < 0.05$). The strength of the relationship was 0.57 as indexed by the standard omega-squared (ω^2). The Tukey HSD test indicated that the mean RGR for treatment 1 ($M = 5.54$) was significantly lower than the means for treatment 4 ($M = 8.14$), 5 ($M = 8.41$), and 6 ($M = 9.26$). To investigate the effect of effective flow rate and biomass on growth, a two-way ANOVA was performed with three levels of seston flux and two levels of volume. Both effective flow rate ($F(2, 11) = 5.13$, $P < 0.05$) and biomass ($F(1, 11) = 13.36$, $P < 0.05$) were statistically significant. The strength of the relationship (ω^2) was 0.21 and 0.31, respectively. The interaction between effective flow rate and biomass was found ordinal; therefore, the main effects were examined by the Tukey HSD test. The Tukey HSD test indicated that the low-biomass treatments ($M = 8.60$) grew faster than the high-biomass treatments ($M = 6.99$).

The second experiment began on July 7 and ended on July 22, 1999 (15 days) and the northern quahogs grew from 3.46 ± 0.11 mm (S.E.) to 6.28 ± 0.07 mm (S.E.). The average chlorophyll-*a* concentration was 11.83 ± 1.16 μg/l (S.E.) and the average treatment biomass ranged from 205.6 ml to 91.6 ml. The chlorophyll-*a* effective flow rate ranged from 231 to 977 $\mu g \cdot min^{-1} \cdot l^{-1}$ roughly correlating with a RGR from 9.58 to 12.73 % increase/day (Fig. 3b). RGR was consistently high within the chlorophyll-*a* effective flow rate range specified. RGR was subjected to a one-way ANOVA and there was no statistical difference between treatments ($F(5, 11) = 1.48$, $P > 0.05$).

The third experiment began on July 22 and ended on August 5, 1999 (14 days) and the northern quahogs grew from 7.04 ± 0.11 mm (S.E.) to 9.96 ± 0.07 mm (S.E.). The average chlorophyll-*a* concentration was 18.55 ± 2.12 μg/l (S.E.) and the average treatment biomass ranged from 184.8 to 84.6 ml. The chlorophyll-*a* effective flow rate ranged from 411 to 1,720 $\mu g \cdot min^{-1} \cdot l^{-1}$ roughly corresponding to a RGR from 7.79 to 10.09 % increase/day (Fig. 3c). The RGR increased slightly with an increase in the chlorophyll-*a* effective flow rate until ~610 $\mu g \cdot min^{-1} \cdot l^{-1}$, at which point growth decreased and leveled off. RGR was subjected to a one-way ANOVA and was found to be statistically significant ($F(5, 11) = 7.13$, $P < 0.05$). The strength of the relationship was 0.64 as indexed by the ω^2. The Tukey HSD test indicated that the mean RGR for treatment 2 ($M = 9.76$) was significantly higher than the means for treatment 4 ($M = 7.97$), 5 ($M = 8.62$), and 6 ($M = 8.38$). In addition, the mean RGR for treatment 4 ($M = 7.97$) was significantly lower than the mean for treatment 3 ($M =$

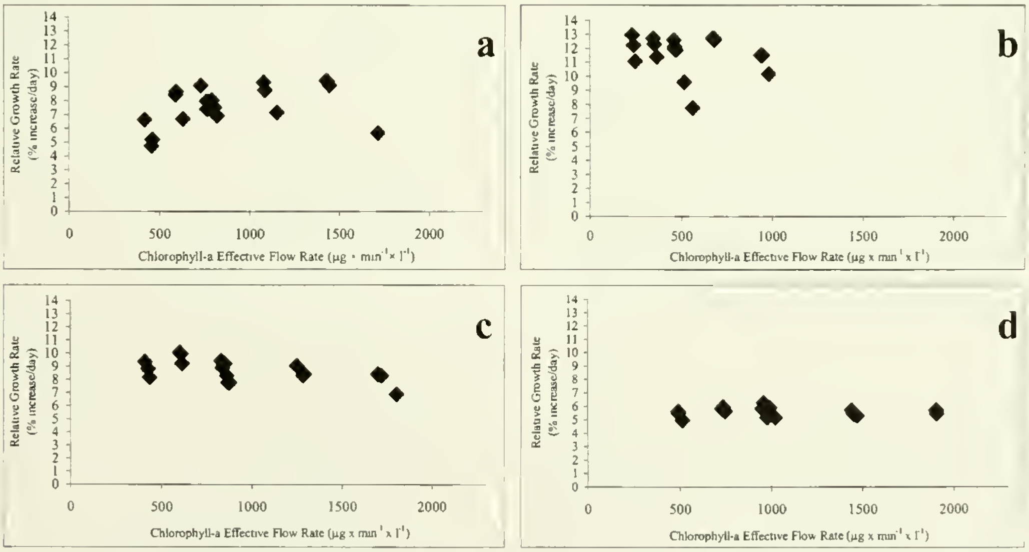

Figure 3. Growth (% increase/day) as a function of chlorophyll-*a* effective flow rate for (a) experiment 1 (June 21 to July 7, 1999 with an average chlorophyll-*a* concentration of 16.42 ± 2.25 μg/l S.E.); (b) experiment 2 (July 7 to July 22, 1999 with an average chlorophyll-*a* concentration of 11.83 ± 1.16 μg/l S.E.); (c) experiment 3 (July 22 to August 5, 1999 with an average chlorophyll-*a* concentration of 18.55 ± 2.12 μg/l S.E.); and, (d) experiment 4 (August 5 to August 19, 1999 with an average chlorophyll-*a* concentration of 17.91 ± 3.17 μg/l S.E.).

9.20). A two-way ANOVA found both effective flow rate (F (2, 11) = 5.99, $P < 0.05$) and biomass (F (1, 11) = 22.33, $P < 0.05$) were statistically significant. The strength of the relationship (ω^2) was 0.21 and 0.45, respectively. The interaction between effective flow rate and biomass was found ordinal; therefore, the main effects were examined by the Tukey HSD test. The Tukey HSD test indicated that the high-biomass treatments (M = 9.25) grew faster than the low-biomass treatments (M = 8.32). The Tukey HSD test also found that the replicates with an effective flow rate of 111.3 μg/min (M = 9.19) grew faster than the replicates with an effective flow rate of 74.2 μg/min (M = 8.87).

The fourth experiment began on August 5 and ended on August 19, 1999 (14 days) and the northern quahogs grew from 9.37 ± 0.12 mm (S.E.) to 11.47 ± 0.08 mm (S.E.). The average chlorophyll-*a* concentration was 17.91 ± 3.17 μg/l (S.E.) and the average treatment biomass ranged from 147.4 to 73.4 ml. The chlorophyll-*a* effective flow rate ranged from 491 to 1,905 $\mu g \cdot min^{-1} \cdot l^{-1}$ roughly corresponding to a RGR from 4.98 to 5.96% increase/day (Fig. 3d). RGR was consistently low within the chlorophyll-*a* effective flow-rate range specified. RGR was subjected to a one-way ANOVA and there was no statistical difference between treatments (F (5, 11) = 0.76, $P > 0.05$).

A one-way ANOVA was performed to compare the RGR between the two-week experiments. This was statistically significant (F (3, 64) = 135.34, $P < 0.05$) with an ω^2 of 0.80. The Tukey HSD test indicated that there was a significant difference between all the mean RGRs, with growth highest in experiment 2 (M = 11.89) and decreasing in experiments 3 (M = 8.81), 1 (M = 7.71), and 4 (M = 5.57).

The Effect of Environmental Characteristics on Growth

The upper one-third RGR varied considerably during the course of the experiment from a high of 10.37 ± 0.43% increase/day (S.E.) on June 22 to a low of 5.03 ± 0.41% increase/day (S.E.) on June 29 (Fig. 4a). During the course of the two-month experiment, RGR decreased sharply (June 22 to June 29), then increased (June 29 to July 17), and then gradually decreased (July 17 to August 19).

Temperature during the experiment varied from 21.4 to 27.3°C (Fig. 4b). Other than a brief drop in temperature in mid July due to a rainstorm, temperature was consistent during the experiment. A linear regression analysis indicated that temperature was not significant in determining growth as indicated by the upper one-third RGR (F (1, 15) = 0.58, $P > 0.05$). Similarly, salinity during the experiment was relatively consistent ranging from 21.4 to 29.9‰ (Fig. 4c). Linear regression analysis determined that salinity was not significant in predicting the upper one-third RGR (F (1, 15) = 0.70, $P > 0.05$). The seston concentration, as indexed by the chlorophyll-*a* concentration, varied substantially during the course of the experiment from peaks of 21.2 ± 1.23 μg/l (S.E.) on June 28 and 22.8 ± 0.86 μg/l (S.E.) on July 3, to a nadir of 9.5 ± 0.09 μg/l (S.E.) on July 13 (Fig. 4d). Generally, as chlorophyll-*a* concentrations increased growth decreased. Similarly, as chlorophyll-*a* concentrations decreased growth increased. Linear regression analysis indicated that this trend was significant (F (1, 15) = 7.46, $P < 0.05$) with a correlation coefficient (R^2) of 0.35 (Fig. 5a). There was a minimal amount of variability between chlorophyll-*a* measurements as exemplified by the low standard errors between measurements. The chlorophyll-*a* concentration during the day, however, varied considerably as indicated by the high standard errors between morning, midday, and evening chlorophyll-*a* determinations. Morning DO was used to quantify the effect of limiting dissolved oxygen on growth as morning DO values were consistently the lowest oxygen values experienced by the northern quahogs. Morning DO values ranged from a high of 8.00 ppm on June 22 to a low of 3.37 ppm on July 8 (Fig. 4e). Morning DO values correlate with the upper one-third RGR during the two-month experiment. As morning DO values decreased growth decreased; conversely, as morning DO values increased growth increased. A linear regression analysis indicated that this trend was significant (F (1, 15) = 10.13, $P < 0.05$) with a correlation coefficient (R^2) of 0.42 (Fig. 5b). Morning dissolved oxygen (ppm) tracked the morning percent saturation of DO. During periods of low morning DO (4–3 ppm), % saturation approached 50% and during periods of high morning DO (7–8 ppm), % saturation ranged from 80 to 100%.

Growth was best characterized with morning DO and chlorophyll-*a* (F (2, 15) = 8.22, $P < 0.05$) resulting in an R^2 of 0.56. As the chlorophyll-*a* concentration increased morning DO decreased and as the chlorophyll-*a* concentration decreased morning DO increased (Figs. 4d and e).

DISCUSSION

The Effect of Food Limitation on Growth

The one-way ANOVAs found significant differences in growth between treatments in experiments 1 and 3, but none in experiments 2 and 4. Experiments 1 and 3 were characterized by relatively high morning DO values, while experiments 2 and 4 experienced relatively low morning DO values. According to the reevaluation of the data (Fig. 1) presented in Manzi et al. (1986), growth as a function of the chlorophyll-*a* effective flow rate (the amount of food passing by a unit biomass of clams) should follow an asymptotic function. Specifically, growth should increase from the origin (zero growth and zero chlorophyll-*a* effective flow rate) with increasing chlorophyll-*a* effective flow rates until a particular point where growth asymptotes or even decreases.

In the first experiment, growth (% increase/day) followed the relationship presented in Figure 1. Growth increased as the chlorophyll-*a* effective flow rate increased until ~650 $\mu g \cdot min^{-1} \cdot l^{-1}$ at which point growth reached an asymptote. The one-way ANOVA found a significant difference in growth between the treatments with a relatively strong relationship as indexed by the standard omega-squared (ω^2 = 0.57). Furthermore, treatment 1 grew significantly slower than treatments 4, 5, and 6. Treatments 4, 5, and 6 represent the asymptote of the function where growth asymptotes regardless of an increase in the chlorophyll-*a* effective flow rate. In addition, treatments 4, 5, and 6 were those with a low initial stocking density of 0.3 l/cm^2. In order to further investigate the effect of effective flow rate and biomass on growth a two-way ANOVA was performed. There were significant differences between growth with the levels of effective flow rate and biomass. In particular, the low-biomass replicates (treatments 4, 5, and 6) grew faster than the high-biomass replicates (treatments 1, 2, and 3).

In the third experiment, the one-way ANOVA also indicated a significant difference in growth between the treatments with an even stronger relationship (ω^2 = 0.64). The functional relationship between growth and chlorophyll-*a* effective flow rate was different from that postulated in Figure 1. Growth increased slightly with increasing chlorophyll-*a* effective flow rate, but then decreased slightly, reaching an asymptote above 1,000 $\mu g \cdot min^{-1} \cdot l^{-1}$.

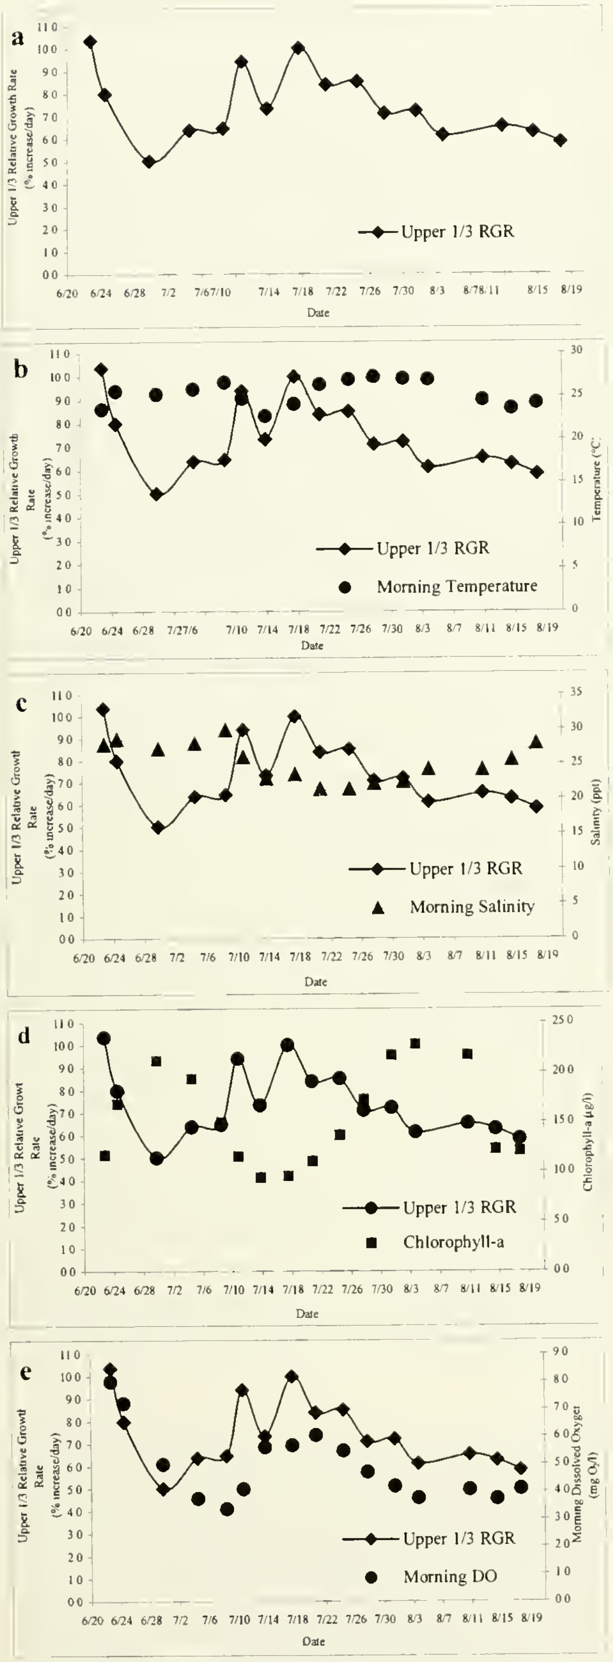

Figure 4. Relative growth rate (% increase/day) for the upper third of replicates (a) from June 21 through August 19, 1999 with (b) morning temperature (°C); (c) morning salinity (‰); (d) morning chlorophyll-*a* (µg/l); and, (e) morning dissolved oxygen (ppm).

This trend is supported by the Tukey HSD test, which indicated that treatment 2 grew significantly faster than treatments 4, 5, and 6. In addition, treatment 3 grew significantly faster than treatment 4. Since treatment 3 and treatment 4 have nearly the same chlorophyll-*a* effective flow rate, a significant difference in growth indicates an effect of biomass on growth, with the higher biomass treatment growing faster that the lower biomass treatment. The two-way ANOVA also found a significant effect of biomass on growth with the high-biomass replicates growing faster that the low-biomass replicates. The two-way ANOVA also indicated a significant effect of seston flux on growth with the replicates with the intermediate effective flow rate of 111.3 µg/min growing faster that the replicates with the lower effective flow rate of 74.2 µg/min.

Experiments 1 and 3 both experienced initially high morning DO values that decreased during the course of the experiment. Experiment 1 had higher initial morning DO values (8–7 ppm) than experiment 3 (5.5–6 ppm). The chlorophyll-*a* concentration also increased substantially during both experiments, with values peaking at 21.19 ± 1.23 µg/l (S.E.) in experiment 1 and 22.83 ± 0.86 µg/l (S.E.) in experiment 3. In addition, both experiments experienced the same range of chlorophyll-*a* effective flow rates. The difference in the relationship between growth and chlorophyll-*a* effective flow rate in experiment 1 and experiment 3 is probably the result of a number of factors. First, since experiment 3 did not experience the initially high morning DO levels observed in experiment 1, the treatments might not have had a chance to separate or grow differentially. Second, the spread in replicates in experiment 3 was considerably smaller than that in experiment 1; therefore, small growth differences between treatments in experiment 3 are essentially accentuated. In other words, the statistical difference between treatments in experiment 3 is a result of the relatively small within replicate variability. In both experiments 1 and 3, maximum growth occurred near treatment 2 in a range of chlorophyll-*a* effective flow rates of 550 to 650 $\mu g \cdot min^{-1} \cdot l^{-1}$. In order to verify this result, growth should be investigated within the chlorophyll-*a* effective flow rate range of 0 to 500 $\mu g \cdot min^{-1} \cdot l^{-1}$.

The benefit of defining a relationship between growth and the amount of food passing by a unit biomass of animals (chlorophyll-*a* effective flow rate) is apparent in the application to other growers. The relationship can be easily applied to upwellers in a variety of locations, provided optimal environmental conditions persist. An aquaculture extension agent could characterize the water conditions at a site to determine that the minimum water quality standards are met, such as temperature, salinity, and dissolved oxygen. The agent could then measure the amount of chlorophyll-*a* and estimate the average food concentration at the site. With this estimate, the grower could determine the biomass and effective flow rate needed to optimize growth in the upweller.

The Effect of Environmental Characteristics on Growth

When environmental conditions were suitable for northern quahog growth, especially in the beginning of experiment 1, the effect of food limitation on growth was apparent. When environmental conditions were less than optimal, as in experiments 2 and 4, growth appears constant over a wide range of chlorophyll-*a* effective flow rates. In other words, growth was not controlled by food limitation, but some other factor. To quantify the effect of environmental conditions on growth, the upper one-third of replicates, the fastest growing northern quahogs, were used to determine

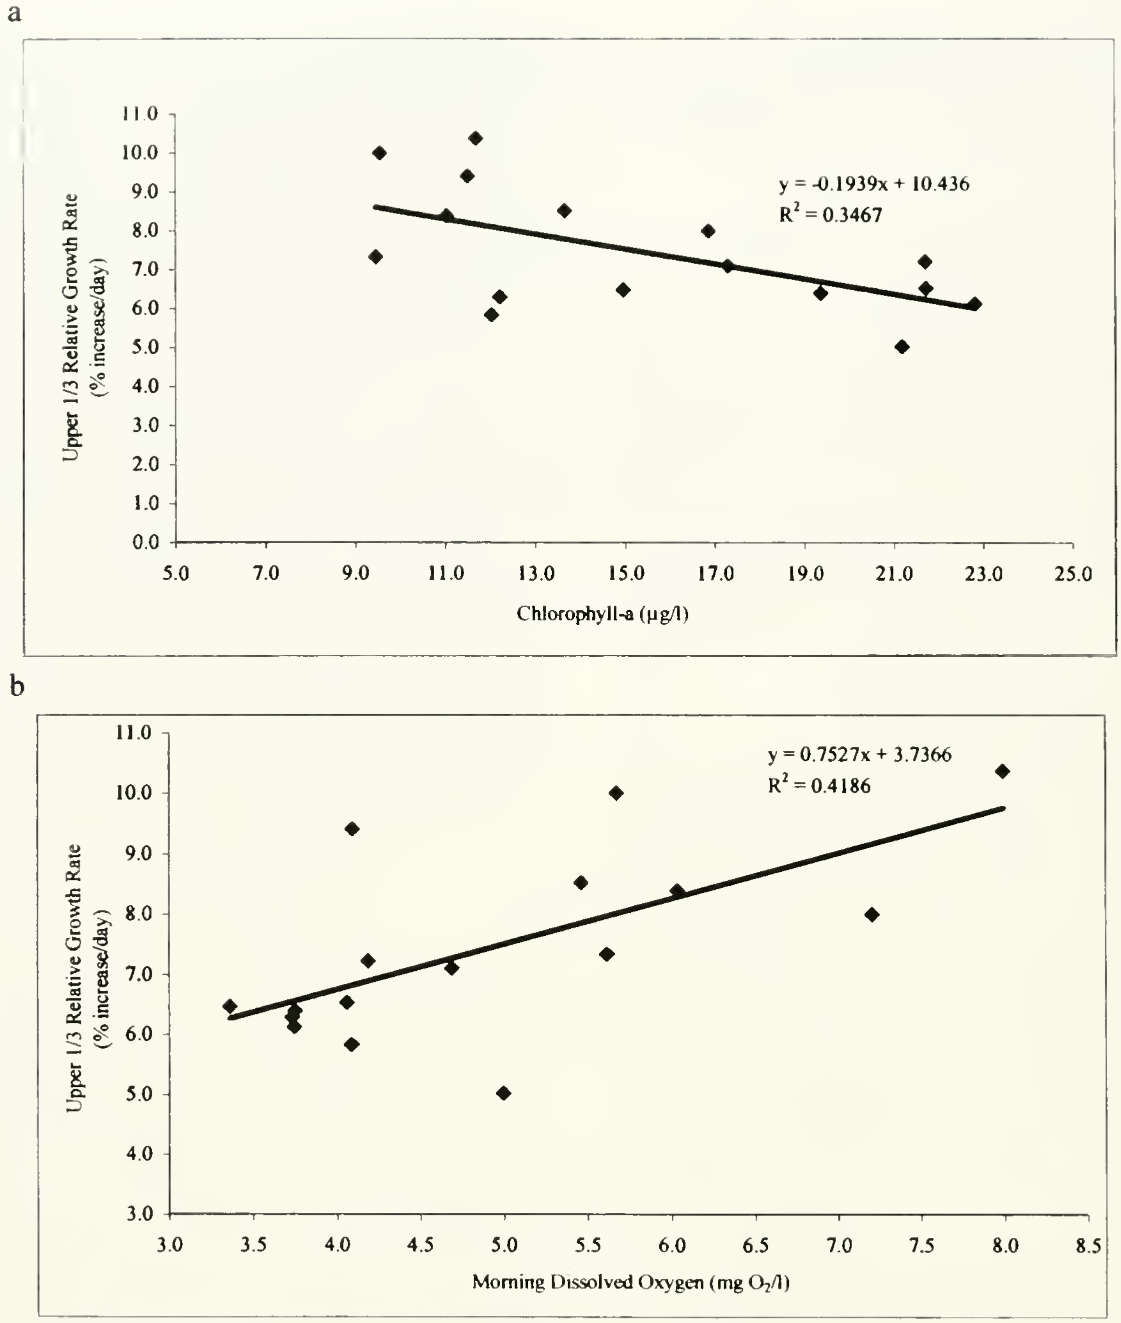

Figure 5. Linear regression of the relative growth rate (% increase/day) for the upper third of replicates from June 21 through August 19, 1999 versus (a) chlorophyll-*a* (µg/l) and (b) morning dissolved oxygen (ppm).

growth. By eliminating the slowest two-thirds replicates, the effect of food limitation on growth was minimized; therefore, differences in growth were constrained by the environmental conditions at the time.

Manzi et al. (1986) concluded that food limited growth in their experimental-scale upweller. Although there were signs of food limitation on growth in experiments 1 and 3, growth in experiments 2 and 4 were controlled by other factors. Malinowski and Siddall (1989) determined that the flow rate limited growth in their upweller system. They surmise that flow through the upweller had to be above a critical threshold in order to create a uniform flow (distribute food evenly among the clam seed), maintain water quality, remove wastes, and provide a sufficient chlorophyll-*a* concentration to the northern quahogs. Although Malinowski and Siddall (1989) were unable to quantify the effect of water quality on growth, they eluded to the importance of environmental conditions on growth.

Over the course of the two-month experiment, growth was positively correlated with morning DO and negatively correlated with chlorophyll-*a*. In late June and early July, the experimental site at Point Judith Pond experienced a pronounced algae bloom. The bloom was evident as an increase and peak in the chlorophyll-*a* concentration (Fig. 4d). There was a clear relationship between chlorophyll-*a* and morning DO, specifically as the chlorophyll-*a* concentration increased, morning DO levels decreased (Figs. 4d and e). The decrease in morning DO was a result of a combination of algae decomposition and algae respiration. At night, the algae were constantly respiring, converting captured energy into simple sugars, an oxygen consuming and carbon dioxide producing process. The algae were also continually dying off and decomposing, again an oxygen consuming process. A second algae bloom in the upper pond was apparent in mid August. Again, the same relationship between chlorophyll-*a* and morning DO was apparent. In late July, the chlorophyll-*a* concentration decreased substantially and morning DO levels increased. This decrease in chlorophyll-*a* was most likely a result of zooplankton grazing described by Bengtson (1982). Alternatively, the decrease in chlorophyll-*a* could have been caused by a crash or die off of a particular species of algae. The cyclic pattern of algae in the upper pond could be further verified by quantifying the species of algae present as well as the amount of zooplankton at the study site.

The relationship between primary productivity (chlorophyll-*a* concentrations) and low dissolved oxygen in shallow coastal and estuarine areas has received considerable attention, as this phenomenon appears to be increasing on a global scale. Diaz and Rosenberg (1995) reviewed the diversity of research characterizing low DO events in the Chesapeake Bay. They found that the cause and ecological consequences of these events varied from tributary to tributary.

Regardless of the specific controlling mechanisms, an increase in algae biomass caused a distinct decrease in morning DO (<5 ppm) resulting in depressed clam growth. The relationship between low DO and depressed clam growth has not been characterized in the literature; however, a number of researchers have successfully characterized changes in stress levels (Sparks & Strayer 1998) and predator behavior (Taylor & Eggleston 2000; Tallqvist 2001) of bivalves exposed to low oxygen concentrations. Hamwi (1969) determined that *Mercenaria mercenaria* were able to maintain a constant rate of respiration with decreasing oxygen levels until 5 ppm. The northern quahog is a classic oxygen regulator (Hamwi 1969). As the oxygen concentration decreases, bivalves can increase their rate of oxygen consumption through two mechanisms: (1) increasing their pumping rate; or (2) increasing their percentage of oxygen utilization. Hamwi (1969) determined that the pumping rate of northern quahogs remained constant with decreasing oxygen concentrations; however, northern quahogs were able to regulate O_2 consumption by increasing the percentage of oxygen utilized. When oxygen levels reached 5 ppm or below, Hamwi (1969) found that oxygen uptake in northern quahogs decreased continuously and an oxygen debt was incurred. Once conditions were favorable, the oxygen debt was rapidly repaid in a matter of hours and northern quahogs were able to function normally.

Although juvenile northern quahogs can survive in oxygen concentrations below 1 ppm for up to three weeks (Stanley & Dewitt 1989), 5 ppm is the critical threshold for northern quahog growth. There have been a number of studies that have investigated the effect of low oxygen levels on survival and tolerance, yet none have investigated the effect of low oxygen levels on growth. Based on the work completed by Hamwi (1969), 5 ppm is the critical threshold for northern quahog growth. When oxygen concentrations fall below 5 ppm, the northern quahogs cannot maintain sufficient oxygen uptake and incur an oxygen debt. In essence, the northern quahogs shut down and stop growing until oxygen levels rise above this critical threshold.

The results of this study stress the importance of sufficient oxygen concentrations for northern quahog growth in upweller systems. A number of methods could be used to ensure optimal oxygen levels in an upweller. The upweller could be moved to a site that experiences lower chlorophyll-*a* values and higher morning DO values, but food for the northern quahog would be compromised. Alternatively, the oxygen concentration in the upweller could be increased. During periods of low morning DO (<4 ppm), the % saturation was below 60; therefore, during periods of low morning DO, oxygen concentrations have the potential of being increased. Future research should investigate the most cost effective and efficient method of increasing dissolved oxygen levels in this upweller as well as in the more traditional passive flow upwellers. With optimal DO levels, the effect of food limitation on growth can be further defined and replicated.

SUMMARY AND CONCLUSIONS

The hypothesized relationship between growth and chlorophyll-*a* effective flow rate was only apparent during the first two-week experiment (experiment 1). Although there were significant differences in growth between treatments in the third two-week experiment (experiment 3), these differences were most likely the result of small within sample variability. For the remainder of the experiment, northern quahog growth was limited by environmental conditions. Specifically, the relative growth rate of the upper one-third of the replicates was positively correlated with morning-dissolved oxygen ($R^2 = 0.42$) and negatively correlated with chlorophyll-*a* ($R^2 = 0.35$). The critical dissolved oxygen threshold for northern quahog growth in the experimental-scale upweller appeared to be 5 ppm, below which growth was adversely affected. Future research should investigate the most effective method for elevating DO levels in commercial floating upwellers.

ABSTRACT The assessment of blood cell viability and defense abilities is a major concern in the study of pathological processes. In this work, we devised and validated flow cytometric assays to measure viability and phagocytic activity of hemocytes from the clam *Ruditapes philippinarum*, a species susceptible to the bacteria-caused Brown Ring Disease (BRD). Validated assays were subsequently used to measure hemocyte parameters following experimental contamination with BRD's etiologic agent *Vibrio tapetis*. Results show that clams that developed BRD symptoms had lower phagocytic rates and a higher percentage of dead hemocytes than those that did not. *In vitro* interactions between hemocytes and *V. tapetis* demonstrated that clam hemocytes are able to phagocytose formalin-fixed *V. tapetis*, but at lower rates than latex beads. Live *V. tapetis* were able to kill clam hemocytes *in vitro*. The *in vitro* assay also showed that phagocytosis increased with increasing temperature from 8° to 21°C. This work demonstrated the efficiency of flow cytometry for measuring molluscan blood cell activities during host/pathogen interactions and points the way for further experiments using this analytical tool.

KEY WORDS: bivalve, bacteria, phagocytosis, hemocyte viability, flow cytometry, *Ruditapes philippinarum*

INTRODUCTION

Changes in overall hemocyte activity have been observed in parasitized bivalves or those experimentally exposed to pathogens (Nottage & Birkbeck 1990; La Peyre et al. 1995; Anderson 1996; Garreis et al. 1996; Allam et al. 2000a, 2000b). Techniques used to investigate these changes generally have serious drawbacks. Microscopy is subjective and involves a considerable expenditure of time, especially when large numbers of samples need to be evaluated. Spectrophotometric methods are based on the measurement of activity in the whole sample and not on a cell-by-cell basis. Flow cytometry, however, has proven to be extremely useful in overcoming these problems. In the field of molluscan research, flow cytometry has been used to quantify phagocytosis (Alvarez et al. 1989; Brousseau et al. 2000; Allam et al. 2001; Fournier et al. 2001) and hemocyte viability (Ashton-Alcox & Ford 1998; Ashton-Alcox et al. 2000; Fournier et al. 2001).

In flow cytometry, particles are passed single-file through a laser beam. The light scattered by the particles indicates their size and internal complexity. Fluorescence, whether autofluorescence or from a fluorescent tag, is measured by specific detectors. Flow cytometric phagocytosis measurements usually involve the use of fluorescent particles that are detectable by the flow cytometer even after phagocytosis has taken place (Alvarez et al. 1989; Brousseau et al. 2000). Specific fluorescent dyes that indicate membrane integrity and permeability, intracellular redox potential, or enzymatic activity are available and can indicate cell viability using flow cytometry (Combrier et al. 1989).

Although molluscan hemocytes have been studied by flow cytometry before, validation of the results is rarely reported. In this work, we refined and verified by microscopy, two flow cytometry-based assays to measure the phagocytic activity and the viability of hemocytes in the clam *Ruditapes philippinarum*. These allowed us to investigate hemocyte activity in clams experimentally infected with *Vibrio tapetis*, the bacterial agent of Brown Ring Disease (BRD) in Europe (Paillard et al. 1994). We further studied the effect of *in vitro* contact between the pathogenic bacterium and hemocytes on hemocyte viability, and compared the uptake of *V. tapetis* with that of similarly sized fluorescent beads. We also investigated the effect of temperature on phagocytosis because temperature is strongly associated with the prevalence and intensity of BRD in nature and under experimental conditions (Paillard et al. 1994; Allam 1998).

MATERIALS AND METHODS

Experimental Animals

Ruditapes philippinarum were obtained from 2 locations: southern Puget Sound, Washington, USA (length = 39.4 ± 0.46 mm, mean ± SEM), and the Bay of Brest, Brittany, France (length = 37.7 ± 0.65 mm). Clams were shipped overnight to the laboratory where they were immediately placed in quarantine, aerated 35-L standing-water tanks (about 35 clams per tank at 13°C and 34 ppt), in which they were kept during the remainder of the study. Clams were fed daily throughout the experiments using a mixture of cultured algae. All the experiments reported here were conducted using clams from the USA, where BRD has never been reported, except for the infection experiment, which was done using French clams.

Clams affected with BRD were obtained by challenging them with *V. tapetis* as previously described (Allam et al. 2000a). Briefly, a 0.5 ml (5×10^7 bacteria) aliquot of a suspension made with exponentially growing *V. tapetis* (ATCC 4600, strain P16) was inoculated into the pallial cavity of each experimental clam. Control clams were inoculated with the same volume of sterile seawater. After 4 weeks of incubation under the conditions described above, hemolymph was collected and processed for phagocytosis and viability assays. The clams were then shucked and BRD development on shells was recorded (Paillard & Maes 1994; Allam et al. 2000a).

Hemolymph Sampling

Animals and hemolymph samples were kept on ice during processing to avoid hemocyte clumping. Hemolymph was withdrawn from the posterior adductor muscle as described by Auffret and

Oubella (1995). Samples were immediately divided into aliquots and diluted in different solutions as described below.

Design and Validation of the Phagocytic Assay

In vitro Incubation of Hemocytes with Beads

Fluorescent latex beads, 2.02 μm in diameter (Fluoresbrite Calibration grade, Polysciences, USA), were dispersed by expelling them through a 26-gauge needle and diluting them with filtered seawater (FSW) to give a final concentration of 6×10^6 beads ml^{-1}. Two hundred microliters of this suspension were placed in each well of a 24-well microplate, which was centrifuged for 10 min at 200 × g at room temperature (~21°C) to form a uniform monolayer of beads on the bottom of each well. Hemolymph samples were immediately diluted with ice-cold sterile seawater (SSW) to give a final concentration of 5 to 7×10^5 cells ml^{-1} and 200-μl aliquots of these suspensions were added to each well to give approximately a 1:10, cell:bead ratio. Following a 30-minute incubation in thermostatic chambers (Minifrige II®, Boekel Industries, Inc., Philadelphia, PA) adjusted to 21°C, conditions determined to be optimal during preliminary assays, the cytoskeleton-inhibitor Cytochalasin B (10 μg ml^{-1}, final concentration) was added to each experimental well to stop hemocyte activity. Attached cells were released by trypsinization (0.4% trypsin in 1% EDTA-saline solution for 10 min) followed by gentle sonication for one minute at room temperature (RT). Microscopic observation verified that this procedure detached cells from wells and also released non-ingested particles from the surfaces of hemocytes. Formalin was then added for a final concentration of 3% to fix the sample, which was transferred to a microfuge tube where it was held on ice until processed, within an hour, by flow cytometry. Because the flow cytometric profile for hemocytes from each clam was unique (see later), it was necessary to have a control (i.e., no phagocytosis) profile for each individual. Thus, a control well was established for each clam in which Cytochalasin B was added at the beginning of the incubation period to prevent phagocytosis. After the incubation, the control wells received the trypsin and formalin treatments as described above.

Flow Cytometry

Flow cytometry was performed on a Coulter EPICS C equipped with an argon laser and operated at a wavelength of 488 nm. Gains and photomultiplier high voltage settings were adjusted to include all cell and bead particles. Forward light scatter (FLS) and green fluorescence (GFL) list mode data were collected. A total of 10,000 particles were counted for each sample. The percent phagocytosis was calculated for each clam by bitmapping (electronic outlining) each of three particle types: (1) free beads; (2) non-bead-associated cells; and (3) bead-associated cells (Fig. 1). The bitmaps had been established previously by running beads alone, then non-bead-associated cells plus free beads, and then samples with phagocytosed beads. For each clam, the sum of counts in bitmaps 2 and 3 represented the total hemocytes in the flow cytometry sample. In each sample, the percent phagocytosis was computed as the ratio of bead-associated hemocytes to total hemocytes × 100. For each clam, the percent phagocytosis was calculated as the difference between the percent phagocytosis in the test wells and the percent phagocytosis in the control well. The percent phagocytosis was always below 0.5% in the control wells. For each sample, mean fluorescence intensity (channel number) was calculated within each bitmap.

Assay Validation

Epifluorescence microscopy was used to compare and correlate the percent phagocytosis results obtained from flow cytometry. Bead-associated and non-bead-associated hemocytes were counted using a Zeiss ICM 405 microscope equipped with a standard FITC filter set. A minimum of 250 cells was counted in each sample. This comparison included control samples with added Cytochalasin B. In addition, the reproducibility of the assay was tested by establishing duplicate experimental wells for each clam and comparing flow cytometric results for the replicates using correlation analysis. Finally, to determine the effect of storage on the percent phagocytosis measurement, samples were collected as described above, processed by flow cytometry, stored in glass tubes at 4°C, and re-analyzed after 3 and 7 days.

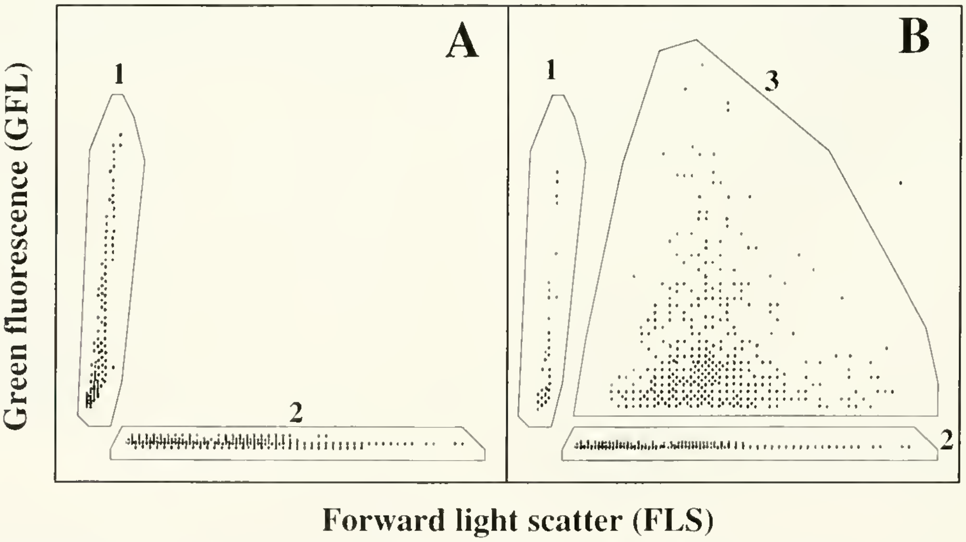

Figure 1. Flow cytometry bivariate plots showing the bitmaps used to calculate bead-associated and non-bead-associated cells in control (A) and test (B) mixtures. Bitmap 1: beads alone, Bitmap 2: non-bead-associated cells, Bitmap 3: bead-associated cells.

Design and Validation of the Viability Assay

In vitro Incubation of Hemocytes with the Fluorescent Vital Stain

The percentage of dead cells was assessed using the fluorescent nucleic acid stain ethidium homodimer-1 (EHD) previously used by Ashton-Alcox and Ford (1998). EHD binds to nucleic acids by intercalation. It does not permeate cells with intact membranes; thus only dead cells, or those with damaged membranes, become fluorescent. Hemolymph samples were diluted in cold Alsever's solution (1:10, v:v) immediately after collection. Then, 2 μM EHD (Molecular Probes, Eugene, Oregon, USA), dissolved in DMSO according to manufacturer's directions, was added. The mixture was incubated at room temperature for 30 minutes. An unstained control sample was made for each clam.

Flow Cytometry

Flow cytometry was used to collect light scatter parameters and log red fluorescence (LRFL) signals for at least 5000 cells. The percentage of dead cells was determined by setting a cursor at the upper limit of the LRFL signal for the unstained control, which was used as the "zero" channel for the stained cells in the parallel treated sample (Fig. 2). The percentage of dead cells was calculated as the ratio of cells above the "zero" channel to total hemocytes × 100.

Assay Validation

Fluorescence microscopy was used to compare and correlate the hemocyte viability results obtained from flow cytometry. Fluorescent and non-fluorescent hemocytes were counted using an epifluorescence microscope as described above. A minimum of 200 cells was counted in each sample. The reliability of the assay was also tested by using hemocytes that had been killed by immersion in boiling water for 5 min. Hemocyte mortality was confirmed microscopically, after EHD uptake, to be 100%, whereas untreated cells were more than 96% viable. Five mixtures of untreated and heat-killed hemocytes were made using 0%, 25%, 50%, 75%, and 100% heat-killed hemocytes. The percentage of viable and non-viable hemocytes was measured flow cytometrically as described above.

Effect of Temperature on Phagocytosis

Because BRD development is partially controlled by temperature, the phagocytosis assay was used to quantify the effect of temperature on phagocytosis by *R. philippinarum* hemocytes *in vitro*. Hemolymph was withdrawn from clams and immediately diluted with ice-cold SSW to give a final concentration of about 5 to 7 × 10^5 cells ml^{-1}. For each clam, 6 test wells and one control well of hemocytes and beads were established. Two replicates were incubated at 8°C, two at 13°C, and two at 21°C in the Mini-frige II® temperature chambers. These temperatures were selected because they are associated with the development of significantly different BRD prevalences and intensities in experimentally challenged clams (Allam 1998). The single control well was incubated at 21°C since preliminary studies showed no evidence of phagocytosis in controls at any tested temperature. All samples were processed for flow cytometry as described above.

In vitro Interactions Between Hemocytes and *V. tapetis*

The first experiment was devised to study the uptake of fluorescently labeled *V. tapetis* by hemocytes. Exponentially growing *V. tapetis*, cultured on marine agar were suspended in phosphate-buffered saline (PBS) to obtain about 10^9 cfu ml^{-1}. The bacteria were then fixed in 2% formalin, washed 3 times with PBS, and resuspended in 1 ml PBS (pH 7.4) containing 1 mg FITC (Sigma). The mixture was incubated for 30 min at RT, washed twice in PBS, and finally resuspended in sterile seawater. Labeled bacteria were then placed in each well of a 24-well microplate, centrifuged to form a uniform layer on the bottom of each well (10 min, 500 × g, 21°C) and used for measuring the phagocytic activity of hemocytes as described above. Six wells were established for each

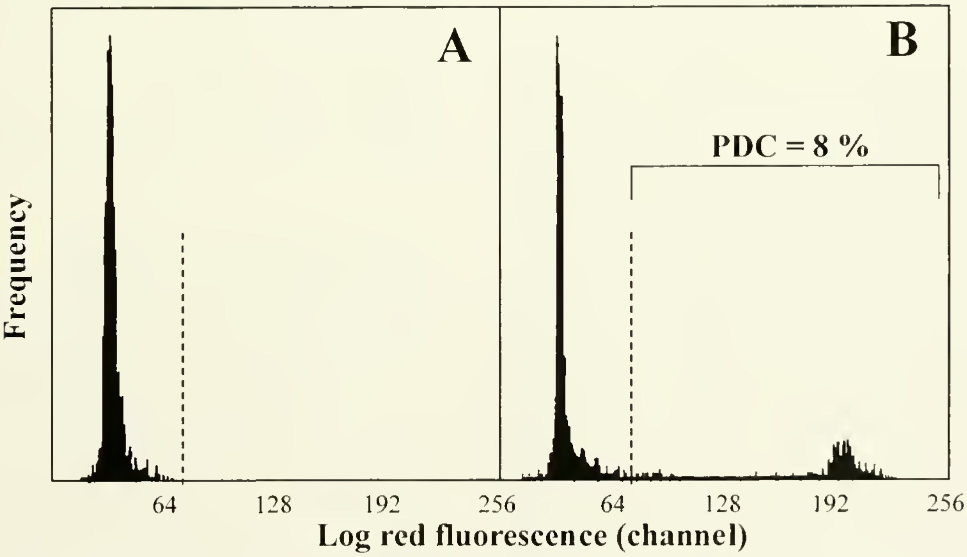

Figure 2. Distribution of log red fluorescence (LRFL) in unstained control and sample stained with ethidium homodimer. A cursor was set at the upper limit of the LRFL signal for unstained control, which was used as the "zero" channel for the stained cells within the sample. PDC: Percent Dead Cells.

clam using the same hemocyte:test particle ratio (1:10): 3 incubated with labeled bacteria (2 test, and 1 control well with Cytochalasin B added), and 3 incubated with standard fluorescent beads (2 test, and 1 control well).

The second experiment investigated the effect of live *V. tapetis* on hemocyte viability. Hemolymph samples were diluted with cold Alsever's solution (1:10, v:v) immediately after collection. Exponentially growing *V. tapetis* were suspended and diluted in sterile Alsever's solution to obtain about 10^7 cfu ml^{-1}. One milliliter of this suspension was transferred to a sterile plastic tube and mixed with 1 ml of diluted hemolymph to give approximately a 1:50, cell:bacteria ratio. Ten μg ml^{-1} of Cytochalasin B was immediately added to the mixtures to prevent phagocytosis. They were then incubated with mild agitation on a rocker plate for 2 h at room temperature. A duplicate tube containing only sterile Alsever's solution and Cytochalasin B was prepared for each clam and was used as a control preparation. After incubation, EHD was added and the percentage of dead hemocytes measured using the flow cytometer as described previously.

Statistics

Percent phagocytosis and viability values were arcsine transformed before the use of statistical tests, however tables show means and standard errors of non-transformed values. Correlation analysis was used in the validation of the phagocytosis and viability assays. Correlation analysis, as well as repeated measures ANOVA, was also used to test the effect of storage time on the percent phagocytosis. Mean values in clams with (symptomatic) and without (asymptomatic) BRD symptoms were compared using a Student's *t*-test. This test was also used to compare the *in vitro* effect of *V. tapetis* on hemocyte viability. Differences were considered significant at $\alpha = 0.05$.

RESULTS

Assay Validation

Phagocytosis

The percent phagocytosis of beads calculated by flow cytometry (19.9 ± 2.5) was significantly ($P = 0.039$) lower than that calculated by fluorescent microscopy (26.4 ± 2.6), but the two methods were highly correlated (N = 24, $r^2 = 0.81$, $P < 0.0001$). Microscopic observation confirmed that the beads associated with hemocytes were internalized. The percent phagocytosis in duplicate wells was also highly and significantly correlated (N = 72, $r^2 = 0.67$, $P < 0.0001$); consequently, two wells per individual was considered sufficient replication in all subsequent experiments. Although there appeared to be a slight decrease in the percent phagocytosis in samples stored for seven days at 4°C (Table 1), a repeated measures ANOVA showed no statistically significant effect of time. Nevertheless, all further flow cytometric samples were processed within 24 hours because there was some microscopic evidence of an increase in broken cells and membrane fragments in stored samples. Fluorescence intensity (channel number) was equal to 5.7 ± 0.3 in non-phagocytic cells (mean ± SEM), 12.6 ± 4.1 in free beads, and 27.4 ± 7.3 in phagocytic cells. No significant changes in fluorescence intensity were observed in preserved samples.

TABLE 1.

Effects of storage on flow cytometric counts of percent phagocytosis in *R. philippinarum*. Samples were processed at the day of collection and re-analyzed after 3 and 7 days of storage at 4°C. Means, standard errors of the means, and correlation coefficients are presented ($N = 24$ clams with 2 replicates each). No significant differences were observed among means (repeated measures ANOVA) which were highly correlated ($P < 0.0001$).

	Day 0	Day 3	Day 7
Mean ± SEM	22.3 ± 1.3	18.8 ± 0.9	19.9 ± 1.1
Day 0	1	0.81	0.85
Day 3		1	0.77
Day 7			1

Viability

The percentage of dead hemocytes calculated by flow cytometry (3.7 ± 1.1) was not significantly different from values measured microscopically (4.2 ± 1.0, $P = 0.69$), and the two methods were highly correlated (N = 10, $r^2 = 0.92$, $P < 0.001$). About 99.9% of heat-killed hemocytes were located within the upper channels on the LRFL histograms, and thus detected by the flow cytometer as dead cells. Flow cytometric estimates indicated that the hemocyte mixture made without addition of heat-killed hemocytes contained 3.8% dead cells, while those containing 25, 50 and 75% heat-killed cells contained 28.1, 52.0 and 75.6% dead hemocytes, respectively.

Disease Effects on Phagocytosis and Hemocyte Viability

Flow cytometric measurements showed a somewhat lower percentage of phagocytic hemocytes (7.2 ± 1.0%, N = 21) compared with those from asymptomatic animals (10.4 ± 1.3%, N = 23, $P = 0.044$) and no difference in fluorescence intensity among phagocytic hemocytes (33.2 ± 9.0 for diseased and 25.1 ± 5.1 for asymptomatic clams, $P = 0.420$). Symptomatic clams had a significantly higher ($P = 0.0006$) percentage of dead hemocytes (13.4 ± 1.0%, N = 54) when compared with asymptomatic clams (9.2 ± 0.5%, N = 20).

Temperature Effects on Phagocytosis

The percent phagocytosis was clearly related to the temperature at which the hemocyte-bead mixture was held (Table 2). This

TABLE 2.

Effect of temperature on *in vitro* phagocytosis of beads by hemocytes from *R. philippinarum* ($N = 24$ clams with 2 replicates each). For each parameter, letters (a, b and c; or x and y) represent significant differences among different temperatures (ANOVA, $P < 0.05$). Fluorescence intensity refers to the peak fluorescent channel of those hemocytes that had phagocytosed beads.

	8°C	13°C	21°C
% Phagocytosis			
Mean ± SEM	7.9 ± 0.7^{a}	14.9 ± 1.0^{b}	21.1 ± 1.2^{c}
Range	2.7–19.3	4.4–25.5	12.5–41.6
Fluorescence Intensity			
Mean ± SEM	15.1 ± 3.0^{x}	24.0 ± 4.4^{y}	29.6 ± 8.3^{y}
Range	10–21	18–33	19–38

percentage at 21°C was about 21%, at 13°C, it was 15%, and at 8°C, it was 8%. Similarly, fluorescence intensity within phagocytic cells was also dependent upon the incubation temperature. This was about 30 and 24 in mixtures incubated at 21 and 13°C, respectively, and only 15 in those held at 8°C (Table 2).

Uptake of V. **tapetis** *versus Beads*

Clam hemocytes phagocytosed fluorescent latex beads at a significantly higher rate (22.3 ± 1.3%) than they did FITC-labeled *V. tapetis* (12.8 ± 2.9%, $P = 0.002$, N = 24).

Hemocyte Killing by **V. tapetis**

The percentage of dead cells increased significantly after incubation of hemocytes with the pathogenic bacterium, *V. tapetis*. In control mixtures, the percentage of dead hemocytes was 6.8 ± 2.2 while it reached 20.4 ± 5.9% in mixtures with *V. tapetis* added (Student's *t*-test, $P = 0.029$, $N = 11$).

DISCUSSION

Flow cytometry has been used in several previous studies to quantify phagocytosis and hemocyte viability in marine bivalves (Alvarez et al. 1989; Ashton-Alcox & Ford 1998; Brousseau et al. 2000; Fournier et al. 2001). However, none of these studies reported validating the methodology by comparing the flow cytometric results against standard microscopic measurements. In this study, we quantified phagocytosis and hemocyte viability in individual clams by both flow cytometry and microscopy. The high correlation between the two methods shows that flow cytometry is not only a rapid and versatile method for analyzing these two important parameters, but that the results are very comparable to more traditional methods for assaying marine bivalve hemocytes.

Notwithstanding the good correlation between flow cytometry and microscopy, differences in means between the two methods may be significant. Some of this disparity undoubtedly comes from uncertainty in drawing bitmaps to delineate presumed flow cytometer particle groupings. In our study, the fact that microscopy estimated a higher percent phagocytosis may be the result of the inclusion of some cell debris in samples analyzed by flow cytometry. Large, bead-free debris could fall above the noise discriminator for forward light scatter and be counted as non-phagocytosing cells, which would decrease the calculated percent phagocytosis. Indeed, microscopic observation revealed the presence of a limited quantity of such cell debris, which increased when samples were stored for several days. Such debris was not generated in the viability assay since the experimental protocol did not involve the addition of trypsin and the mild sonication used in the phagocytosis assay to detach adhered cells. Probably for this reason, the percentages of dead cells obtained using flow cytometry were not different from those measured microscopically.

Critical to phagocytic assays is the detachment of cells from the incubation vials and the separation of non-ingested particles from the phagocytic cells. Trypsinization is generally used to detach cells (Alvarez et al. 1989) while a variety of methods have been developed to discriminate non-ingested particles (De Boer et al. 1996; Mortensen & Glette 1996; Lopez-Cortes et al. 1999). We found that a single procedure, trypsinization in the presence of EDTA followed by gentle sonication, was quite effective in both detachment and separation steps. The centrifugation step over a sucrose gradient (Alvarez et al. 1989) is not required here to separate non-bound beads from phagocytic cells since the forward light scatter allows easy differentiation between these particles based on size.

In this study, fluorescent latex beads were used as standard experimental particles for phagocytosis, as in the work of Alvarez et al. (1989) and Brousseau et al. (2000) who studied phagocytosis by hemocytes in *Crassostrea virginica* and *Mya arenaria*, respectively. These commercially available, fluorescent beads are extremely convenient for reproducible flow cytometric work due to their standardized sizes and fluorescence, qualities that are difficult to establish by labeling natural microorganisms. It must be recognized, of course, that latex beads may not evoke the same response from hemocytes as would foreign cells. Indeed, the present work demonstrated that the uptake of labeled *V. tapetis* was significantly lower than that of beads, despite precautions taken to ensure the same experimental conditions and hemocyte-to-particle ratios. Differences between the two test particles may be the result of specific interactions between hemocytes and beads or bacteria involving recognition factors that retard the uptake of formalin-fixed bacteria. Using microscopy, Lopez-Cortes et al. (1999) studied the phagocytic activity of *R. philippinarum* against *V. tapetis* and noted that the uptake of bacteria depended on the *V. tapetis* strain used. They also noted that viable *V. tapetis* were more efficiently phagocytosed than were the formalin-fixed bacteria and concluded that this was related to the presence of "specific recognition molecules" on the outer membrane of *V. tapetis* that combine with hemocyte receptors and that might be altered during fixation. Most work using labeled bacteria as test particles has been done after fixation of the microorganisms, which stabilizes the tag intensity because it prevents cell division or other processes that could alter intensity. Nevertheless, with appropriate controls, the use of live tagged bacteria should be included in cytometric assays to investigate the role of bacterial epitopes in recognition processes.

The development of BRD was associated with a significant decrease in phagocytic activity by hemocytes and an increase in the percentage of dead hemocytes. The lower phagocytic activity in diseased clams could be related to the percentage of dead hemocytes, since dead or moribund hemocytes are not capable of phagocytosis. Previous work has shown that clams with BRD have a high percentage of dead cells in the hemolymph compared to healthy animals and that this percentage increases with the development of the disease (Allam et al. 2000a, 2000b). The loss of phagocytic capacity and the death of hemocytes may result from deterioration of the physiological condition in severely infected clams (Plana et al. 1996), or from direct killing of hemocytes by *V. tapetis*. Indeed, results presented here demonstrate that *V. tapetis* is able to kill clam hemocytes *in vitro*.

It is often of interest to know the number of particles a phagocyte has ingested (phagocytic index) as well as the proportion of phagocytosing cells. The peak fluorescence intensity in the hemocytes that did ingest beads provided an index for the relative number of beads ingested by each cell. From this, it can be concluded that although clams with BRD symptoms had a smaller proportion of phagocytic hemocytes compared to asymptomatic clams, there was no difference in the number of beads each cell ingested.

Our results show a positive correlation between temperature and both percent phagocytosis and the phagocytic index of latex beads and agree with previous studies of other marine bivalves (Feng & Feng 1974; Foley & Cheng 1975; Alvarez et al. 1989; Tripp 1992; Chu & La Peyre 1993). It is relevant that the development of BRD seems to be at least partially controlled by water temperature (Paillard et al. 1997; Allam 1998). Laboratory experiments have shown high prevalence and intensity of the disease when clams are incubated at 8°C and 13°C compared to clams incubated at 21°C (Allam 1998). Conversely, there are improved repair processes (recalcification) at 21°C as compared to the lower temperatures. It is possible that the low prevalence of BRD at 21°C is related to better performance of the clam's defense system, including phagocytosis. The pathogen may also be less virulent at this temperature, although growth of *V. tapetis* is not inhibited at 21°C (Maes 1992; Paillard et al., unpublished).

In summary, we have described and validated flow cytometric methods to measure the phagocytic activity and viability of hemocytes from the clam, *Ruditapes philippinarum*. Additional types of cytometric measurements will undoubtedly be adapted from vertebrate systems for use with molluscs and other invertebrates. For example, reactive oxygen species (ROS) generated by phagocytic cells represent a current concern of bivalve pathobiologists and ecotoxicologists (Winston et al. 1996; Bramble & Anderson 1997; Lambert & Nicolas 1998). The successful use of flow cytometry for ROS measurements in aquatic mammals (De Guise et al. 1995) and fish (Verburg van Kemenade et al. 1994) indicate that flow cytometric methods can also be adapted for this purpose in bivalves. As new cytometric assays come into use, the developmental protocol should include some type of verification against a method that is considered the standard for that assay.

ACKNOWLEDGMENTS

TRANSPLANTS OF INTERTIDAL SHELLFISH FOR ENHANCEMENT OF DEPLETED POPULATIONS: PRELIMINARY TRIALS WITH THE NEW ZEALAND LITTLE NECK CLAM

M. J. STEWART* AND R. G. CREESE
Leigh Marine Laboratory, University of Auckland, P.O. Box 349, Warkworth, New Zealand

ABSTRACT The New Zealand little neck clam, *Austrovenus stutchburyi* (Wood 1828), is widely distributed in sheltered intertidal habitats around New Zealand and has long been harvested by recreational and traditional fishers. Clam abundances have declined on many beaches due to excessive harvesting and habitat change, such as sedimentation and pollution.

The feasibility of transplanting clams as a method of shellfish enhancement was tested. Manipulative field experiments using tagged clams examined parameters likely to affect growth and survival of transplanted clams, including the size of seed used, density and shore level at which seed is planted out, and the season in which the transplant is undertaken.

Juvenile clams (10–18 mm) had a mean recovery rate of 30% after 1 y. Growth was highest for clams transplanted to low on the shore, but mortality was also highest for these clams. Optimal placement of juvenile seed for enhancement would be at mid-shore levels, where more clams were retained and reasonable growth still occurred. A much higher recovery rate (60%–90%) was achieved for adult clams (25–32 mm), and they were more likely to remain in the new area. These pilot trials demonstrate that transplant is feasible and would be particularly successful for adult clams.

KEY WORDS: New Zealand *Austrovenus stutchburyi*, clam, enhancement, transplant, growth, season, survival

INTRODUCTION

The commercial exploitation of soft shore bivalves in New Zealand has been at low levels, with the exception of the surf clam, *Paphies ventricosa* (Stace 1991). Other species, however, traditionally played an important part in recreational fisheries and in traditional Maori food gathering (Dobbinson et al. 1989; Turner 1997; Stace 1991). Although considered nationally abundant, many populations have become locally depleted (Browne & Pawley 1995; Pawley et al. 1996; Pawley et al. 1997; Morrison et al. 1999, and considerable anecdotal evidence). *Austrovenus stutchburyi*, also known as the New Zealand little neck clam (Belton 1986), is one of the most abundant of these soft shore bivalves, but populations are experiencing declines in some areas. In the Auckland region in particular, temporary closures have been put in place in an attempt to counter declining stocks. The causes of these declines and the subsequent need for stringent countermeasures have not been adequately identified or addressed, but have commonly been hypothesized as increased sedimentation, high levels of contaminants in sediment and water, and overharvesting. These causes are all associated with urban development in coastal areas.

Current management of shellfish populations in New Zealand is largely restricted to the imposition of daily bag limits and local bans, although these are often not well enforced (Kearney 1999). Natural recruitment may lead to the recovery of clam beds if harvesting bans continue and are enforced, but recovery may be unacceptably slow. This appears to be the case in Auckland, where beds have not returned to historical densities despite a 7-y harvesting ban (Morrison et al. 1999).

There are two main commercial approaches to shellfish enhancement which have been used in coastal environments around the world: (1) the spawning and rearing of spat in a hatchery, and (2) the collection of spat from the wild (Malouf 1989; Peterson et al. 1995; Marelli & Arnold 1996). Both are then followed by a period of on-growing (usually in a land-based facility) before transplantation to the site of enhancement. Another, more traditional technique is the use of "spawner transplants," which involves transplanting naturally established shellfish from locations where the species is abundant to "enhancement" sites (usually sites where numbers are very low). In Japan, clams and oysters have been transplanted to enhance stocks for centuries (Wada 1993). It is also a traditional management practice for hard clam (*Mercenaria mercenaria*) fisheries in the eastern states of the United States (Kassner & Malouf 1982). There are a number of earlier studies where European clams (*Cardium edule*) were taken from areas either of high spat fall or of high density and transplanted to areas of low density (Hancock 1969; Mason 1969). Recent transplants of adult scallops in the western Bogue Sound, North Carolina, resulted in enhanced recruitment of 568% compared to 3% for control sites (Peterson et al. 1996).

In New Zealand, enhancement techniques are not developed to the same level as those widely used overseas (Creese & Cole 1995). Although it is technically possible to rear New Zealand clams in the laboratory (Stephenson & Chanley 1979), reliable production of large numbers of spat has proved difficult, and no commercial or sizeable hatchery has yet been established to produce the quantities needed. Enhancement using adult clams had been suggested but not tested in New Zealand prior to the commencement of this research (Dobbinson et al. 1989).

Manipulation of several factors, shown separately to influence the survival of seed (juvenile or adult shellfish), can greatly improve the success of enhancement (Peterson et al. 1995). The literature on New Zealand clams and on international enhancement attempts identified several factors that might influence the transplant success of infaunal bivalves. The transplants of clams described in this paper manipulated not just one, but several factors that the literature suggested might be important in successful transplant of shellfish. Although the literature suggests that separately these factors might be important in restoration success, the interactions among them may be just as important as the individual factors themselves. A multifactorial design was used to detect all possible effects of density, size of seed, season, and shore level, including the interactions of these factors. Predation could not be feasibly incorporated into this already large experimental design, so this was investigated separately (authors' unpublished data).

In the long term, it would be hoped that transplanting clams would increase success of spawners and thereby recruitment. However, the primary objective of this experimental transplant was to assess the feasibility of the technique as a method for future enhancement, and to determine what factors might affect the success of transplants. In the long term, increased recruitment of clams or changes in overall community structure would be important variables by which to measure the outcome of enhancement. However, for this 1-y, small-scale project, it was decided that growth and survival of transplanted clams would be the most direct measures of the outcome of transplant.

METHODS AND MATERIALS

Experiments were carried out in the Whangateau Harbour near Leigh in North Eastern New Zealand, with clams transplanted from Lews Bay to Point Wells (Fig. 1). Clams were collected from Lews Bay at low tide over 2 d, taken to the Leigh Marine Laboratory, and held in a saltwater flow-through system. Clams were double tagged, with aluminum pieces glued to the shell (Stewart & Creese 2000) and also with colored enamel paint to denote treatments.

At each of the control and experimental sites, the experiment was set up in a grid pattern with treatments (three replicates of each) assigned to plots (each 0.25 m^2) within the grid using an incomplete block design. There were a total of 15 plots at each site. Each plot was 1 m from any other plot and shared no border. *Austrovenus stutchburyi* are relatively sedentary and throughout the experiment no clams were observed to move between plots. When the clams were planted out, the sediment from each 0.25-m^2 plot was excavated and sieved through a 2-mm mesh sieve to remove any resident macrofauna and thereby standardize the initial state of sediments in the plots. To prevent desiccation and predation of newly transplanted clams before arrival of the incoming tide, clams were placed in the excavated holes and partially covered with sieved sediment. It was observed that, despite being covered initially, most clams would emerge and rebury themselves fully by the next low tide.

Lews Bay, from where clams were originally collected, served as a control site to enable the effect of translocating clams and site effects to be distinguished. Control clams were subjected to the same stress as those transplanted to Point Wells. Because clams are of a small size high on the shore, and are larger lower on the shore (Larcombe 1971), controls for each size class were only set up in the area from which those clams were collected. That is, small clams collected from high on the shore were returned to high on the shore, and large clams collected from low on the shore were returned to low on the shore (Fig. 2).

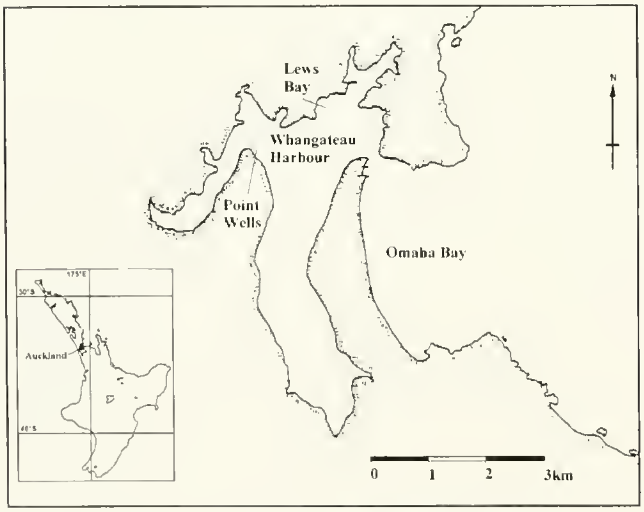

Figure 1. Location of study sites, Lews Bay and Point Wells in Whangateau Harbour, near Leigh in northeastern New Zealand.

To investigate the effect of shore level on growth and survival of transplanted clams, experiments at Point Wells were set up at two shore levels, mid (150 m from mean high water spring [MHWS]) and low (350 m from MHWS) (Fig. 2). Preliminary surveys of the site revealed a low abundance of clams at the high shore, consistent with other studies of clam distribution in the region (Larcombe 1971; Kearney 1999).

Within the transplant experiments, the effect of size was investigated by using two sizes of seed: "small" (10–18 mm shell length), which represented nonspawning clams, and "large" (25–32 mm), which represented an adult spawning size (Larcombe 1971). Two densities were compared to investigate whether it is better to space clams out or to pack them into smaller, more easily managed plots. The two densities compared were 200 clams/0.25 m^2 for the packed treatment and 50 clams/0.25 m^2 for the spaced treatment. Two transplant experiments were conducted, one commencing in March 1998 (summer transplant experiment) and one in September 1998 (winter transplant experiment), allowing comparison between two planting seasons.

A third trial (disturbance experiment) was established to assess the effect of disturbance from the bimonthly excavation of plots used in the two transplant experiments. At the low shore site at Point Wells, an additional three replicates of large clams at the 50/0.25 m^2 density were set up at the start of each experiment. These were excavated only at the end of the experiment, and growth and survival of clams were compared to those in plots disturbed every 2 mo.

Figure 2. Small cockles were collected from high on the shore at Lews Bay and transplanted to mid and low shore levels at Point Wells. As a control, some small cockles were also returned to high on the shore at Lews Bay. Large cockles were collected from low on the shore at Lews Bay and transplanted to mid and low shore levels at Point Wells. As a control, some large cockles were also returned to low on the shore at Lews Bay.

Analysis

The effect of shore level was essentially a separate investigation at Point Wells. If those clams returned to Lews Bay had been planted out at mid-shore and low-shore levels as at Point Wells, this would not have served as a control, because clams would had to have been transplanted to different levels from which they were collected at Lews Bay. Because the "shore level" treatment was not balanced between Point Wells and Lews Bay, the two shore levels at Point Wells were treated as separate sites, additional to Lews Bay, for statistical analysis. The names "Mid Point Wells" and "Low Point Wells" continued to be used in order to retain their site identity.

Mortality

Weekly visits were made to each site and visual searches undertaken for any dead shells (cluckers), which remained on the surface. This was used as an estimate of apparent mortality (Arnold 1984; Dobbinson et al. 1989), to minimize disturbance from frequent digging.

Upon completion of all experiments (January 1999), plots were identified using the metal detector to locate the aluminum-tagged cockles (Stewart & Creese 2000). Plots had no external markings, which avoided interference with plots on public beaches. All clams were excavated and brought back to the laboratory. This enabled a direct measure of the number of clams remaining. Sediment in each plot was washed through a 2-mm sieve and tagged individuals were retained. A number of tagged cluckers were also retrieved during this process. The area (~1 m) immediately surrounding each plot was also sieved until no further tagged clams were retrieved in two successive sieves. In some instances, "finger ploughing" (James & Fairweather 1995) of the sediment was also used. When no additional clams were retrieved either through finger ploughing or sieving, the metal detector was used to locate any missed individuals. The detector was passed over the surface for a distance of up to 5 m away and when a "hit" was detected, the sediment was finger ploughed to retrieve the clam. This was repeated until no more clams were detected over the entire plot and surrounding area.

For each replicate plot, the number of clams in each of four categories was recorded; alive, missing, dead as undamaged empty valves, and dead as empty valves with observable shell damage.

Because the "summer transplant experiment" ran for 11 mo and the "winter transplant experiment" ran for 5 mo, a direct comparison of mortality could not be made between seasons. However, data for the first 5 mo of the summer transplant experiment were analyzed to provide a legitimate comparison between seasons. For mortality, this was done using only the number of shells retrieved during visual searches, and therefore it is a comparison of apparent rather than actual mortality. At the end of the experiment, survival (estimated from the number of live clams retrieved) was analyzed separately for the two seasons. Data were tested for normality and homogeneity (using Cochran's test) prior to performing analysis of variance (ANOVA).

Growth

Because clams were not numbered individually, growth was assessed by following changes in the modal length of size cohorts over time. Every 2 mo, a subsample of 20 clams was remeasured from each 0.25-m^2 plot. Subsampling avoided undue disturbance to plots. Plots and clams were relocated using the metal detector and clams were excavated, with care taken to minimize disturbance to those clams not measured. To ensure that a random sample was taken every time, a strip was randomly drawn through the plot and clams were sampled in this area. Comparisons of growth over the full experimental period could not be made between seasons. Interim calculations were made for growth after 5 mo for the summer transplant experiment.

RESULTS

Mortality

Apparent mortality of clams was estimated from the number of tagged cluckers retrieved after 5 mo for each season. A four-factor ANOVA was performed using the factors "season," "site," "size," and "density." There was no significant effect of season or density on apparent mortality ($P > 0.05$), nor any interaction involving these factors. The pattern of mortality between sites was not the same for large and small clams, giving a significant interaction ($P < 0.01$) between site and size. Mortality for large clams was highest at Mid Point Wells, but for small clams it was highest at Low Point Wells (Fig. 3). Survival was significantly different between large and small clams ($P < 0.01$), with mortality higher for large clams than for small ones (Fig. 3). In addition, a significant difference between sites ($P < 0.01$) was detected. Apparent mortality was lowest at Lews Bay, the site of origin for all transplanted clams (Fig. 3).

Survival was assessed from the number of clams retrieved at the end of both summer (after 11 mo), and winter (after 5 mo) transplants. The average survival was 75%–90% for large clams transplanted in winter, and greater than 60% for large clams trans-

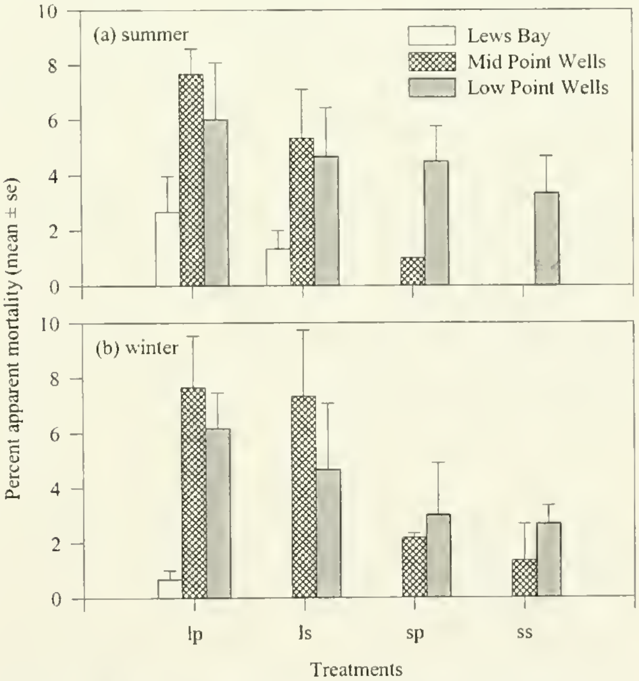

Figure 3. Mean percent apparent mortality, estimated from the retrieval of cluckers across treatments after 5 mo [from March to July for the summer transplant experiment (a) and September to January for the winter transplant experiment (b)]. $n = 3$ replicated plots at each site. lp = large cockles (25–32 mm shell length) at packed density (200/0.25 m^2), ls = large cockles at spaced density (50/0.25 m^2), sp and ss = small cockles (10–18 mm shell length) at packed and spaced densities, respectively.

planted in summer, with the exception of Lews Bay (Fig. 4). Even for small clams, average survival was greater than 30% at all sites except Low Point Wells in summer (Fig. 4). Survival at Lews Bay was confounded by storm events removing an entire shell bank containing the large clams in the winter transplant experiment, as well as many of the large clams in the summer transplant experiment. Therefore, data from Lews Bay were excluded from the analysis. Three-way ANOVAs were performed separately for each of the summer and winter transplants for the Mid Point Wells and Low Point Wells sites only, with the other factors being "size" and "density." With Lews Bay excluded, the two Point Wells sites effectively become "shore level" treatments. For the summer transplant experiment, both the "size × density" interaction ($P = 0.04$) and the "shore level × size" interaction ($P < 0.01$) were significant. Survival for large clams was similar between Mid Point Wells and Low Point Wells, but survival of small clams was lower at Low Point Wells (Fig. 4). Significantly more large clams were retrieved than small ones ($P < 0.01$), and overall survival of large and small clams was highest at Mid Point Wells ($P < 0.01$). The significant "density × size" interaction is due to fewer small clams in the spaced density treatment surviving than in the packed density treatment (Fig. 4). For large clams, survival was similar between density treatments (Fig. 4). Results for winter transplants are similar, but the "size × density" interaction was not significant ($P = 0.08$) (Fig. 4).

Because the storm events that affected experiments at Lews Bay affected only large clams planted low on the shore and not small clams planted higher on the shore, two-way ANOVAs on survival were run for small clams only. That is, the factor "size" was removed and only "site" (Lews Bay included) and "density" were analyzed. For both summer and winter transplants, there was no significant "site × density" interaction. However, both site and density were significant factors. In the summer transplant experiment, survival of small clams at Low Point Wells was significantly lower than at Mid Point Wells or Lews Bay (Student-Newman Kews test, $P < 0.05$). Survival was not significantly different between Mid Point Wells and Lews Bay ($P > 0.05$). For the winter transplant experiment, survival of small clams was significantly different among all three sites ($P < 0.05$), with lowest values at Low Point Wells (Fig. 4).

The majority of small clams not retrieved in the final sample (either as whole or damaged valves) could not be accounted for (Fig. 5). At Lews Bay, the majority of large clams not retrieved were also missing (Fig. 5a and b) presumably due to the storm events. However, at the Point Wells sites, the majority of large clams not retrieved in the final sample were accounted for by either whole valves or damaged valves, retrieved during visual searches carried out during the year. Most retrieved valves were still intact, with no evidence of damage that might indicate predation (Fig. 5). Damaged shells were mainly crushed half valves or had chipped ventral margins.

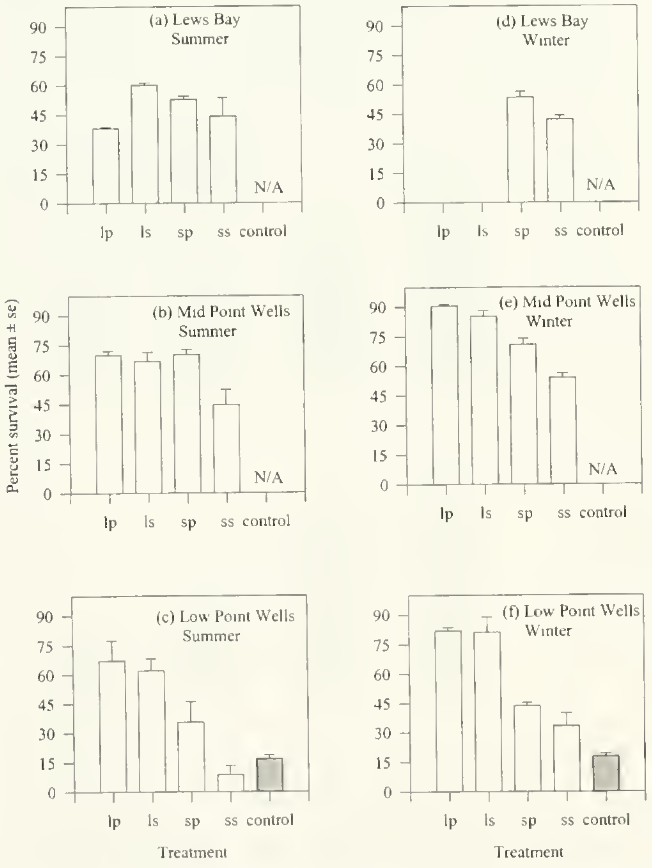

Figure 4. Mean percent survival taken from the number of live tagged cockles retrieved at the end of the experiment (11 mo for the summer transplant and 5 mo for the winter transplant). $n = 3$ replicate plots. Size and density treatments as in Figure 3. Disturbance controls (Low Point Wells site only) are shown in grey.

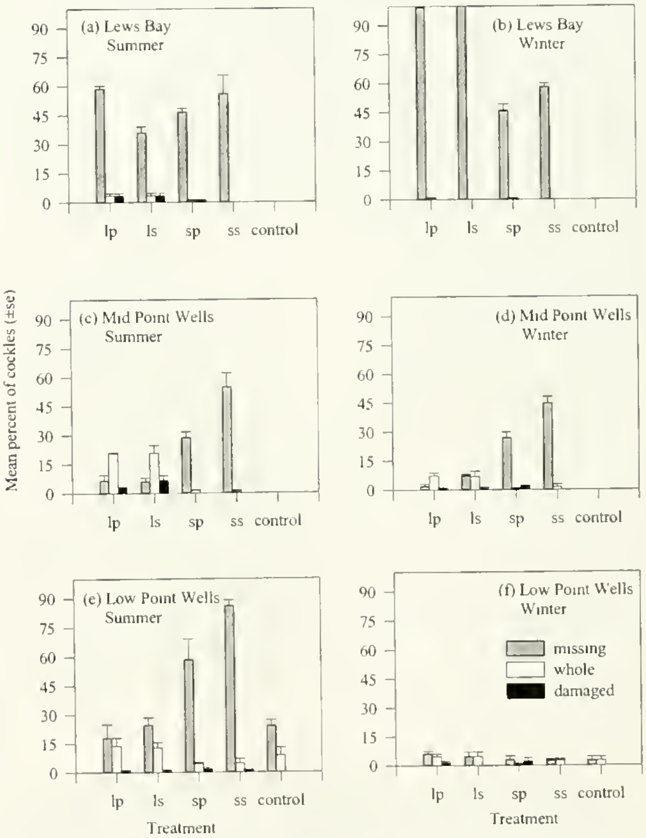

Figure 5. Mean percent of cockles missing, and mean percent of damaged and whole valves retrieved by visual searches at the end of the experiments (11 mo for summer experiment and 5 mo for winter experiment). $n = 3$ replicate plots at each site.

Growth

Mean shell length was initially taken from random samples of 20 individuals taken from each plot every 2 mo. These individuals were considered representative of the experimental population. Inter-replicate variation was found to be virtually zero, so replicate treatments were pooled for graphical representation. Because there was little change in mean size until toward the end of the experiment (when water temperature increased), the difference in growth between treatments was analyzed in terms of the change between the initial mean shell length of transplants and the mean shell length at the end of the experiment.

Growth was analyzed separately for each experiment using a three-way ANOVA with the factors "site," "size class," and "density." For both seasons, there was a significant ($P < 0.05$) three-way interaction ("site × size × density"), but some patterns can be seen in the data. Large clams grew only 1–2 mm during the experiment (Fig. 6). Small clams, however, showed pronounced growth in some treatments, particularly at the Low Point Wells site (Fig. 6). Interestingly, growth in the small clams was readily identifiable by direct observation of the shell. A clear disturbance mark could be seen in the shell, indicating when they were first placed out in the field. No other clams in the area showed such as pronounced growth check. Clams taken from the high shore level at Lews Bay and transplanted to Point Wells grew more than those returned to the site of origin at Lews Bay (Fig. 6).

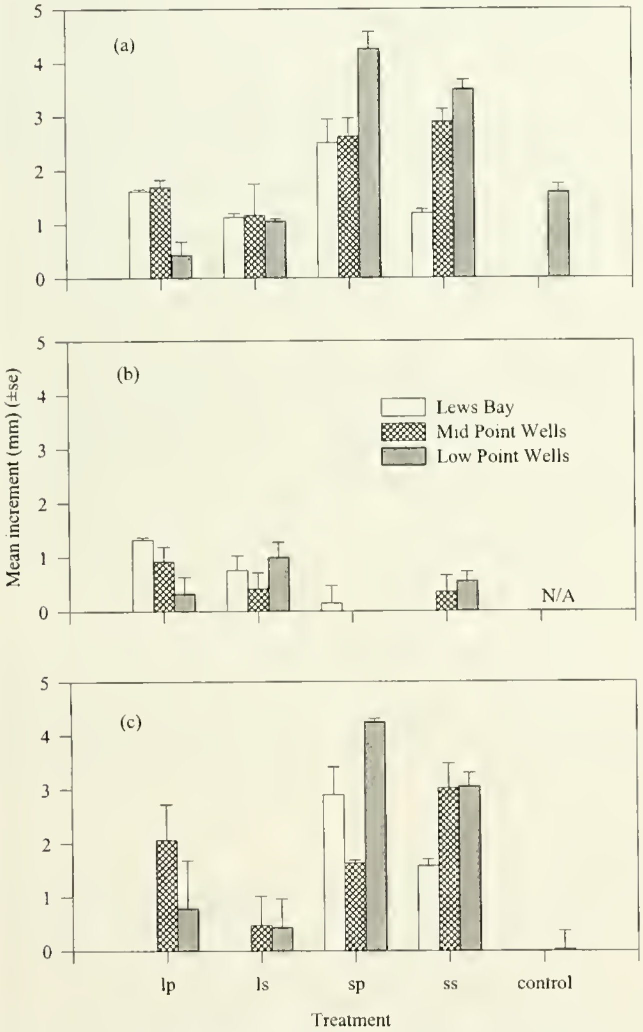

Figure. 6. Mean change in shell length (mm) after 11 months (March–January) for the summer transplant experiment (a) and after 5 months (March–July and September–January) for the summer (b) and winter (c) transplant experiments, respectively. $n = 3$ replicate plots at each site. Control plots (Low Point Wells only) for disturbance are shown in the gray bars.

DISCUSSION

Although the initial collection and tagging of clams did appear to cause a clear growth check mark, the disturbance of clams for ongoing sampling during the experiment appeared to have no effect on growth or survival. The absence of a digging effect is consistent with results from previous manipulations of these clams (Martin, unpubl. data).

Apparent mortality of large clams was lowest when they were returned to their site of origin at Lews Bay. At the end of the experiment, however, no large clams transplanted in winter and few large clams transplanted in summer were retrieved from Lews Bay, due to storm events. Until this point, mortality, estimated both by the numbers of cluckers retrieved and by observations made during ongoing sampling, was lower than for the Point Wells sites. We are confident that this trend of lower mortality at the site of origin would have continued in the absence of storm interference. Lower mortality for clams returned to the site of origin indicates that survival of transplanted clams was affected by environmental characteristics of particular sites, because all clams underwent the same transplant process.

The majority of small clams not retrieved at the end of the experiment could not be accounted for. These clams may have either died and their shells were lost, or they may have migrated out of the area. Small clams were observed to move away from the initial experimental plots more than large clams. If emigration is the main source of "loss," and these clams remain within the general vicinity of the transplant plot, then enhancement may still be considered successful, because these clams will still contribute to the population. If they have migrated away from the area entirely, then the effect on enhancement success is the same as mortality. Tethering of clams would allow better assessment of whether these clams are dying (with subsequent loss of their shells) or if they are migrating. However, we suggest that a minimum survival rate for transplanted clams of 30% (as achieved in our experiment), although not great, may be a realistic management option and preferable to doing nothing and accepting the present situation of declining stocks and poor recruitment.

The majority of enhancement projects are conducted using juvenile shellfish, simply because large numbers can be produced in a hatchery and they do not require costly on-growing to a larger size before planting out. However, planting out of larger shellfish is often more successful (Peterson et al. 1995; Marelli & Arnold 1996), a result attributed to high mortality of juvenile shellfish, possibly from predation. This inverse relationship between size and mortality rate is often explained in terms of prey size refuge (Whetstone & Eversole 1977; MacKenzie 1979; Arnold 1984; Kraeuter & Castanga 1989; Peterson et al. 1995; Marelli & Arnold 1996). For this reason, Marelli and Arnold (1996) consider that broadcasting (i.e., the seeding out of very large numbers of unprotected juveniles) is not an effective stock enhancement technique.

Our experiments enabled a comparison between the survival of small and large transplanted clams. As predicted by the published studies cited above, survival of large clams was much higher than for small clams (generally >60% and up to 90%).

The survival rates obtained in this study compare favorably with transplants of the hard clam *Merceneria merceneria* (mainly juveniles) in the United States. Peterson et al. (1995) achieved 35% survivorship over 14 mo. Marelli and Arnold (1996) were less successful with 95% mortality after 80 d. In earlier trials by Flagg and Malouf (1983), greater than 10% survival was only achieved for those clams larger than 20 mm, and even clams of this size suffered 100% mortality in areas with large whelk populations. A minimum survival for small clams of 30% could well be acceptable for enhancement, but a greater initial number of transplants would be required to compensate for subsequent losses. To achieve the desired level of enhancement, it may also be necessary to follow the initial transplant with a number of smaller secondary transplants. It would be laborious to collect such large numbers of *A. stutchburyi* from the field, and enhancement may only be feasible if viable hatchery production, using local spawning stock, could be established.

Damaged shells recovered in this study had either crushed valves, likely to be attributable to birds or crabs, or chipped ventral margins, likely due to whelks. No large crabs were observed in the area and the only birds observed were lone pairs of oystercatchers, *Haemstropus ostralegus*. Other potential predators may have been stingrays or fish, because a number of feeding pits were observed in the area. However, predation by stingrays would have left a noticeable disturbance in the experimental grid, which was never observed.

Peterson et al. (1995) found that survivorship was greater for *Mercenaria mercenaria* clams planted in late fall/winter, but average growth was greater for clams planted in late summer. However, clams transplanted in summer were in the field for at least 2 mo longer than winter-transplanted clams. This temporal difference is mentioned, but no adjustments were made for comparison of the two seasons. Thus, the period of exposure was compared, and not season.

In our study, growth of transplanted *A. stutchburyi* was more dependent on the time of year than on the treatment. Large clams showed minimal growth, probably due to having already attained near maximum size of 35 mm (Larcombe 1971; Dobbinson et al. 1989). Small clams showed pronounced growth at some sites. This growth did not begin until late winter (September) for clams planted out in March, and was most noticeable in the spring (November). For those clams planted out in September, an increase in size was already noticeable 2 mo later, in November. Small clams showed the greatest increase in shell length when transplanted, from high on the shore at Lews Bay (the original site) to low on the shore at Point Wells. This same shore level effect was found by Dobbinson *et al.* (1989) in Otago Harbour, southern New Zealand. *A. stutchburyi* low on the shore are generally larger than those high on the shore (Wood cited in Morton & Miller 1973; Larcombe 1971; Dobbinson et al. 1989). Larcombe (1971) hypothesizes that this is due to poor growth conditions, in particular food availability (due to increased exposure time), restricting growth at higher shore levels. Clams transplanted to low on the shore at Point Wells grew considerably more than those returned to the site of origin at Lews Bay, indicating that clams high on the shore at Lews Bay are unlikely to realize their full growth potential. If this is the case, then translocating these clams to areas lower on the shore at enhancement sites may be a way of increasing the biomass yield (Dobbinson et al. 1989).

Dobbinson et al. (1989) found virtually no effect of density on growth of *A. stutchburyi*. Density manipulations by Stephenson (1981) and Blackwell (1984), however, resulted in apparent intraspecific competition, limiting growth and increasing mortality. Martin (1984) found higher growth rates in treatments where density was experimentally reduced. The effect of density on growth and survival in our study is difficult to interpret because of an interaction with the effect of size. Higher retrieval of clams in densely packed treatments may have been because clam movement was restricted at the higher density, and therefore more clams were retained. If so, retention of transplanted clams may be improved if they are planted out in dense clumps rather than spaced over a beach. This would also make post-transplant monitoring easier.

In conclusion, high survival for large clams and reasonable survival for small clams indicates that the transplant of New Zealand clams is a feasible technique for enhancement. It is recommended that transplant of clams for enhancement should be undertaken with adult clams, because these show the highest survival, are easier to collect, and are more likely to remain within an area. Recent studies have demonstrated that infaunal bivalve recruitment can be dependent on the adult density (Peterson & Summerson 1992; Peterson et al. 1996; Arnold et al. 1998). Large clams may therefore also have the added benefit of adding to the population sooner (through spawning and subsequent recruitment of new clams), thereby speeding the recovery of an area.

ACKNOWLEDGMENTS

This work was funded in part by the Auckland Regional Council. The transplant experiment was achieved with the help of many students at the Leigh Marine Laboratory. The manuscript was improved by the comments of an anonymous reviewer.

MORTALITIES OF *ENSIS ARCUATUS* (JEFFREYS) (SOLENACEA) IN WESTERN IRELAND

EDWARD FAHY,[1] MARIA LYONS ALCANTARA,[1] MARK NORMAN,[2] RONAN BROWNE,[2] VINCENT ROANTREE,[2] AND NICK PFEIFFER[3]
[1]*Marine Institute, Abbotstown, Dublin 15, Ireland;* [2]*Taighde Mara Teó, Carna, Co Galway, Ireland;*
[3]*Atlantic Diving, 25 William St W., Galway, Ireland*

ABSTRACT Mortalities of the razor clam *Ensis arcuatus* were widespread in western Ireland in the spring months of 2001. Loss of biomass from one razor clam bed was estimated at 74%. Larger razor clams were more susceptible. Histological and bacteriological examinations and TEM were carried out on moribund and live individuals but no pathological cause was identified. Gonadal staging revealed that large *Ensis arcuatus* were partially or completely spent. Mortality is explained as a post-spawning phenomenon, which was unusually severe in 2001.

KEY WORDS: *Ensis arcuatus*, razor clams, shellfish mortalities, western Ireland

INTRODUCTION

In 1997, a hydraulic dredge fishery for razor clams commenced in the Irish Sea where extensive beds of *Ensis siliqua* had been discovered. A market developed, largely in Spain, and, when the Irish Sea fisheries became exhausted, additional beds were sought on the western Irish seaboard. The inshore waters of Cos Galway and Mayo contain thinly dispersed *E. arcuatus*, which form sufficiently dense concentrations to reward commercial exploitation only in special and limited circumstances. These patches are invariably in the lee of reefs and islands that provide shelter from the Atlantic swell.

Investigations were undertaken on these razor clam beds to provide biological data on the growth and reproduction of *Ensis arcuatus* (Fahy et al. 2001b); in the course of these studies we encountered the phenomenon described here, which is evaluated in the context of information emerging from the wider biological enquiry.

Investigations on the local ecology of *E. arcuatus* had been carried out in Cill Chiaráin Bay, Co Galway, in August 2000. In March of the following year, a mass mortality of the species was reported there by a local fisherman, prompting a second assessment. Cill Chiaráin Bay (9°45′W: 53°20′N) is occupied by a major Irish shellfish cooperative, Comharchuman Sliogéisc Chonamara Teó, managing oyster and scallop, and concern for the possible involvement of a disease in the mortalities prompted further investigations. Other shellfish species were not, however, similarly affected, and the fisherman who first reported the event also reported mortalities of *Ensis arcuatus* over a wide area south of Slyne Head (10°10′W:53°7′N), extending to Inishmann in the Aran Islands (9°36′W:53°24′N). Survey work by one of the authors (E. F.) in the vicinity since has confirmed that the phenomenon was widely distributed and that it has affected large numbers of the species.

MATERIALS AND METHODS

The distribution of *E. arcuatus* in a part of Cill Chiaráin Bay was first investigated in August 2000. Divers sampled by pouring 1 L of granular salt over a quadrat 0.33 m^2 and collecting all razor clams which emerged from the substratum within it. Initially, the area was investigated along north-south and east-west transect lines but, when heavier densities of the animals were located (the razor clam "bed"), sampling was concentrated on those areas. The length of every individual was measured on a fish measuring board and the biomass in each quadrat was estimated from a weight at length curve, the parameters of which were calculated in August 2000. Repeat sampling of the bed was conducted on April 23, May 29, and August 23, 2001.

Samples of razor clams, *Ensis arcuatus*, taken from Cill Chiaráin Bay in April (24 individuals) and May 2001 (29 individuals) were processed for histology. Animals were dissected and immediately fixed in Carson's fixative for 48 h. Cross sections were cut so as to include as many organs as possible. Tissue samples were processed in an automatic processor for 10 h. In the processor, the tissues were passed through different grades of alcohol and xylene and then impregnated and embedded in paraffin wax. Tissue sections were cut at 3 μm and stained in an automatic stainer with hematoxylin-eosin; they were then mounted on silinized slides and air dried.

Some of the razor clams collected in April displayed postmortem tissue changes, so the following month a distinction was made between 13 moribund individuals that were lying on the surface of the substratum and 29 live razor clams that emerged from the substratum in response to granular salt having been spread within a quadrat.

The stage of gonadal development was assigned to the samples collected in May following microscopic examination using the terminology of Gaspar and Monteiro (1998): the six stages of gametogenic development progress from stage 0 (inactive) through stages I (early active gametogenesis), II (late active gametogenesis), III (ripe), IV (partially spent), to V (spent).

Tissues from two moribund individuals were fixed in Carson's fixative for 48 h for electron microscopy. They were washed several times in 24 h in a bath of cold cacodylate buffer (at 4°C) and then fixed in 3% glutaraldehyde. Samples were washed in cacodylate buffer then postfixed in 1% OsO4 (for 1 h at 4°C) and washed again in cacodylate buffer, dehydrated in ascending grades of ethanol, and subsequently embedded in epoxy resin. Thin sections were cut with a diamond knife using an ultramicrotome, stained with uranyl acetate and lead citrate, and examined under an electron microscope.

Bacteriological culture plates were used for primary isolation of pathogens. The media employed included blood and seawater agars and thiosulfate citrate bile salt sucrose agar (TCBS) for detection of *Vibrio*. A BioNor (Norway) monoclonal antibody agglutination kit was used to detect the possible presence of *V. anguillarum*.

TABLE 1.

Single-factor ANOVA comparing razor clam biomasses in Cill Chiaráin on four occasions: August 2000, and April, May, and August 2001.

Summary

Groups	Count	Sum	Average	Variance
36982	21	2502.274	119.1559	8031.401
37012	8	606.9071	75.86338	2704.084
37104	24	2657.337	110.7224	10344.37

ANOVA

Source of Variation	SS	DF	MS	F	*P*-value	*F* crit
Between Groups	11019.4	2	5509.698	0.65988	0.521356	3.182606
Within Groups	41477.1	50	8349.542			
Total	428496.5	52				

RESULTS

When the razor clam bed was examined in April 2001, dead and dying razor clams were much in evidence on the substratum or standing half-clear of it, together with freshly empty but undamaged shells. Similar conditions obtained when the site was visited 1 mo later. Razor clams on the bed in Cill Chiaráin Bay are not so densely concentrated when compared with parts of the *Ensis siliqua* bed on the east coast, for example (Fahy et al., 2001a) and there was wide variance in estimates of biomass on each occasion it was sampled. A single-factor analysis of variance (ANOVA) suggests that mean biomass altered highly significantly (Table 1) and more detailed comparisons revealed the differences in biomass to be highly significant between August 2000 and May 2001 ($P < 0.001$); biomass also differed highly significantly between August 2000 and August 2001. The reduction in biomass between August 2000 and May 2001 was 74% (Fig. 1).

Length frequency distributions of live razor clams recovered by divers in August 2000, May 2001, and August 2001 are shown in Figure 2, along with the length frequency of moribund animals in April 2001. In May, there were signs that some of the larger animals recorded the previous August (corresponding with the moribunds recorded in April 2001), were absent from the population, although smaller size categories were not recorded either in May 2001. A notable difference between the years is the large incidence of juveniles, corresponding to recently spatted 0-group animals in August 2001. To compare the year-to-year changes in length distributions, therefore, only animals greater than 7 cm were considered. The two length frequencies differ significantly ($P < 0.05$) (Table 2); contrary to expectation, however (the moribunds had apparently been the largest size group), the greatest discrepancy is in the abundance of small- to medium-sized animals in the second year.

Gonadal staging of live and moribund razor clams in May (Table 3) revealed that the majority were female, but all were either stage IV or V (partially or completely spent).

Histological examination of razor clams sampled in April 2001 revealed that ciliates were occasional on the gills, and there was a low incidence of *Nematopsis* oocytes (Gregarines) in the connective tissue of the mantle and gills of some animals. Low numbers of *Chlamydia*-like organisms were found in some epithelial cells of the digestive gland of some razor clams. The levels of infestation of any pathogen were so low that they could not be associated with the mortalities. Some animals presented postmortem tissue changes. Abnormal nuclei were found in the connective tissue cells of some razor clams. Transmission electron microscopy (TEM) analysis of these samples confirmed that the abnormalities were related to necrosis and not to a pathogen.

Some razor clams collected in May 2001 had *Chlamydia*-like organisms in the epithelial cells of the digestive gland and some had *Nematopsis* oocytes in the connective tissue. One individual in May had a heavy infestation of metazoan sporocysts. But again, mortalities could not be attributed to any of these. The presence of an unexplained "deposit" in some digestive diverticular cell cytoplasm was noted.

Bacteriological analysis indicated the presence of *Vibrio* sp. (possibly *V. fluvialis*), the natural flora of the environment. Results of serological agglutination tests for *V. anguillarum* were negative.

DISCUSSION

Occasional mass mortalities of razor clams, *Ensis* sp., are attributed to several causes, among them storms (Tebble 1966) and

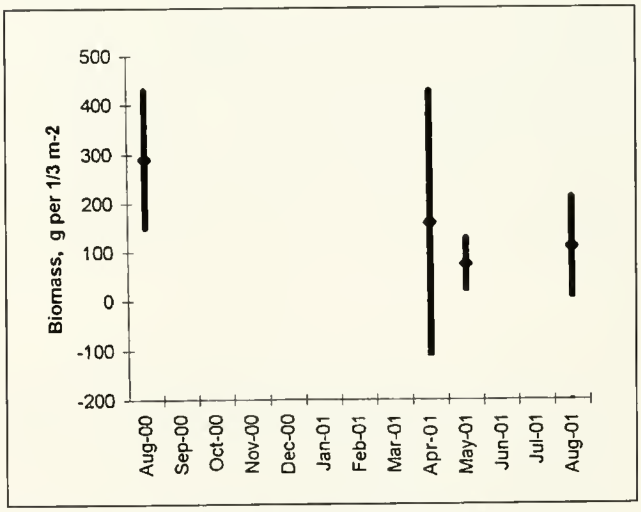

Figure 1. Mean values (±1 SD) of razor clam biomass in Cill Chiaráin Bay at times between August 2000 and August 2001.

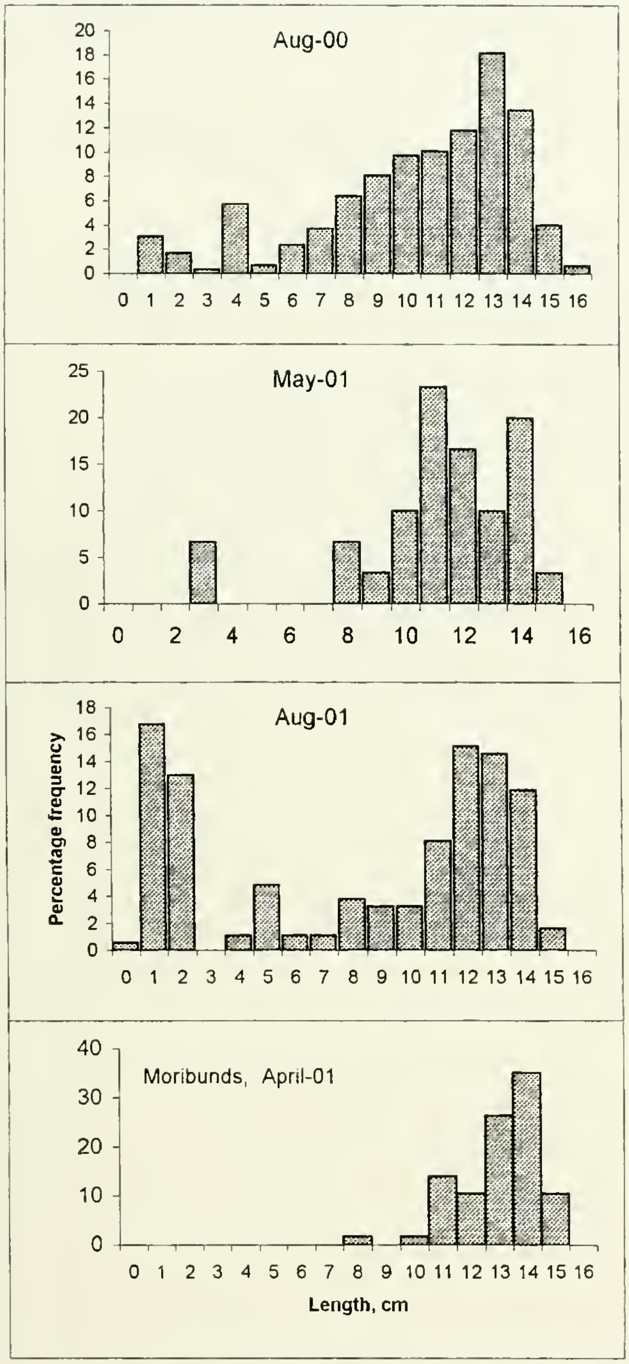

Figure 2. Length frequency distributions of *Ensis arcuatus* in August 2000 and in May and August 2001, and distributions of moribund animals in April 2001.

"adverse environmental conditions" (Howard 1998). Mortalities of the Pacific razor clam, *Siliqua patula*, explained by infection with *Rickettsia*-like organisms, referred to as nuclear inclusion X, have been reported in several locations in the United States (Elston 1986).

Razor clam mortalities in western Ireland in the spring of 2001 were too widespread to be attributed to a local environmental explanation. They occurred within (and outside) a large shellfish cooperative and there was concern lest the oysters and scallops that are managed within the cooperative might be infected with a pathogen, but simultaneous mortalities were not observed among these.

TABLE 2.

Length frequencies (above 7 cm) of razor clams in August 2000 and August 2001, compared by chi-square.

Length (cm)	August 00	August 01	August 00	August 01	Chi-square
7	4	2			
8	7	6	12	8	2.0
9	9	5	9	5	3.4
10	11	5	11	5	7.3
11	12	13	12	13	0.1
12	14	24	14	24	4.5
13	21	23	21	23	0.2
14	16	19	21	22	0.0
15	5	3			
16	1	0			
	100	100	100	100	17.6

$N - 1 = 6$; at 6 degs of freedom, chi-square $= 12.6$, therefore, $P < 0.05$.

The razor clams that made up the mortalities were apparently predominantly large *E. arcuatus*, the dominant bivalve species in this vicinity (Fig. 2). Although it is accepted that larger individuals would be more visible to a diver collecting specimens, the size groups which appeared to have been removed from the population are of small to medium size (Table 2), when August 2000 is compared with August 2001, although sampling in April and May 2001 suggested the largest clams were most affected. The question is why the small- to medium-sized razor clams were not better represented among the moribunds. Razor clams are highly mobile, probably the most mobile of the bivalves after scallops, and they are known, for example, to rapidly recolonize favorable ground after dredging operations, so some immigration to the depleted clam bed from the surrounding lower densities is likely to have taken place after the event. *E. arcuatus* is widely distributed in the vicinity and its length frequency distribution in the areas of greatest clam concentration (the "bed") was similar to that among the more thinly dispersed population in the waters surrounding it in August 2000 (Fahy et al., 2001b). The razor clam bed in this part of Cill Chiaráin Bay is understood to occupy more sheltered and hence more favorable conditions for the animals.

Recorded mortalities were confined to animals of mature size (the smallest mature *E. arcuatus* recorded in the course of biological investigations was 8.5 cm, corresponding with an age of 2–3 y).

TABLE 3.

Gonadal staging for apparently healthy (live) and moribund razor clams from Cill Chiárain Bay in May 2001.

Status	Sex	Gonadal Developmental Stages	Number of Individuals	Percentage
Moribund	Female	V	5	56
		IV	1	11
	Male	V	1	11
		IV	2	22
Live	Female	V	13	65
		IV	4	20
	Male	V	1	5
		IV	2	10

Although it is possible that the smallest dead razor clams were undersampled, the mortalities appeared to be heavily skewed toward the largest, oldest individuals. There are signs that some spawning by *E. arcuatus* takes place in every month of the year, but it is more prevalent in the population from October to April; there were signs of only one spatfall, on the other hand, in June or July. The latter would correspond with spawning in March–April, which must therefore be the most significant spawning time in this species.

If postspawning mortality is a normal occurrence in *E. arcuatus*, the incident in the spring of 2001 must have been exceptional. A regular loss of 74% biomass, although it was followed in this case by a considerably larger spatfall than in the previous year, would have serious consequences for populations of a species with a longevity of up to 18 y, of which 27% of the population on the bed and 38.4% of the more widely dispersed population in the Bay in 2000 were more than 10 y old. These are the age groups that contribute most to the biomass.

A natural postspawning mortality is the proffered explanation for the razor clam deaths in Co Galway in 2001.

ACKNOWLEDGMENTS

The authors offer thanks to Frank Berthe and Bruno Chollet of the IFREMER EU reference laboratory for shellfish diseases for their continuous advice and for carrying out the electron microscopy studies.

ECOLOGICAL AND MORPHOLOGICAL FEATURES OF THE BIVALVE *ASTARTE BOREALIS* (SCHUMACHER, 1817) IN THE BALTIC SEA NEAR ITS GEOGRAPHICAL RANGE

MICHAEL L. ZETTLER
Baltic Sea Research Institute, Seestr. 15, D-18119 Rostock, Germany

ABSTRACT During 1999 and 2000 macrozoobenthos surveys were made in the Mecklenburg Bight (western Baltic Sea). In total 116 stations were investigated between March and September. *Astarte borealis* showed a wide distribution at depths between 12 and 26.5 m. Mean abundance at these depths was 47 ind./m^2 with a biomass (AFDW) of 0.5 g/m^2. Maximum densities observed at these depths were 541 ind./m^2 and 16 g/m^2, respectively. In comparison to a data set of the 1960s, a decreased *A. borealis* population was found. *A. borealis* ranged from 1.2 to 28.7 mm in shell length. Most (78%) individuals in the population measured <10-mm shell length, indicating strong recruitment in the Bight during recent years. Larger size classes (>20 mm) were observed only sporadically and in low numbers. Shell length to wet weight and ash free dry weight correlations are given. Mean wet meat yield was 14.5%. The individual ash free dry weight decreased with increasing shell length from 9.1% (<5 mm) to 5.6% (>25 mm) with a mean value of 7.4%. All results were compared with data from populations in Russian Arctic and adjacent waters.

KEY WORDS: *Astarte borealis*, distribution, abundance, size, meat yield, Baltic Sea, Mecklenburg Bight

INTRODUCTION

The bivalve, *Astarte borealis*, is an arctic-boreal species that occurs in Arctic, North Atlantic and adjacent waters (Zettler 2001). Some data are known from the North Pacific waters such as Japan, Sea of Ochotsk, Behring Street, British Columbia and at the Aleutian Islands (e.g., Coan et al. 2000; Higo et al. 1999; Skarlato 1981). *A. borealis* find its most extensive distribution in Arctic waters of Russia (e.g., Antipova 1978; Filatova 1957; Gagaev 1989; Matveeva 1977). It extends from the Barents Sea, via Kara and Laptev Sea to Chukchi Sea and to areas of northern Alaska, Greenland (Ockelmann 1958) and Spitzbergen (Hägg 1904). At the Grand Banks off Newfoundland, it reaches high abundance in sandy bottoms around 130 m depth (Prena et al. 1999). In Europe this bivalve extends from Iceland (Thorarinsdottir 1997) and off Faeroes and Norway (Brattegart & Holthe 1997) to the northern North Sea (Johansen 1916) via Kattegat (Rasmussen 1973) into the western Baltic Sea and reaches there, its eastern limit of distribution in the Bornholm basin (see Fig. 1) (Demel & Mulicki 1954; von Oertzen & Schulz 1973). Thus, the Baltic population represents the most southern occurrence, an outpost of the mainly arctic area of distribution. The largest populations in the Balic are found in the Kiel and Mecklenburg Bights in depths below 15 m (Kühlmorgen-Hille 1963; Schulz 1969; Zettler et al. 2000). *A. borealis* is among the longest living species in the Baltic and is an important indicator of environmental conditions. Beside salinity and sediment structure, oxygen concentration has a strong influence on the composition of Baltic Sea fauna and flora. Although *A. borealis* is highly resistant to oxygen depletion (von Oertzen 1973; Oeschger 1990) frequent and long lasting periods of anoxic conditions finally diminish or kill the species. This has resulted in a severe decrease of the Baltic Sea population of *A. borealis* during recent decades in the deeper parts of the Mecklenburg Bight (Gosselck et al. 1987; Schulz 1968).

Information on the population biology and morphological features (growth, age, size) of this species is limited. Some investigations on production, growth, population size, and morphological features were carried out in Russian Arctic Waters (Antipova 1978; Gagaev 1989; Matveeva 1977). Within the framework of an autecological analysis of glacial relict species in the Baltic Sea, investigations on the reproduction of *A. borealis* were carried out in addition to experiments concerning its resistance and metabolic adaptations (von Oertzen 1972, 1973; von Oertzen & Schulz 1973). Schaefer et al. (1985) studied biometric features of *A. borealis* in Kiel Bight, the westernmost part of the Baltic Sea. They investigated several relationships between shell length and weight and their applicability for taxonomical distinguishing of species of the genus *Astarte*.

The purpose of this study was to investigate the distribution, frequency and biomass of *A. borealis* in Mecklenburg Bight as the first extensive study on the population characteristics of this important indicator species near its geographical range. A further aim was to compare these results with existing data of the 1960s compiled by Schulz (1969). From one monitoring station (stn. 018), we have a long time data set to show the development of *A. borealis* within the last decades.

Area of Investigation

The Mecklenburg Bight is part of the Belt Sea and belongs to the transition area between North Sea and Baltic Sea (Fig. 1 and Fig. 2). It is connected with Kiel Bight via Fehmarnbelt and with Kattegat via the Belts. To the East, the Kadet Trench crossing the Darsser Rise connects it with the Baltic proper.

During 1999 and 2000 macrozoobenthos surveys were made in the Mecklenburg Bight. In total 116 stations were sampled between March and September (Fig. 2). Station depth ranged from 5 to 29.6 m. The sediment varied from fine sand at the shallowest stations to sand mixed with silt and clay at the deepest stations. Sediment characteristics and current data for the area have been published by Lange et al. (1991).

MATERIALS AND METHODS

Profiles of salinity were recorded throughout the water column using a CTD (conductivity/temperature/depth probe) system. Samples for bottom water oxygen were taken with a 5-l water sampler (mounted on the CTD) at 0.5 m above the bottom and oxygen levels determined by Winkler titration. Benthic samples were taken with a 0.1 m^2 Van Veen grab. Due to sediment conditions, grabs of different weights were used. Three replicates of

grab samples were carried out at each station. The samples were sieved through a 1-mm screen and animals preserved with 4% formaldehyde in the field. For sorting in the laboratory a stereomicroscope with 10–40× magnification was used.

The shell length of all collected individuals was measured with a vernier calipers to the nearest 0.1 mm for the length-frequency distribution and the length-meat weight relationship. In total about 414 specimen were measured. The valves and the wet meat of the

specimen were weighted separately. Dry weight (DW) and ash free dry weight (AFDW) were determined to the nearest 0.01 mg. Length-frequency distribution for each station was calculated for 5 mm size classes. For the shell length to height relationship, 221 individuals from the 1999/2000 survey and 49 valves of *A. borealis* from the Zoological Collection of the University of Rostock (sampled in the 1980s from the Mecklenburg Bight) were measured.

The distribution map of *A. borealis* in the Mecklenburg Bight was made using Surfer 7.0 programme of Golden Software Inc. The recent distribution was compared with the results from Schulz (1969), whose data were transformed into the Surfer program to obtain a comparable map. For the long time series (1985 to 2000) of the monitoring station 018, the data of the Baltic Sea Research Institute Warnemünde and data from literature were used (Al-Hissni 1989; Voigt 1991).

RESULTS

Bottom Water Variables

Salinity throughout the water column ranged between 7.5 and 27.8 psu, while bottom water salinity of areas inhabited by *A. borealis* varied between 11.0 and 26.3 psu in 1999/2000. No oxygen depression was observed during the surveys. Up to a depth of 18 m, more than 5.0 mg/l oxygen was measured. In deeper parts of the Bight the oxygen content decreased to a minimum of 1.0 mg/l. *A. borealis* were found in an oxygen range of 1.5 to 8.1 mg/l. The

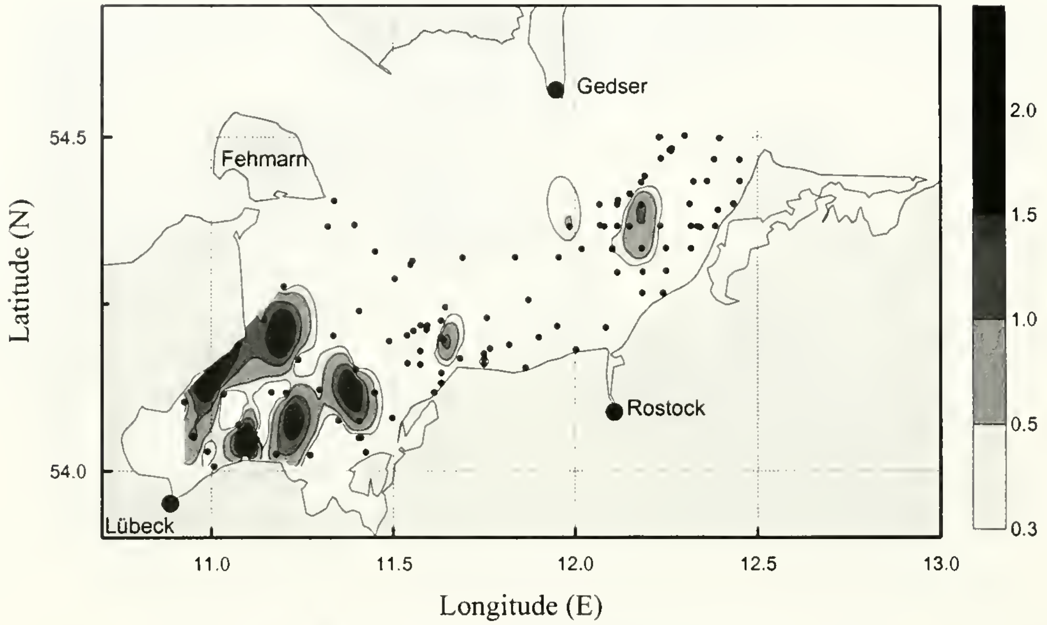

Figure 4. Biomass distribution of *Astarte borealis* (AFDW g/m^2) in 1999/2000.

mean oxygen content in areas inhabited by the bivalve was 6.27 ± 1.98 mg/l.

Distribution, Abundance and Biomass

In 1999/2000, *A. borealis* was distributed between 12 and 26.5 m depth in the Mecklenburg Bight. The species showed a very patchy density distribution (Fig. 3a). In the shallow areas 10 m depth with fine sand sediments, no *A. borealis* were found. Furthermore, the muddy zones of the outer Mecklenburg Bight and the outer Kadet Trench with strong currents and stony substrates were not inhabited. The highest abundance was found in the southeastern part of the Bight with a maximum of 400 to 500 ind./m^2 and an AFDW of 4 g/m^2 (water depth around 16.5 m). Thirty-five years ago (in the mid 1960s), *A. borealis* reached medium densities between 10 and 50 ind./m^2 with a maximum of 100 ind./m^2 in the eastern central part of the Bight (Schulz, 1969) (Fig. 3b). At depths below 20 m of the innermost area (Lübeck Bay) and western outer Bight no *A. borealis* were found. The comparison of the main distribution areas of the 1960s with the results of the present study showed a clear change.

The highest biomass was observed at the coast off Holstein and Mecklenburg (water depth about 16.0 m) with an ash free dry weight (AFDW) of 5–16 g/m^2 (Fig. 4). Within water depths of 12 and 27 m, *A. borealis* reached a mean abundance of 47 ind./m^2 and a biomass (AFDW) of 0.5 g/m^2.

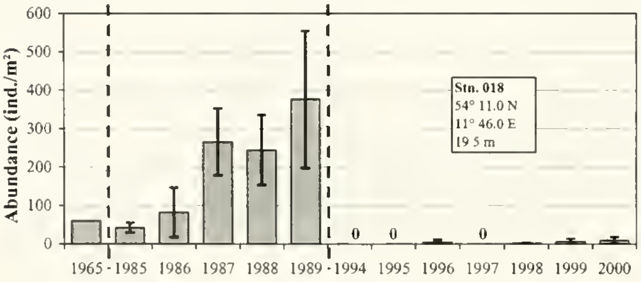

Figure 5. Changes in mean abundance (±S.D.) of *Astarte borealis* at stn. 018 over the last 15 years in comparison with data from the mid 1960s (Schulz 1969).

The development of the abundance of *A. borealis* at stn. 018 (see Fig. 2 for location) during the last 15 years is shown in Figure 5. From 1985 to 1989 abundance increased from around 50 ind./m^2 to about 400 ind./m^2. By the mid 1990s and through to 2000 abundance at the same station declined dramatically to 10–20 ind./m^2.

In the present study the highest abundance was observed in depths between 12 and 22 m (Fig. 6). In this depth range, *A. borealis* settled in an abundance of between 20 and 100 Ind./m^2.

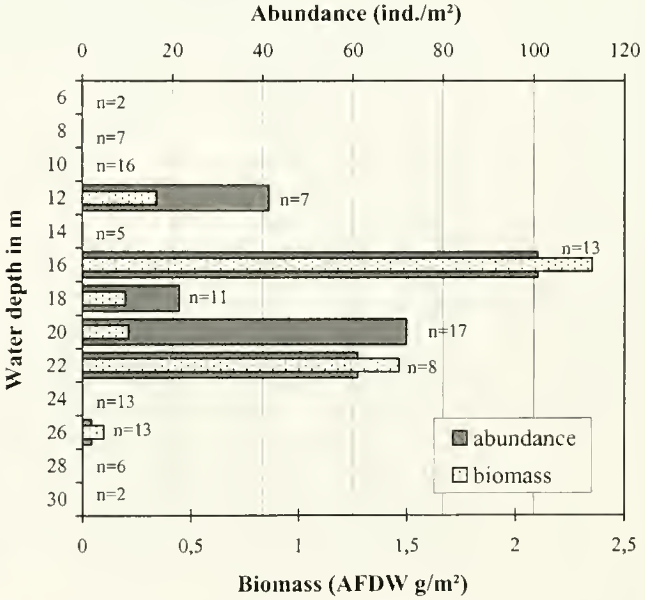

Figure 6. The vertical distribution of abundance (ind./m^2) and biomass (AFDW g/m^2) of *Astarte borealis* in the Mecklenburg Bight in 1999/2000 (n = number of included stations of each depth intervall).

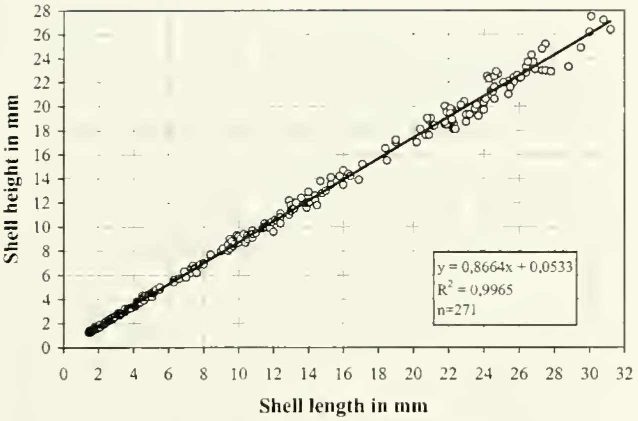

Figure 7. Shell height-length relationship of *Astarte boeralis* from the Mecklenburg Bight.

The biomass (AFDW) reached average amounts of 1.8 g/m^2 at 15–22 m with a maximum of 2.4 g in 15–16 m interval. In shallower and deeper areas no or only single specimens were found.

Population Structure, Meat Yield and Growth

Measured shell lengths of *A. borealis* ranged from 1.2 to 31.2 mm (Note, this range included both the survey and the collection material, see earlier). The shell length to shell height relationship is linear as indicated in Figure 7. The mean ratio length to height was 1.15 ± 0.04 and varied from 1.05 in minimum up to 1.25 in maximum, independent of shell length.

The population structures of selected stations are shown in Figure 8. The size structure varied between the stations. The 0–10 mm size class composed about 78% of the population. Larger size classes (>20 mm) were observed only sporadically and in low numbers. The dominant 0–5 mm size class at most of the investigated stations represents the survivors of the settlement during the last two years. Only at stn. 25 was the size structure dominated by older specimens.

Relationships between shell length and individual weights (whole wet weight, wet meat weight and ash free dry weight) are shown in Figure 9. These graphs include all measured specimen (1.2 mm to 28.7 mm) from the 1999/2000 survey. The smallest meat wet weight was 0.09 mg at a shell length of 1.2 mm and the largest one was 1.17 g at 28.3-mm shell length. The estimated mean regression line indicates the average meat yield per unit shell length of *A. borealis*. Differences between the station means were not statistically significant. The ash free dry weight varied between 0.08 mg (1.9 mm in length) and 0.29 mg (28.5 mm in length). The estimated regression lines of weights for different stations did not differ significantly. The results indicate that throughout the Mecklenburg Bight *A. borealis* contained approximately the same meat per unit shell length for the range of length considered. The mean wet meat yield (percentage of total wet weight) of different size

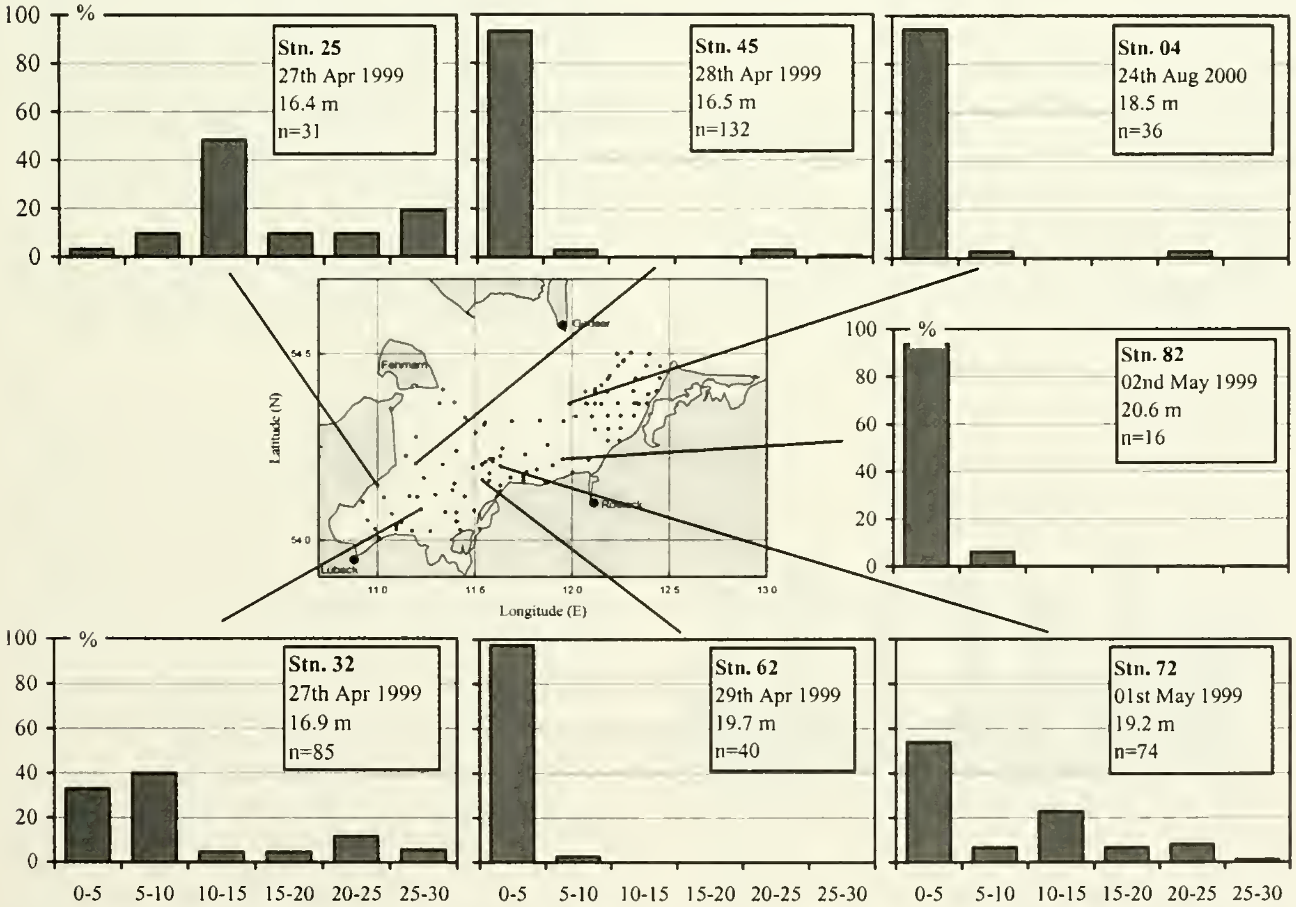

Figure 8. Shell length-frequency distribution for 5 mm size classes of *Astarte borealis* at several stations in depths between 16.4 m and 20.6 m in Mecklenburg Bight in 1999/2000.

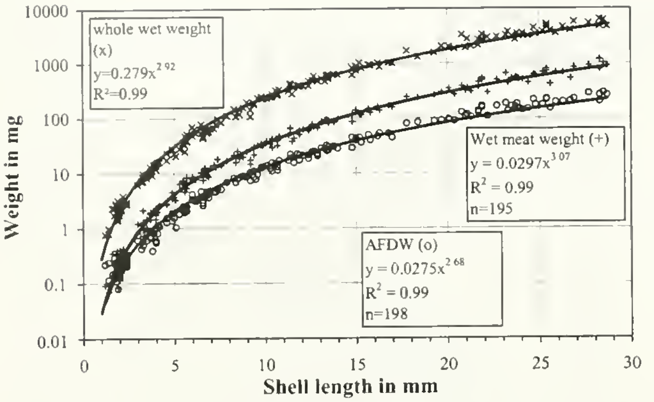

Figure 9. Estimated relationships between shell length and whole wet weight (+), wet meat weight (×) and ash free dry weight (o) for *Astarte borealis*. The corresponding equations for the calculated best fit regression lines are given in the figure.

classes varied in a range between 12.21% and around 16.4% with a minimum at 5% and a maximum at 23% (Fig. 10). The mean meat was 14.5%. With 9.1%, the highest amount of organic content (ash free dry weight) appeared in the 0–5 mm shell size class. The lowest organic content was 5.6% in the 25–30 mm size class. The difference was significant (*t*-test, $p < 0.001$). The mean organic content of dry weight ranged from 4.05% to 31.2% with a mean value of 7.4%.

DISCUSSION

Distribution, Abundance and Biomass

The occurrence of *A. borealis* in the Mecklenburg Bight has been known since the 19th century when the first investigations on the benthic fauna of the Baltic Sea took place (von Martens 1871; Wiechmann 1869/70). While the main Baltic populations live in the Kiel Bight and in parts of Sound and Belt, the distribution in the Mecklenburg Bight and the Arkona Basin represent the most eastern recent occurrence of this species in the Baltic Sea (see Fig. 1 and von Oertzen & Schulz 1973). Due to the decreasing salinity, *A. borealis* has its natural limit of distribution in areas east of Arkona Basin. Formerly, the distribution reached the deep parts of the Bornholm Basin as far as the Slupsk Furrow (Demel & Mulicki 1954; Jaeckel 1952; von Oertzen & Schulz 1973). Due to long lasting oxygen depletion in the last decades the bivalve had nearly disappeared in this area (Andersin et al. 1978). Today, *A. borealis* occurs in this region only in the Slupsk Furrow and only in depths between 60 and 70 m (Warzocha 1995).

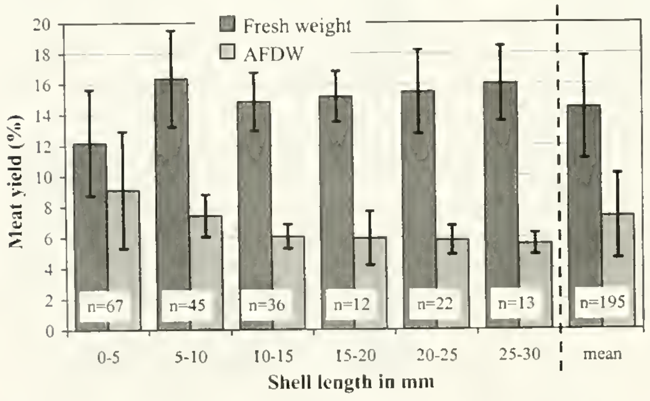

Figure 10. Mean individual percentage of wet meat yield and ash free dry weight in 5-mm size classes of *Astarte borealis* from the Mecklenburg Bight in 1999/2000 (±S.D.).

The investigation of Schulz (1969) from 1962 to 1965, giving the distribution pattern of *A. borealis* in the Mecklenburg Bight, was used for comparison with the present study. In the 1960s, densities were between 10 and 50 ind./m^2 in mean (maximum 320 ind./m^2). During the 1980s, the abundance of the bivalve increased in waters near 20 m depth (e.g., at the monitoring station 018) (Köhn 1989; Voigt 1991). Due to a long period of oxygen depletion in the deeper part of the Lübeck Bay (the inner part of the Mecklenburg Bight), no *A. borealis* were found in the 1980s (Gosselck et al. 1987; Prena et al. 1997). In the 1990s, the density of *A. borealis* decreased in shallower regions of the Mecklenburg Bight, too. Recently, a mean abundance of approximate 50 ind./m^2 in depths between 11 and 26 m could be observed. The highest abundance and biomass was observed in the region between 16 and 22 m. The mean biomass reached 1 g/m^2 AFDW (17 g/m^2 wet weight). In comparison, at the beginning of the 1950s during the investigations of Kühlmorgen-Hille (1963) in the Kiel Bight *A. borealis* occurred in a mean abundance of between 4 and 52 ind./m^2. At the beginning of the 1970s Arntz et al. (1976) observed in the Kiel Bight the highest frequency and abundance in depths between 10 and 20 m with 74–83 ind./m^2 (max. 570 ind./m^2, 1240 g/m^2 wet weight). In adjacent waters of the Arkona Basin Löwe (1963) found *A. borealis* in quite high amounts of 13 g/m^2 wet weight. The largest biomass with about 70 g/m^2 he observed off the island of Falster and at the entrance of the Sound. Outside the Baltic in Russian Arctic waters, the main distribution area of the species, *A. borealis* colonises the littoral zone and reaches an abundance of about 200 ind./m^2 and a biomass of about 620 g/m^2 wet weight (Antipova 1978; Gagaev 1989; Matveeva 1977). *A. borealis* belongs to the most productive bivalves in this region (Gagaev 1989).

According to von Oertzen (1972), *A. borealis* has an extremely prolonged period of ripe eggs and sperms. The main spawning season is presumably in spring with the possibility of "portion spawning" the whole year (Köhn 1989; Matveeva 1977; von Oertzen 1972). *A. borealis* prefers sandy substrates and mixed sediments avoiding muddy sediments (e.g., Arntz et al. 1976; Schulz 1969). In the deeper parts (>22 m) of the Mecklenburg Bight, oxygen depletion in late summer prevents successful recruitment and growth of the juveniles. However, *A. borealis* is one of the most tolerant species to oxygen deficiency and to hydrogen sulphide (von Oertzen 1973; Oeschger 1990). Probably, the possibility of the high tolerance to oxygen deficiency is restricted to the adults, whereas the juveniles are more susceptible, causing settlement only in favourable years and depths. The lack of recruitment events is described for populations of Kiel and Mecklenburg Bight by Werner et al. (1974) and Köhn (1989). In shallower zones (between 15 and 20 m), no major hypoxic episodes have been observed in the recent past (Matthäus et al. 1999). Although recruitment can take place in the shallower areas, conditions for growth are suboptimal, probably due to the lower nutrition supply, lower salinity and higher temperature (Arntz et al., 1976; von Oertzen, 1973). In depths shallower than 11 m the mean salinity, 8–12 psu, is probably too low. The range of potency of *A. borealis* is 8–35 psu with an optimum between 14 and 30 psu (Jaeckel 1952; von Oertzen 1973).

Population Structure

The largest living *A. borealis* found in this survey was 28.3 mm long and 24.7 mm high. Valve material of the Zoological Collection of the University of Rostock (sampled in the 1980s) had a maximum length of 31.2 mm (26.4-mm height). Lenz (1882) found specimen of 36 mm in length (31-mm height) in the Lübeck Bay. The shell is quadrate to subtrigonal and compressed with a total shell length of 38 mm at boreal outposts (e.g., Baltic Sea, Jaeckel, 1952) and 55 mm in the Arctic Sea (Coan et al. 2000, Filatova 1957) with a mean of 25–45 mm (Dance 1977). In general, the shell length exceeds the height and the height/length indices vary from 0.8 to 0.9 (e.g., Ockelmann 1958). However, *A. borealis* is a variable species with several forms and varieties (see Zettler 2001). In the past, the great variability in morphological features resulted in a number of new species and subspecies descriptions (see Zettler 2001). Recent investigations of Hopner Petersen (2001) show a large variety of shell morphology within the genus *Astarte*. The material discussed in the present study had a high constancy in respect to the relation between length and height (Fig. 7).

Statements on population dynamics or size structure of *A. borealis* are very sparse in the literature. Some Russian studies (Gagaev 1989; Matveeva 1977) and few investigations on Baltic populations (Köhn 1989; Voigt 1991; Werner et al. 1974) have been carried out. During the studies of Köhn (1989) and Voigt (1991) in the Mecklenburg Bight the populations were dominated (89%) by individuals <6 mm in length. Larger sizes were observed only sporadically. In the present study, juvenile individuals were dominant at most of the stations investigated. Adult specimens (>20 mm) were only observed in high abundance in the inner part of the Mecklenburg Bight (Fig. 8). Köhn (1989) pointed out that only individuals >20 mm are reproductive. In the White Sea *A. borealis* reaches sexual maturity in sizes >17 mm (Matveeva 1977). The maintenance of the stock in the Mecklenburg Bight depends on few adults and/or probably on drifting of lecitothrophic (non-pelagic) larvae from regions nearby. In areas with strong currents, longer immigration distances are imaginable (Rasmussen 1973). In the Kiel Bight and in Russian Arctic waters however, the population structures are more balanced (Werner et al. 1974; Gagaev 1989).

Meat Yield

The mean wet meat yield of *A. borealis* of 14.5% in the present study is similar to reported values of Köhn (1989). He found organic contents (wet) between 9% and 30% for a population in the Mecklenburg Bight. Ansell (1975) observed a soft tissue content for *A. elliptica* of 14.3–23.5% and dry tissue weights of 3–5% in British waters depending on the reproductive cycle. In the Mecklenburg Bight, in the present study, the mean individual ash free dry weight of *A. borealis* decreased from 9.1% to 5.6% with increasing size classes. The increasing mean wet yield and the decreasing ash free dry weight with increasing shell length indicates relatively higher water content of bigger bivalves. The length specific wet weight (shell length – wet weight relationship) in this study was similar to that reported for *A. borealis* of the Kiel Bight and Russian Arctic waters. In the Mecklenburg Bight, the calculated wet weight for an individual of 25 mm shell length was 3.42 g. The wet weight of *A. borealis* in the East Siberian Sea reported by Gagaev (1989) was 3.49 g and in Kiel Bight 4.22 g (Schaefer et al. 1985). According to Köhn (1989) the meat wet weight of a 25-mm specimen of *A. borealis* is 534 mg compared with 572 mg in the present study.

In conclusion, the present study shows ecological and morphological features of *Astarte borealis* in the Mecklenburg Bight near its eastern distributional boundary within the Baltic Sea. Further investigations must deal with growth rates and morphology of *A. borealis* within the Baltic and adjacent waters. The causes of the decline of this cold-adapted arctic-boreal species in much of the Baltic remain unclear. The comparative population dynamics at different water depths and/or within different sediment structures and the dispersion and settlement patterns of the larvae in this "border" area are of special interest.

ACKNOWLEDGMENTS

The author thanks Christine Peters, Ines Glockzin for helpful technical assistance, the Zoological collection of the University of Rostock for supplying valve material, and the referees for their helpful and interesting remarks.

IS SURVIVAL GENOTYPE-DEPENDENT IN NORTH AMERICAN POPULATIONS OF FARMED BLUE MUSSELS, *MYTILUS* SPP?

R. W. PENNEY AND M. J. HART
Department of Fisheries and Oceans, Science, Oceans, and Environment Branch, P. O. Box 5667

ABSTRACT We monitored survival and allele frequencies at five enzyme loci in single year-class cohorts of cultured *Mytilus* spp. during a 14 month period from sleeving of seed to harvest at three commercial mussel farms in Notre Dame Bay, Newfoundland, Canada. Among-site genetic heterogeneity at all five individual loci and over all loci combined was evident among the three seed sources. Significant temporal genetic heterogeneity occurred at all three sites. The observed intra-site temporal heterogeneity was not related to genotypic state since neither the relative proportions of homozygotes and heterozygotes at each of the five loci individually, nor the mean heterozygosity over five loci, changed significantly within sites over time. Significant change in genotypic frequencies at the *Gpi* locus was the primary contributing factor to the overall temporal genetic heterogeneity within each of the three sites. Significant temporal changes in genotypic frequencies at each of the *Mpi*, *Lap*, *Pgm*, and *Odh* enzyme loci inconsistently appeared among the three sites. A significant directional shift in genotypic frequencies, consistent across all three sites, gave evidence of genotype-dependent survival selection differentially favoring survival of *Gpi* genotypes with electrophoretically slower alleles in comparison to genotypes with electrophoretically faster *Gpi* alleles during sub-tidal rope culture of *Mytilus* spp. populations in Newfoundland. We also conclude that temporal genetic heterogeneity is a common occurrence in suspended rope culture of Newfoundland blue mussel populations and is likely a significant contributory factor in the extensive geographic genetic population structuring previously reported among mixed *M. edulis* - *M. trossulus* populations.

KEY WORDS: *Mytilus*, genotype-dependent, survival, genetic heterogeneity

INTRODUCTION

In northeastern North America, two separate mytilid species, *Mytilus edulis* and *M. trossulus* are recognized (Koehn et al. 1984; Varvio et al. 1988; McDonald et al. 1991). In Atlantic Canada, the distribution of both species is widespread (McDonald et al. 1991; Mallet & Carver 1992) and the two form hybridized mixed-species assemblages (Saavedra et al. 1996). Newfoundland is, apparently, a zone of natural distributional overlap between these two mytilid species since most populations consist of mixtures of both species varying widely in relative frequency (Bates & Innes 1995; Penney & Hart 1999).

Within the overlap zone in Newfoundland, sites in close proximity to each other display inter-site genetic heterogeneity on a magnitude scale comparable to sites much larger distances apart (Penney & Hart 1999). Such scales of genetic heterogeneity suggest the potential for significant stock- or site-related variability in growth, survival, or other characteristics among adjacent sites throughout the mixed-species zone. For commercial industry, factors that significantly affect productivity within and among mussel farms is of great importance. Genotype-dependent temporal survival selection processes have previously been noted in inter-tidal, mixed-species communities involving *M. galloprovincialis* and *M. edulis* in England (Gardner & Skibinski 1991; Skibinski & Roderick 1991; Gardner 1994) and in a mixed *M. edulis* and *M. trossulus* intertidal assemblage in Nova Scotia (Pedersen et al. 2000).

In cultured stocks, inter-site variation in mortality rates related to genetic (stock) differences are known to exist (Mallet et al. 1987, 1990) and may significantly affect production in suspended culture (Mallet & Carver 1989). There is also evidence that between-site mortality differences are maintained when the stocks are transferred to new sites (Mallet et al. 1990; Myrand & Gaudreault 1995) suggesting that among-site survival variation is related to stock genetics rather than environmental factors. Mortality and growth variation related to genotype (*M. edulis* vs. *M. trossulus*) was reported to significantly influence productivity at one farm site in Nova Scotia (Mallet & Carver 1995). Since the combination of stock mortality and growth rate primarily define production in suspended culture, among-site stock and/or genotype-dependent variation in either parameter due to selective processes may be an important determinant of inter-site variability in farm production indices.

In this study, we investigate survival patterns in three hybridized *M. edulis* - *M. trossulus* assemblages of cultured mussels in Newfoundland, Canada, over the latter phase of the production cycle, namely from sleeving of seed mussels to harvest. We use empirical observations of temporal change in allele frequencies at five enzyme loci to test the hypothesis that genotype-dependent selection processes occur within rope-cultured mixed *M. edulis*-*M. trossulus* populations and, by inference, may be a significant contributory factor influencing genetic heterogeneity, survival, and production variability among mussel farms in Newfoundland.

METHODS

Seed mussels from collector ropes were sleeved in standard commercial plastic mesh on each of three farms in Notre Dame Bay, Newfoundland in August, 1998 (Fig. 1). In each case, the seed mussels were derived from collector ropes set out on each farm in 1997. Seed mussels were mechanically de-clumped prior to sleeving to ensure random distribution across all sleeves. Each sleeve was 1 meter in length and was vertically suspended at 0.5-meter intervals from horizontal mainline ropes with flotation sufficient to ensure stable suspension at depths of approximately 10–12 meters. One week after gear placement, three replicate sleeves were retrieved from each farm site. From measured sections of each sleeve, all the mussels were removed and counted and 100 individuals were randomly selected for allozyme analysis (total of 300 from each site). The one-week delay in taking the first

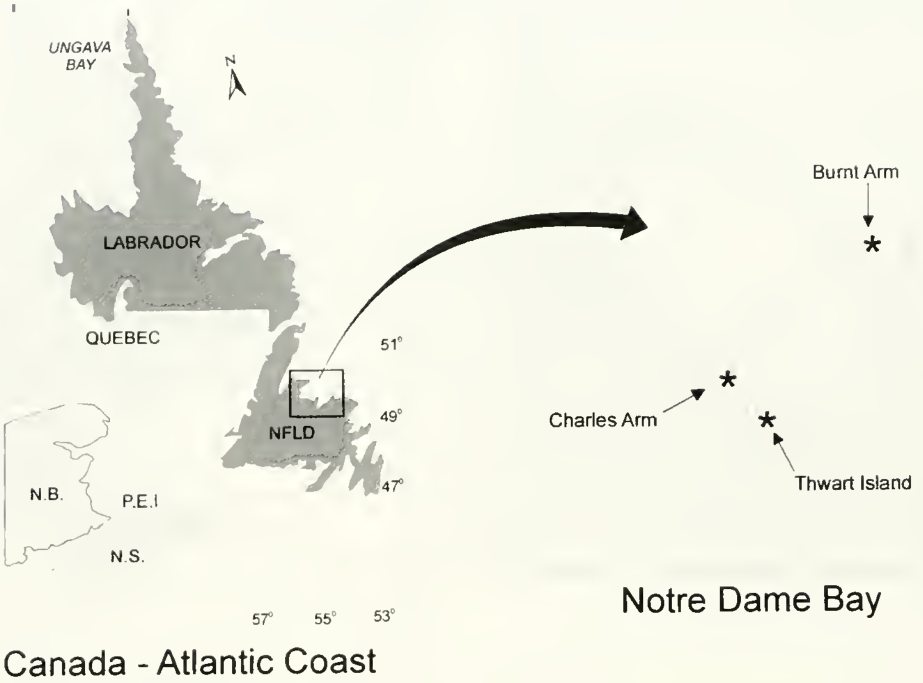

Figure 1. Geographic location of the three farm sites in Notre Dame Bay, Newfoundland.

sample was necessary to allow for mussel acclimation and attachment to the sleeving material and thus eliminate drop-off of any mussels that failed to properly attach themselves via their byssal threads.

Each farm site was similarly sampled in May, 1999 and again in October, 1999 at which time the majority of mussels had reached or exceeded the minimum commercial harvest size of 55 mm. Survival over time was calculated as the difference in mean number of mussels sleeve^{-1} in May, 1999 and in October, 1999, compared to the initial sample. In this context, changes in survival do not distinguish between changes due to mortality versus drop-off from the culture gear.

Hepatopancreas tissue was excised from each selected mussel, lyophilized, and stored at 5°C for later allozyme analysis. Five polymorphic loci were investigated: mannose phosphate isomerase (*Mpi*, EC 5.3.1.8), aminopeptidase-I (*Lap*, EC 3.4.11.-), phosphoglucomutase (*Pgm*, EC 2.7.5.1), glucose-6-phosphate isomerase (*Gpi*, EC 5.3.1.9), and octopine dehydrogenase (*Odh*, EC 1.5.1.11). A small amount of freeze-dried material was ground to a fine powder with 0.5M Tris HCL pH 8.0 buffer containing 20% glycerol and 0.2% NAD. Subsequent electrophoresis and staining on cellulose acetate plates followed the general procedures of Hebert and Beaton (1989), although a constant current of 2 mA per plate was used during the electrophoretic runs. The procedure for *Lap* was modified to run with Tris glycine pH 8.6 buffer. For *Odh*, we modified the stain for *Gpi* suggested by Hebert and Beaton (1989) to use octopine as the substrate instead of fructose-6-phosphate. Allele nomenclature is similar to that employed by previous authors (Koehn et al. 1984; McDonald & Koehn 1988) with the exception that alleles at the *Odh* locus were numbered consecutively from 0–9 in order of increasing electrophoretic mobility from the origin. The latter exception was necessary since we were unable to match *Odh* electromorphs on our plates with previously published allele frequencies.

Analysis of allele frequencies for population differentiation and probability estimation of log-likelihood G tests of genetic heterogeneity within and among genotype classes and within and among sites utilized the software package F-Stat for Windows™, version 2.9.1 (Goudet et al. 1996). All other statistical analyses used the SAS software system (SAS Institute Inc. 1988). Significance levels of all test statistics involving multiple comparisons were Bonferroni-adjusted. Non-parametric analysis of variance of ranks and Kruskal-Wallis rank test statistics (SAS Institute Inc. 1988; Sokal & Rohlf 1995) were calculated to test for directional, intra-site, temporal trends in genotypic frequency distributions at the *Gpi* locus. For these analyses, the twelve observed Gpi alleles were assigned an ordinal rank score based on electrophoretic mobility, with faster alleles scoring lower than slower alleles (e.g., Gpi^{110} = rank 1; Gpi^{107} = rank 2, etc.). Thus for diploid loci, the genotypic rank assigned each individual is the mean rank score of its two constituent alleles (e.g., for an individual of genotype $Gpi^{110,107}$, rank = 1.5, etc.). For Kruskal-Wallis tests with $n > 2$ sample dates, SAS calculates a χ^2 approximation of the Kruskal-Wallis test statistic for significance testing (SAS Institute, Inc. 1988).

RESULTS

Seed mussels were collected from three farms located in Burnt Arm, Charles Arm, and at Thwart Island in Notre Dame Bay on the northeast coast of Newfoundland (Fig. 1) and transferred to commercial plastic mesh sleeves in August, 1998, for grow-out. Electrophoretic assays of the three seed mussel populations detected four alleles at the *Mpi* locus, six at the *Lap* locus, eight at the *Pgm* locus, eleven at the *Odh* locus, and twelve at the *Gpi* locus. Gene diversity per locus at the three sites was very low (<0.20) at the *Odh* locus, moderate (0.40–0.50) at the *Mpi* locus, relatively high (0.60–0.75) at *Lap* and *Pgm*, and highest (>0.80) at *Gpi*. Log-likelihood G test scores from inter-site comparison of the three seed mussel populations in August 1998, revealed significant ($p < 0.001$) among-site population genetic heterogeneity at all loci individually as well as over all loci combined (Table 1). At the *Mpi* locus, Mpi^{100} predominated at Burnt Arm and Charles Arm while Mpi^{94} was the allele at highest frequency at Thwart Island (Fig. 2). Pgm^{100} was the most common allele at the *Pgm* locus at both Burnt Arm and Charles Arm while the frequency of Pgm^{111} was highest at Thwart Island. At the *Lap* locus, Lap^{98} was the most common allele at Charles Arm but at Burnt Arm and Thwart Island the frequency of Lap^{96} was greatest. Gpi^{98} predominated at Charles Arm while, at both Burnt Arm and Thwart Island, the frequency of Gpi^{96} was highest. At *Odh*, the three sites differed only in frequency of relatively rare alleles. The frequency of Odh^{3} was greatest for all three sites.

In August, 1998, mean mussel density on the sleeves varied among sites from 450 mussels m^{-1} at Charles Arm to 790 mussels m^{-1} at Burnt Arm and 890 mussels m^{-1} at Thwart Island. Survival to May, 1999 (calculated as within-site change in mean mussel density since August, 1998) was not significantly different among sites (ANOVA, $P > 0.05$). Mean survival during the first 9 months of grow-out (to May, 1999) was 81.2% at Charles Arm, 76.9% at Thwart Island, and 78.0% at Burnt Arm (Fig. 3). After 14 months on the sleeves (October, 1999), mean survival at Charles Arm was significantly less than the other two sites (ANOVA, $P < 0.05$). Mean survival at Charles Arm was only 37.4% compared to 51.6% at Thwart Island and 51.7% at Burnt Arm. Log-likelihood G test scores for among-site comparisons of population genetic structure after 9 and 14 months of grow-out (May and October, 1999 respectively) were also significant (Table 1) indicating the initial among-site genetic heterogeneity was maintained during the course of the grow-out period.

During the same 14 month grow-out period, significant intra-site temporal changes in allele frequencies at one or more loci were found at all three sites (Table 2). After the first 9 months of grow-out (to May, 1999), log-likelihood G test scores were significant over all loci combined at all three sites indicating significant temporal change in genetic structure had occurred over this period. Significant intra-site temporal population differentiation at the *Gpi* locus was evident at all three sites. Intra-site population genetic differentiation was also evident at the *Mpi* locus at Burnt Arm, the *Pgm* and *Odh* loci at Charles Arm, and at the *Odh* locus at Thwart Island. This pattern continued through to October, 1999 after 14 months of grow-out by which time further genetic differentiation at the *Odh* locus had become evident at Burnt Arm and at the *Lap* locus at Thwart Island.

To determine whether the observed intra-site temporal genetic differentiation revealed by the log-likelihood G tests gave evidence of selective survival patterns, we further examined the dataset for (a) non-random mortality related to genotypic state (e.g., differential survival of homozygotes vs. heterozygotes) at either of the five loci individually or over all loci combined; and (b) non-random mortality favoring specific single locus genotypes. With respect to (a), for all five loci individually, the relative proportions of homozygotes vs. heterozygotes within all three sites did not significantly change over the 14 month grow-out period (Fisher's exact test; $P > 0.05$). Within-site variation in mean multi-locus heterozygosity was also not significantly related to time (sample date) and the interaction effect of time × site was not significant (ANOVA; $P > 0.05$) at all three sites (Table 3). Thus, we conclude the observed intra-site temporal variation in population genetic structure revealed by the log-likelihood G tests is not explained by selective survival related to genotypic state at either of the five loci individually or on the basis of multi-locus heterozygosity (multi-locus homozygotes vs. heterozygotes). Multi-locus heterozygosity did significantly vary however among sites (ANOVA, $P < 0.01$; Table 3). Mean multi-locus heterozygosity was lowest at Charles Arm, highest at Burnt Arm and intermediate between these two at Thwart Island (Fig. 4). However, only the May and October means at Burnt Arm and Charles Arm were significantly different (Tukey, $P < 0.05$).

TABLE 1.

*** $p < 0.001$

With respect to (b), we then tested the hypothesis that the observed intra-site temporal genetic differentiation could be explained by non-random mortality favoring specific single locus genotypes. To accomplish this, we tested for temporal patterns of change in genotypic frequencies (χ^2) with specific individual alleles (homozygotes and heterozygotes combined) versus those without at each site × locus combination wherein the log-likelihood G test was significant. Homozygotes and heterozygotes were combined for this analysis due to the previously noted non-significant temporal change in frequencies of homozygotes and heterozygotes at all three sites. With respect to the *Lap*, *Pgm*, and *Odh* loci, the observed temporal changes in frequency of genotypes with or without all individual alleles were not significant after Bonferroni-adjustment of significance levels for multiple test comparisons. For the *Mpi* locus, a significant G test score was observed only at Burnt Arm (Table 2). At this site, the relative frequencies of genotypes which included the Mpi^{100} allele were significantly reduced while the relative frequencies of genotypes which incorporated the Mpi^{94} allele were significantly increased during the August, 1998, to October, 1999 period. These frequency changes remained significant after Bonferroni correction of probabilities for multiple comparisons. Frequency changes at Burnt Arm for genotypes with all other *Mpi* alleles were not significant after Bonferroni correction of probabilities.

At the *Gpi* locus, χ^2 tests of temporal patterns of change in genotypic frequencies involving specific alleles varied across the three sites (Fig. 5). At Burnt Arm, significant (χ^2, $P < 0.05$) frequency reductions occurred within genotypes which included the Gpi^{107}, Gpi^{102}, and Gpi^{96} alleles, while genotypic frequencies with the Gpi^{93}, Gpi^{89}, Gpi^{86}, and Gpi^{83} alleles all increased. At Charles Arm, a significant reduction in individuals with genotypes that included Gpi^{107} also occurred while genotypic frequencies with Gpi^{100}, Gpi^{96}, and Gpi^{89} all increased. At Thwart Island, a trend towards increasing frequency of individuals with Gpi^{93} and Gpi^{86} occurred with reductions in the frequency of individuals with the more electrophoretically mobile Gpi^{98} and Gpi^{96}. Frequency changes over time for all other *Gpi* alleles at each of the three sites

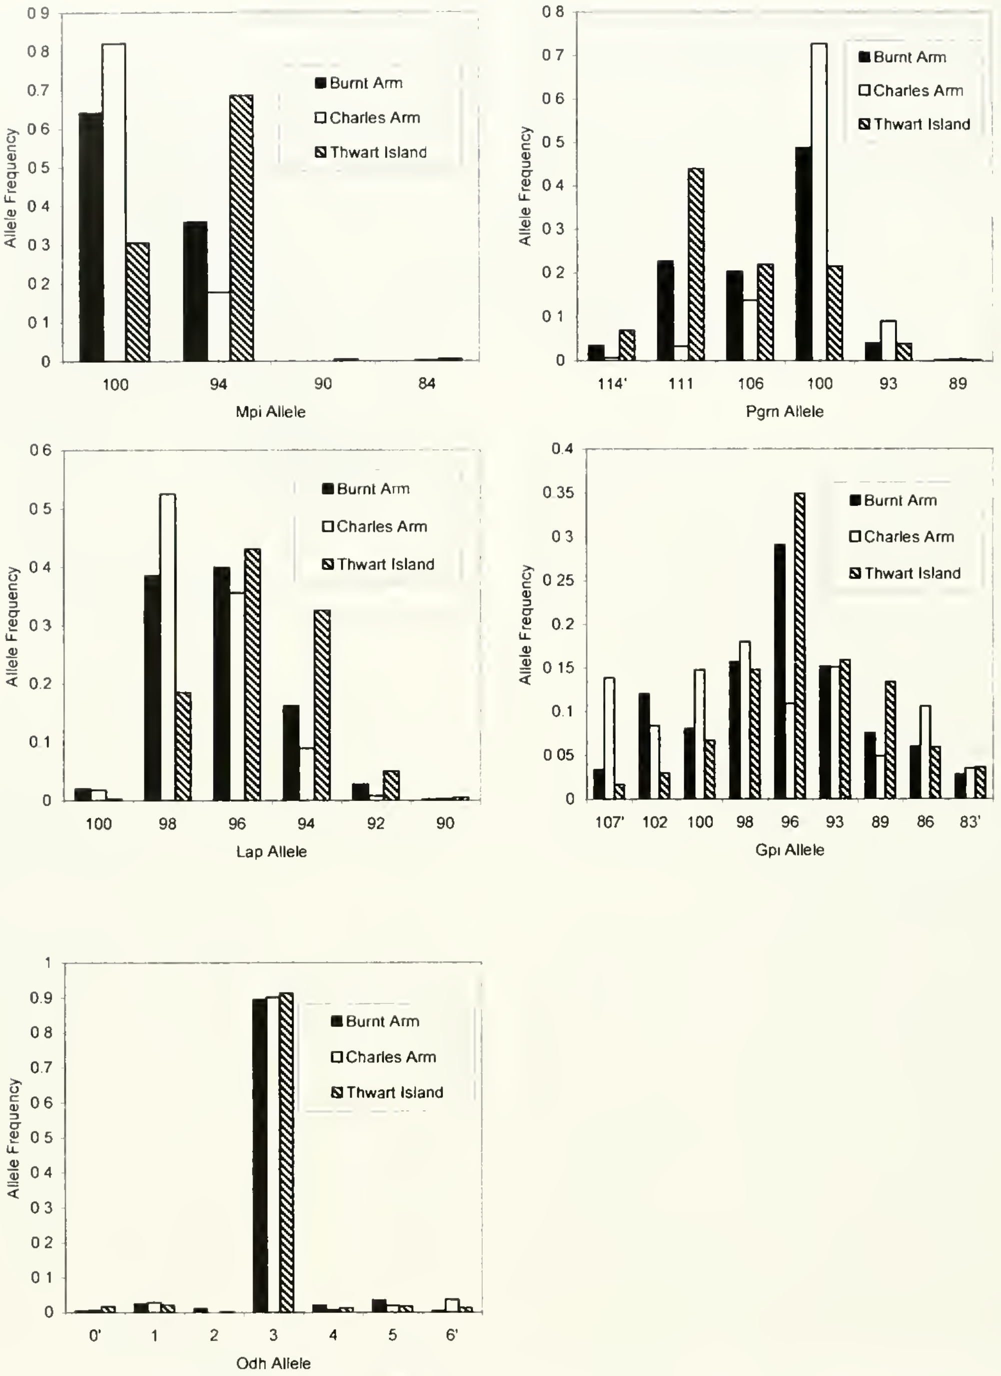

Figure 2. Inter-site comparison of allele frequencies at the *Mpi*, *Pgm*, *Lap*, *Gpi*, and *Odh* enzyme loci in seed mussel populations at Burnt Arm, Charles Arm, and Thwart Island at the start of the rearing trials in August, 1998. Allele frequency numbers with a ' (e.g., *Pgm* allele114') include frequencies of adjacent rare alleles.

were not significant (χ^2, $P > 0.05$) when significance levels were Bonferroni-adjusted for multiple comparison tests.

However, while the frequencies of the same individual *Gpi* alleles were not consistently significantly differentiated among sites over time, the overall *Gpi* genotypic frequency distribution significantly shifted in favor of electrophoretically slower alleles at all three sites (Table 4). At the *Gpi* locus, mean genotypic rank scores within all three sites significantly increased over time. Also, Kruskal-Wallis H tests revealed the median genotypic rank score also significantly increased within all three sites over time. These results indicate a consistent directional change in the overall genotypic frequency distribution had occurred at all three sites. *Gpi* genotypes carrying alleles of higher electrophoretic mobility were significantly reduced in favor of those with alleles of relatively lower electrophoretic mobility at all three sites during the 14-month grow-out period. We infer this directional shift in *Gpi* genotypic frequencies which is consistent across all three sites is evidence of genotype-dependent selective survival processes dif-

ferentially favoring alleles of relatively lower electrophoretic mobility at this locus during sub-tidal, rope culture of *Mytilus* spp. in Newfoundland.

DISCUSSION

Two recent studies (Gilg & Hilbish 2000; Pedersen et al. 2000) have provided evidence that both cohort mixing as well as selective survival processes work to produce significant temporal genetic heterogeneity in mixed-species, intertidal mytilid communities. However, ours is the first to examine the potential for similar selection processes within suspended rope-cultured populations in commercial culture. In the present work, we have found significant within-site genetic heterogeneity among samples taken over a 14 month grow-out period for three mixed-species populations. The probability that our results were affected by cohort mixing seems remote. This would have required an undetected re-settlement on the culture sleeves with a new larval cohort some time after the original gear setup date in August, 1998. Such an occurrence would have been easily detected due to the disparity in length frequencies between the older mussels and the new cohort on the sleeves. Our length frequency data show no evidence of such cohort mixing. A more parsimonious explanation for the observed intra-site differences among sample dates is that temporal genetic heterogeneity occurred within the original populations from time of sleeving in August, 1998, through to harvest size in October, 1999.

Both Gilg and Hilbish (2000) and Pedersen et al. (2000) reported genotype-dependent mortality patterns in *Mytilus* spp. populations that resulted in population structuring along species lines. In the case of the former, an intertidal mixed population of newly-settled *M. edulis, M. galloprovincialis*, and their hybrids in SW England became heterogeneous on the basis of tidal height. In the latter, a directional selective mortality pattern favoring *M. trossulus* at the expense of *M. edulis* was demonstrated in a mixed intertidal *M. edulis* and *M. trossulus* assemblage in Nova Scotia. In our study, the mussel populations at all three sites could be classified as hybridized, mixed-species (*M. edulis, M. trossulus*, and their hybrids) stocks based on their *Mpi* genotypes (Varvio et al.

1988; McDonald & Koehn 1991). All three populations showed evidence of significant temporal genetic heterogeneity over the 14 months from sleeving to harvest. However, the relative proportions of *Mpi* genotypes changed only at one site, Burnt Arm. This seems to go against the general applicability of the hypothesis that genotype-dependent mortality among *Mpi* genotypes (e.g., *M. edulis*, *M. trossulus*, or their hybrids) might be the primary cause of the temporal genetic heterogeneity we observed among cultured Newfoundland stocks as Pedersen et al. (2000) found within one rocky intertidal community in Nova Scotia.

Several factors may be contributory to the different conclusions we have reached compared to Pedersen et al. (2000). Presumably, selective processes favoring one genotype over another will only manifest themselves under conditions that induce differential degrees of stress. Since both *M. edulis* and *M. trossulus* are endemic throughout Atlantic Canada, we may infer that both species are generally adapted to the range of environmental conditions and habitat types encountered throughout that range. However, it is entirely likely that naturally occurring pelagic larval dispersal and settlement will sometimes result in mussels being placed in habitats where differential selection of genotypes can occur. The intentional transfer of seed mussels to new areas, as in the case of commercial mussel farming, could likewise produce an environment where differential selection could occur. Thus the appearance of differential selection processes would be site-specific, perhaps even on micro-geographic scales, and may change with time on any particular site as stressful conditions appear and disappear due to natural environmental variability. The range of environmental conditions experienced by rope-cultured, sub-tidal mussels is less extreme and likely less stressful than those experienced by natural inter-tidal assemblages and this may explain the different conclusions we have reached compared to Pedersen (2000). Alternatively, selection processes may also change with age (Gilg & Hilbish 2000). Our study was not directly comparable to that of Pedersen et al. (2000) on the basis of age since we started our work with seed mussels considerably older than the newly recruited mussels they studied.

In our study, the temporal genetic patterns we observed may have been produced not by mortality per se but rather by drop-off from the culture gear. On vertically suspended sleeving substrates used in commercial mussel culture, selective processes affecting strength of attachment by byssal threads may result in drop-off. While not sufficient to cause mortality per se, such episodes nevertheless cause loss to the culture system and result in apparent if not real mortality. Such selective processes may not be apparent in intertidal habitat where mussels with similarly weakened byssal attachment are physically better supported and thus better able to retain their placement. We know that byssal thread formation varies in mytilids in response to environmental variation (Young 1985). Strength of attachment also varies among species due to interactions between hydrodynamic forces and interspecific variation in shell shape (Willis & Skibinski 1992; Bell & Gosline 1997). Co-occurring cultured *M. edulis*, *M. trossulus* and their hybrids differ in shell shape within the populations we studied (Penney & Hart 1999). Whether or not interactions among strength of attachment, genotype-dependent physiological variability, and/or shell shape contributes to the temporal genetic heterogeneity we observed is the subject of continuing research efforts.

Previously, heterozygosity at individual loci or mean heterozygosity over several loci have been implicated in selective survival mechanisms among mytilid populations; (Koehn & Gaffney 1984, Tremblay et al. 1998). A higher degree of mean multi-locus heterozygosity over several enzyme loci has been associated with lower energy requirements for maintenance metabolism (Diehl et al. 1986; Hawkins et al. 1986, 1989) thus imparting a differential survival advantage to heterozygotes. In the present work, variable survival in relation to heterozygosity, either at individual loci or as a mean over all loci, was not a significant factor.

In our study, all enzyme loci did not contribute equally to the observed temporal genetic heterogeneity. Only the *Gpi* locus pro-

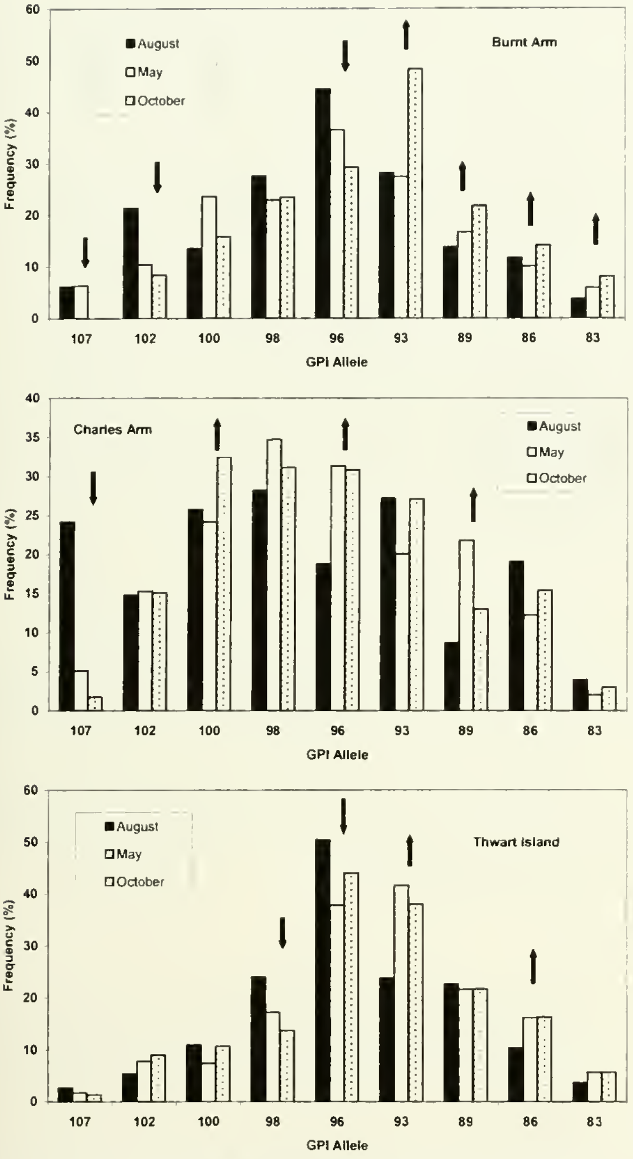

Figure 5. Intra-site change in genotypic frequencies with various *Gpi* alleles (homozygotes and heterozygotes combined) from August, 1998 to October, 1999. Arrows indicate specific alleles for which the χ^2 test for change in frequency over time of those with the allele (homozygotes and heterozygotes combined) vs. those without was significant after Bonferroni adjustment of significance levels for multiple tests. Arrow direction indicates an increase (upwards) or decrease (downwards) in frequency over time. Alleles without arrows did not significantly change in frequency over time. Allele frequency numbers with a ' (eg. *Gpi* allele 83') include frequencies of adjacent rare alleles.

duced significant temporal genetic heterogeneity with any pattern suggesting the presence of consistent selection processes. Temporal variation among electrophoretic variants at any locus implies the existence of selective processes differentially imparting a survival advantage over time. This does not necessarily imply a direct relationship between polymorphisms at a particular locus and survival. Variation at individual enzyme loci may simply serve as an indirect marker of another linked genetic condition that is subject to selective pressure (Beaumont et al. 1990). During our commercial rearing trials at three sites in Newfoundland, the population genotypic frequency distribution at the *Gpi* locus was shifted over time in favor of electrophoretically slower alleles. We infer from this frequency shift that selective survival processes favoring survival of *Gpi* genotypes incorporating relatively slower alleles exist during sub-tidal rope culture of blue mussels in Newfoundland. Although, this pattern of temporal change (high mobility alleles reduced, low mobility alleles increased) was consistent among all three sites, the same *Gpi* alleles were not always significantly implicated across all three populations. We found no evidence that any individual *Gpi* allele was consistently selected for or against at all three sites during the grow-out period. With the current dataset, we are unable to identify a causal mechanism that would adequately explain these observed patterns. However, our failure to detect a significant relationship between survival and the same specific individual *Gpi* alleles which was consistent over all three sites may be related to the widely different genetic population structure at these three sites. All three sites had allele frequencies significantly different from one another at all loci on all three sample dates during the rearing trials. A different result may well have occurred if the three populations had been genetically homogeneous initially. Until such time that a causal physiological mechanism is found, our inference of a genotype-dependent selective relationship between *Gpi* polymorphisms and survival in subtidal mussel culture based on directional shifts in genotypic frequencies will remain contentious.

Several previously published studies offer some insights which may help identify a causal physiological mechanism for the observed relationship between *Gpi* genotype and survival in subtidal, rope culture. The *Gpi* locus exhibits a considerable degree of polymorphism among most species of bivalve molluscs (Koehn et al. 1976) including North American mussel populations (McDonald et al. 1991; Penney & Hart 1999). Latitudinal clines that parallel thermal gradients have been observed at the *Gpi* locus in a variety of marine finfish and invertebrate species (see Hall 1985) suggesting a possible relationship between allelic variation at the *Gpi* locus and temperature. Available evidence in support of this possibility is inconclusive. In a series of laboratory experiments with larval and juvenile mussels, Beaumont et al. (1988, 1990) recorded significant genotype-dependent mortality at the *Gpi* locus. However, in neither case was this related to either temperature or salinity.

In contrast, the work of Hall (1985) does provide some evidence to support a potential relationship between *Gpi* and temperature. Glucosephosphate isomerase (*Gpi*) acts in the glycolytic pathway catalyzing the interconversion of fructose-6-phosphate and glucose-6-phosphate (Hall 1985). In experiments involving purified extracts of glucosephosphate isomerase derived from *Gpi*^{100} and *Gpi*^{96} genotypic individuals, Hall (1985) demonstrated the two variants had similar catalytic activity at 5–10°C but the electrophoretically faster *Gpi*^{100} enzyme became more efficient at higher temperatures between 15–25°C. In a similar experiment involving the sea anemone, *Metridium senile*, Hoffmann (1984) noted superior activity at higher temperatures for genotypes with the electrophoretically faster of two *Gpi* alleles and that the population variation in frequency of these two alleles exhibited a latitudinal cline along the eastern North American coast with the faster allele dominant in populations south of Cape Cod.

Both these studies suggest a possible selective advantage favoring relatively faster *Gpi* alleles in high temperature environments and further suggest a possible explanation for the observed decline in electrophoretically faster alleles in favor of slower ones in our study. The seed mussels in our study are at least in part derived from spawning of intertidal mussels which must regularly encounter periods of high air temperatures in the 20–25°C range during periods of emersion in summer. We may speculate that this produces selective temporal adaptation among intertidal populations in favor of electrophoretically faster *Gpi* genotypes while electrophoretically slower *Gpi* genotypes would be favored in suspended subtidal culture where temperature maxima are much lower (<20°C). Alternatively, the observed temporal variation at the *Gpi* locus may be linked to other factors unrelated to temperature such as selection for continuous immersion versus periodic emersion, a factor which might provide a different genotype-survival relationship in natural, intertidal populations versus those in sub-tidal rope culture.

In summation, our work has established that temporal genetic differentiation is apparently a common feature among rope-cultured blue mussel populations in Newfoundland and a *Gpi* genotype-dependent selective survival relationship significantly influences survival of *Mytilus* spp. during sub-tidal rope culture. This temporal genetic heterogeneity is likely a significant contributory factor in the extensive geographic genetic population structuring noted earlier among mixed *M. edulis* - *M. trossulus* populations in Newfoundland (Penney & Hart 1999). Identification of causal mechanisms controlling these temporal shifts in genotypic frequencies may permit commercially motivated selection of seed stocks with enhanced survival probabilities for culture operations. Commercial utilization of such seedstocks may help boost farm production and profitability.

ACKNOWLEDGMENTS

We thank the owners and staff of Thimble Bay Farms Ltd., B&C Mussel Growers Ltd., and Noel Bros. Mussel Farms Ltd. for their support and assistance maintaining experimental mussel gear at their respective farm sites. Special thanks to Nadine Templeman for her unfailing efforts in the laboratory conducting electrophoretic assays. An earlier draft of this manuscript was much improved by the helpful suggestions of Dale Parmiter and Geoff Veinott, Fisheries and Oceans Canada, St, John's, Nfld., and by two anonymous reviewers.

EFFECTS OF FOOD QUALITY AND QUANTITY ON FEEDING AND ABSORPTION IN BLACK-RIBBED MUSSELS, *SEPTIFER VIRGATUS* (WIEGMANN) (BIVALVIA: MYTILIDAE) DOMINATING WAVE-EXPOSED HABITATS IN HONG KONG

QIN-FENG GAO,[1] ZHENG-LIN WANG,[2] WAI-HING WONG,[3] AND SIU-GIN CHEUNG[1,*]
[1]Department of Biology and Chemistry, City University of Hong Kong, Tat Chee Avenue, Hong Kong SAR, China; [2]Department of Oceanography, The Ocean University of Qingdao, Qingdao, China; [3]Department of Ecology and Evolution, State University of New York at Stony Brook, Stony Brook, New York 11794-5245

ABSTRACT The black-ribbed mussel *Septifer virgatus* is an ecologically important species dominating exposed rocky shores in tropical and subtropical areas of Asia. The present study investigates its feeding and digestive responses to variations in food quantity and composition under laboratory conditions. Individuals were exposed to either one of five rations composed of different percentages of silt and the green microalga *Dunaliella tertiolecta*. Clearance rate (CR: $l\ h^{-1}$) was correlated weakly with both food quantity and quality whereas rejection rate (RR: $l\ h^{-1}$) showed a strong positive correlation with total particulate matter (TPM: $mg\ l^{-1}$), with the lowest threshold of TPM for pseudofaeces production estimated at $10\ mg\ l^{-1}$. Organic fraction in pseudofaeces was also significantly lower than organic content in water (f), evidence of pre-ingestive selection. Absorption efficiency (AE) was a negative exponential function of TPM and a negative quadratic function of organic ingestion rate (OIR). Gut passage time (GPT) showed a negative relationship with food quantity and ingestion rate (IR: $mg\ h^{-1}$). As food concentration increased (TPM), GPT of *S. virgatus* remained high when OIR was low ($<0.4\ mg\ h^{-1}$); further increases in OIR resulted in reductions of both GPT and AE. A prolonged GPT at low OIR resulted in a rapid increase in AR from 0.1 to $0.3\ mg\ h^{-1}$; further increases in OIR, however, did not cause a significant increase in AR. The existence of the regulative mechanism facilitates maximum absorption in wave-exposed habitats characterized by low seston concentrations.

KEY WORDS: *Septifer virgatus*, feeding, seston composition

INTRODUCTION

Both the concentration and composition of suspended particles in intertidal seawater undergo large fluctuations as consequences of the effects of tides, waves, currents, discharges of freshwater from rivers, and temporal variations in the abundance of phytoplankton and zooplankton. The feeding behavior of suspension-feeding organisms, therefore, is affected strongly by fluctuations in the food environment. To compensate for fluctuations in food availability, various mechanisms have been developed in bivalves which include regulation of feeding rate, production of pseudofaeces, selection of nutritious particles, and alteration of digestive efficiency (Hawkins et al. 1990; Bayne et al. 1993; Bacon et al. 1998). The relationships between suspension feeding and food concentration and quality have been studied in temperate, but not, generally, tropical bivalves. Such studies have provided insights into the trophic roles of bivalves in temperate aquatic ecosystems (Navarro et al. 1992; Hawkins et al. 1996) and identified optimum food conditions for aquaculture purposes (Beiras et al. 1993; Navarro et al. 1996).

In contrast to the Green mussel *Perna viridis* which is extensively cultured in southeast Asia and dominates sheltered and polluted harbours in Hong Kong characterized by turbid waters, the Black-ribbed mussel *Septifer virgatus* (Wiegmann) dominates wave-exposed rocky shores in Hong Kong characterized by clean water and low seston concentrations (Morton & Morton 1983; Seed & Richardson 1999). It forms a conspicuous band approximately 1.0 m wide in the eulittoral and the structural complexity of the mussel bed provides refuge and suitable habitat for a wide diversity of associated organisms (Ong Che & Morton 1992; Seed & Brotohadikusumo 1994). The species matures at a shell length of approximately 15 mm, about 1 year after recruitment and, like other local mytilids, *S. virgatus* is dioecious with a bimodal pattern of spawning and recruitment in any one year (Morton 1995). Although it is an ecologically important species on wave-exposed shores, far less is known about its ecology (Seed & Richardson 1999) and feeding behaviour as compared with that of temperate species such as *Mytilus edulis* and the tropical and subtropical mussel *Perna viridis* (Hawkins et al. 1998; Wong & Cheung 1999, 2001a,b). The present study is the first to investigate the feeding and digestive responses of *S. virgatus* to variable food quantity and quality under laboratory conditions.

MATERIALS AND METHODS

Collection and Maintenance of Experimental Animals

In December 1999, individuals with shell lengths of between 38 and 42 mm were collected from the eulittoral population of *Septifer virgatus* at Cape D'Aguilar on the southeastern extremity of Hong Kong Island, Hong Kong, and transported to the laboratory. Individuals of this size range were used because this was the dominant size group in the habitat. Epibionts on the shell of each individual were removed, and the mussels acclimated to laboratory conditions for 25 days before experimentation. During acclimation, individuals were fed daily with the green microalga, *Dunaliella tertiolecta*.

Preparation of Diet

Five diets with different quantities of sediments and the microalga *Dunaliella tertiolecta* were prepared. The sediments were collected adjacent to the population of *Septifer virgatus* at the study site and dried and ashed at 600°C to burn off organic matter in the sediments. The residual matter was grounded up in a pestle, sieved through a 37 μm sieve and mixed with *D. tertiolecta*, for

which the organic matter content had been pre-determined. Diet characteristics, including total particulate matter (TPM: mg l^{-1}), particulate organic matter (POM: mg l^{-1}), particulate inorganic matter (PIM: mg l^{-1}) and organic content (f = POM/TPM), are identified in Table 1. The ranges of TPM and f used in the present study were comparable to those reported for the study site where TPM ranged from 4.5 to 36.0 mg l^{-1} with an annual mean of 9.5 mg l^{-1} and f ranged from 0.15 to 0.57 with an annual mean of 0.33 (unpublished data).

Experimental Procedures

Each individual of *Septifer virgatus* was kept in a separate beaker (250 ml) and supplied with one of the diets via continuously-flowing seawater pumped from a reservoir by an 8-channel peristaltic pump. A beaker without animals was considered as the control. The experiment was replicated so that results of fourteen mussels were obtained for each diet. The particles in the reservoir were kept in suspension by aeration and stirring. A preliminary experiment was done to determine the appropriate flow rate to be used in this study. We have tested four flow rates (20, 40, 60, and 80 ml min^{-1}) with seven individuals each. Results showed that clearance rate was significantly lower at 20 ml min^{-1} whereas no significantly difference was obtained among the other three flow rates. A flow rate of 40 ml min^{-1}, therefore, was used in this study. The reduction in particle concentration at this flow rate was found to be less than 40%. This helped to ensure significant particle reduction between inflow and outflow for accurate determination of CR at the same time avoiding recirculation of water in the beakers which would otherwise have resulted in underestimation of CR (Hildreth & Crisp 1976; Hawkins et al. 2001). Seawater samples were collected from a beaker without an experimental mussel (i.e., the control) at fixed time intervals of about 30 min. The collected samples were filtered through ashed and pre-weighed 25 mm GF/C filters and rinsed with isotonic ammonium acetate solution. The filter papers were dried in an oven at 90°C, weighed, ashed in a muffle furnace at 450°C and reweighed to determine TPM (mg l^{-1}), POM (mg l^{-1}), PIM (mg l^{-1}) and f values for the filtered particles.

Before the start of the experiment, individuals of *Septifer virgatus* were kept in filtered seawater to empty their guts for about 50 min which was the maximum evacuating time being obtained in a preliminary experiment for a 40 mm individual. The maximum evacuating time was determined by feeding the mussels with the microalga *Dunaliella tertiolecta* for 24 h. They were then starved in beakers containing flowing filtered seawater and pseudofaeces and faeces produced were collected continuously. The time when no more faeces and pseudofaeces produced was considered as the maximum evacuating time which was estimated at 50 min. After emptying the gut, all pseudofaeces and faeces produced in the first hour were removed. Each individual was then exposed to an experimental diet for 150 to 180 min and faeces and pseudofaeces were collected with caution during and at the end of the experiment to prevent resuspension of faeces and pseudofaeces. After food supply was stopped, the mussels were maintained in the beakers for another 40 to 50 min until no more faeces and pseudofaeces were produced. The minimum gut passage time rather than the mean gut passage time (Decho & Luoma 1991) was measured and defined as the difference in time between initial filter-feeding by each individual and the first appearance of faeces disregarding extracellular and intracellular digestion. The total, inorganic and organic weight of pseudofaeces and faeces were determined by the same methods as those described for seawater samples. The following rates were then computed: total matter rejection (RR: mg h^{-1}), organic matter rejection (ORR: mg h^{-1}), inorganic matter rejection (IRR: mg h^{-1}), total egestion (defecation) (ER: mg h^{-1}), organic matter egestion (OER: mg h^{-1}) and inorganic matter egestion (IER: mg h^{-1}) (Hawkins et al. 1996).

TABLE 1.

Characteristics of experimental diets.

Diet	TPM (mg l^{-1})	PIM (mg l^{-1})	POM (mg l^{-1})	f (POM/TPM)
A	6.13 ± 0.21	3.72 ± 0.12	2.41 ± 0.11	0.39 ± 0.007
B	8.10 ± 0.22	5.69 ± 0.18	2.41 ± 0.11	0.30 ± 0.011

E	20.33 ± 1.28	14.34 ± 0.06	5.98 ± 0.46	0.30 ± 0.02

TPM: total particulate matter; PIM: particulate inorganic matter; POM: particulate organic matter; f: organic content of suspended matter. Values are mean ± S.D.

Calculation of the Feeding Parameters

Food processing rates (feeding and absorption) were calculated following Iglesias et al. (1992). Assuming that absorption of inorganic matter through the digestive system was negligible (Cranford & Grant 1990), the sum of IRR and IER was considered to represent the rate of inorganic matter filtration (IFR: mg h^{-1}). Clearance rate (CR: l h^{-1}) was then estimated as CR = IFR/PIM. Filtration rate of total particulate (FR: mg h^{-1}) was computed as FR = CRxTPM and filtration rate of particulate organic matter (OFR: mg h^{-1}) as OFR = CRxPOM. Ingestion rates of total particulate matter (IR: mg h^{-1}) and of particulate organic matter (OIR: mg h^{-1}) were estimated as IR = FR-RR and OIR = OFR-ORR and hence, the organic content of absorbed food could be estimated as AR (mg h^{-1}) = OIR-OER, and absorption efficiency (AE) = AR/OIR.

Preingestive selection efficiencies for total filtered organic matter (SEo) were estimated as: SEo = 1 – (p/f) (Navarro et al. 1992), where p is the organic content of the pseudofaeces and f is the organic content of the suspended matter. In view of a very narrow size range of animals we used, no attempt has been made to weight-standardized the measured feeding rates.

Statistical Procedures

To obtain functional relationships between feeding responses and food parameters, a set of regression equations was fitted to experimental data, following standard least-squares procedures. Regression analyses were performed by simple linear and nonlinear procedures, depending on the most appropriate function to be fitted in each case (Zar 1999). Multiple regression analysis was conducted when feeding behavior was correlated with more than one diet parameters, and the collinearity between the independents was tested with collinearity statistics of SPSS (Belsley et al. 1980; SPSS Inc. 1999a). When the independent(s) were highly correlated with others, they would be eliminated from the independent list and the model was reconstructed until all the intercorrelations between the independents were removed from the regressive model. Residuals were also analyzed to check the normality, constant variance of predicted dependents and other necessary assumptions of the regression model. Data were transformed if necessary to meet the regressive requisites, i.e., normality of datum distribution and homogeneity of variances.

Analysis of variance (ANOVA) was used for comparisons among different treatment groups. Prior to analysis, raw data were diagnosed for normality of distribution and homogeneity of variance with Kolmogorov-Smirnov test and Levene test, respectively. The specific function and procedures followed for each feeding response will be presented with the results. All the statistical procedures were performed with software SPSS for windows, release 9.0 (SPSS Inc. 1999a,b).

RESULTS

Clearance Rates and Filtration Rates

The relationship between CR and food availability was weak but significant and can be described by the multiple regression equation as:

$$CR = 0.18 + 0.09/TPM + 0.13\ f(r^2 = 0.19,\ F_{2,67} = 6.56,\ P < 0.001)$$

There was no significant relationship between FR and f. FR, however, was positively related to POM and the equation that describes the relationship is:

$$FR = 0.79 + 0.57\ POM\ (r^2 = 0.72,\ F_{1,68} = 185.57,\ P < 0.001)$$

Pseudofaeces Rejection, Selection Efficiency and Ingestion of Filtered Food

The organic content of particulate matter (f) was significantly higher than that of the pseudofaeces for Diet C, D and E of which pseudofaeces were produced (Table 2). As TPM increased, pseudofaeces production increased with the increase in FR (Fig. 1) and can be described by the equation:

$$RR = -0.439 + 1.014\ \ln(FR)\ (r^2 = 0.84,\ F_{1,68} = 365.04,\ P < 0.001).$$

There was a significant positive relationship between TPM and RR ($RR = 0.54 + 0.08\ TPM\ (r^2 = 0.786,\ P < 0.001)$). No significant relationship, however, could be established between RR and f, showing that the rejection rate was related to the quantity (TPM) but not the quality (f) of suspended matter. As pseudofaeces were only produced for Diets C, D, and E, the lowest threshold of TPM for pseudofaeces production was about 10 mg l^{-1}.

Selection efficiency (SEo) is a measure of the efficiency in selecting the organic fraction of food when pseudofaces are being produced. There was an inverse relationship between SEo and TPM. No significant relationship between SEo and f, however, could be established. The corresponding equation is:

TABLE 2.

Comparisons between the organic content of the diet (f) and that of the pseudofaeces (e) for diet C, D and E where pseudofaeces were produced.

Diet	f (mean ± SD)	e (mean ± SD)	t value	Degree of Freedom	p
C	0.22 ± 0.02	0.12 ± 0.058	5.10	8	<0.001
D	0.11 ± 0.01	0.071 ± 0.016	6.91	7	<0.001
E	0.30 ± 0.02	0.199 ± 0.068	5.56	13	<0.001

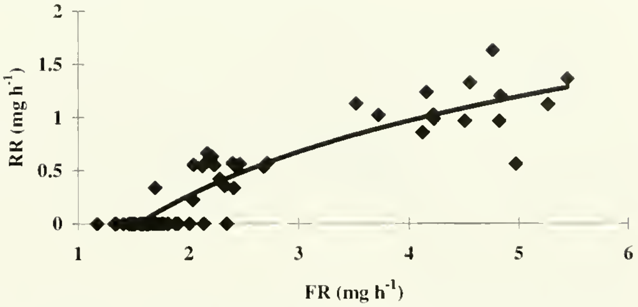

Figure 1. The relationship between filtration rates (FR: mg h^{-1}) and rejection rates (RR: mg h^{-1}) in *S. virgatus*.

$$SEo = 0.77 + 1.51/TPM\ (r^2 = 0.49,\ F_{1,68} = 66.34,\ P < 0.001)$$

Ingestion rate (IR) is estimated as the difference between filtered food and rejected pseudofaeces. Both IR and OIR were not significantly correlated with f but IR was a positive power function of TPM and OIR a linear function of POM which can be described by the following equations:

$$IR = 1.02\ TPM^{0.06}\ (r^2 = 0.82,\ F_{1,68} = 328.11,\ P < 0.001)$$

$$OIR = 0.048 + 0.186\ POM\ (r^2 = 0.91,\ F_{1,68} = 672.81,\ P < 0.001)$$

The more the particles were filtered, the more they were ingested, resulting in a positive linear relationship between IR and FR:

$$IR = 0.50 + 0.64\ FR\ (r^2 = 0.94,\ F_{1,68} = 1013.45,\ P < 0.001)$$

Absorption Rate and Absorption Efficiency

AR was a positive linear function of f (Fig. 2). As OIR increased, AR increased rapidly until OIR reached about 0.4 mg h^{-1} (Fig. 3). The rate of increase of AR, however, was slower when OIR increased further. The corresponding equations are:

$$AR = 0.09 + 0.85\ f(r^2 = 0.63,\ F_{1,68} = 126.27,\ P < 0.001)$$

$$AR = 0.45 - 0.05/OIR\ (r^2 = 0.74,\ F_{1,68} = 192.70,\ P < 0.001)$$

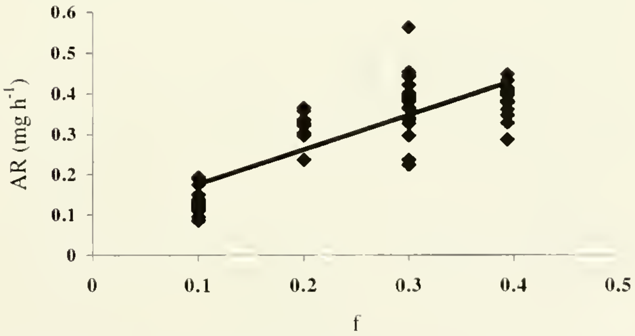

Figure 2. Absorption rates (AR: mg h^{-1}) as a function of organic content (f) of seston in *S. virgatus*.

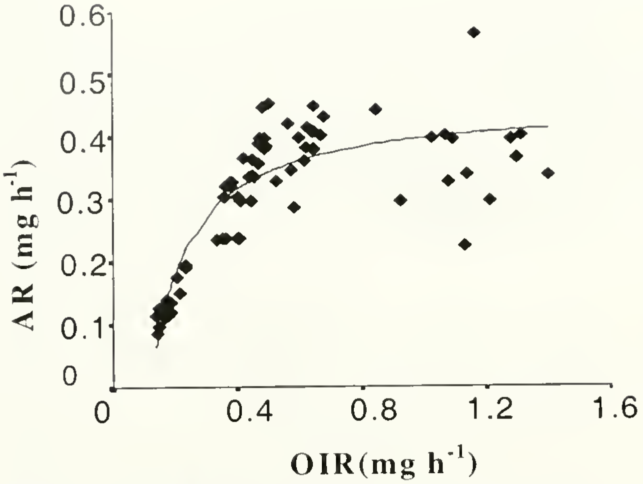

Figure 3. The relationship between absorption rates (AR: mg h^{-1}) and organic ingestion rates (OIR: mg h^{-1}) in *S. virgatus*.

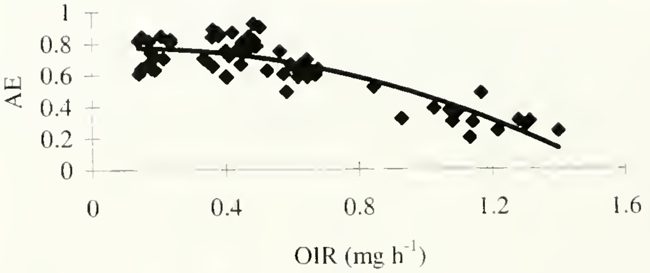

Figure 5. The relationship between absorption efficiency (AE) and organic ingestion rates (OIR: mg h^{-1}) in *S. virgatus*.

AE decreased exponentially with an increase in TPM in the water and was a negative quadratic function of both POM (Fig. 4) and OIR (Fig. 5). The corresponding equations are:

$$AE = 0.962e^{-0.041TPM} \ (r^2 = 0.42, F_{1,68} = 61.28, P < 0.01)$$

$$AE = 0.726 + 0.037 \ POM - 0.017 \ POM^2 \ (r^2 = 0.73, F_{2,67} = 88.03, P < 0.001)$$

$$AE = 0.77 + 0.07 \ OIR - 0.38 \ OIR^2 \ (r^2 = 0.74, F_{2,67} = 96.36, P < 0.001)$$

Gut-Passage Time

Gut-passage time (GPT) for particles was a negative exponential function of TPM (Fig. 6) and a negative quadratic function of OIR (Fig. 7), showing that the time the food particles stayed in the gut was prolonged when OIR was low. GPT, however, was much reduced when OIR increased. The respective equations are:

$$GPT = 59.32 \ e^{-0.07TPM} \ (r^2 = 0.76, F_{1,68} = 213.54, P < 0.001)$$

$$GPT = 21.28 + 49.07 \ OIR - 43.04 \ OIR^2 \ (r^2 = 0.42, F_{2,67} = 24.16, P < 0.001)$$

DISCUSSION

Rates of Clearance, Filtration and Pseudofaeces Production

Food availability is regarded as one of the most important factors affecting the feeding behaviour of bivalves. To compensate for fluctuations in food availability, various mechanisms have been developed which include regulation of feeding rate, pseudofaeces production, selection of nutritious particles and alterations to digestive efficiency (Hawkins et al. 1990; Bayne et al. 1993; Bacon et al. 1998). As particle concentration increases, ingestion is commonly regulated by a reduction in clearance rate and the production of pseudofaeces in mussels (Widdows et al. 1979), scallops and clams (Navarro et al. 1992; Bacon et al. 1998). A similar reduction in clearance rate with food availability was also recorded for another locally dominant mussel, i.e., *Perna viridis*, under both laboratory (Wong & Cheung 1999) and field conditions (Hawkins et al. 1998; Wong & Cheung 2001a,b). In contrast, the correlation between clearance rate and food availability (TPM and f) in *Septifer virgatus* was weak, showing that ingestion of particulate organic matter was not regulated through clearance rate. In *Mytilus trossulus*, CR was independent of increasing seston quality at relatively high seston loads (20 and 50 mg l^{-1}) (Arifin & Bendell-Young 1997). Positive correlations between clearance rates and the TPM of natural seston have been reported upon for *Mytilus edulis* (Newell & Shumway 1993; Hawkins et al. 1996) and *Cerastoderma edule* (Iglesias et al. 1992). CR of *Crassostrea gigas* was maintained high and constant when TPM was 50 mg l^{-1} but decreased with further increases (Barillè & Prou 1994). Nevertheless, all species should have an upper limit to the rate of particle processing (Bayne & Newell 1983). It was expected, therefore, that the CR of *S. virgatus* would ultimately decrease when TPM increased to a level higher than that experienced in the present study.

With clearance rate relatively independent of food quantity, filtration rate increases with POM, as shown here for *Septifer*

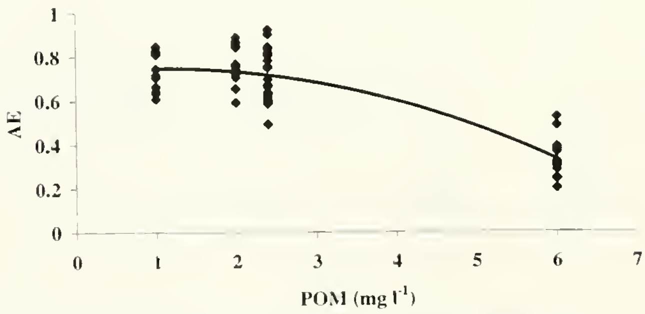

Figure 4. Absorption efficiency (AE) of *S. virgatus* as a function of particulate organic matter (POM: mg l^{-1}) in the water.

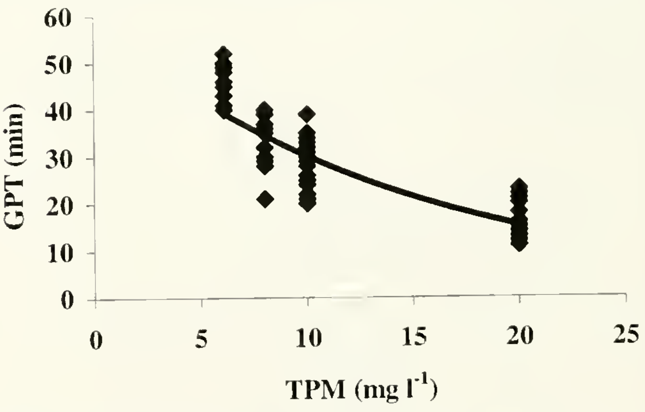

Figure 6. Gut passage time (GPT: min) of *S. virgatus* as a function of total particulate matter (TPM: mg l^{-1}) in the water.

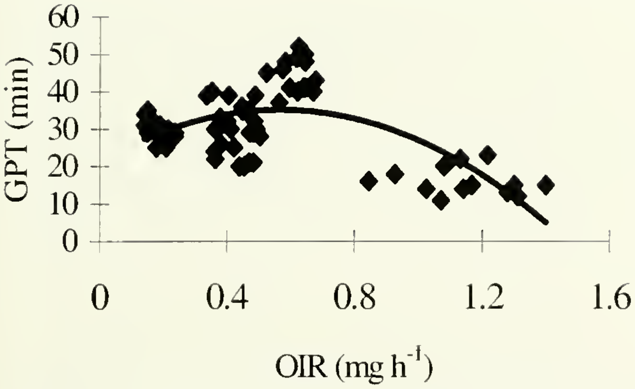

Figure 7. The relationship between gut passage time (GPT: min) and organic ingestion rates (OIR: mg h^{-1}) in *S. virgatus*.

virgatus. Reports on the relationship between filtration rate and food concentration, however, were variable. Winter (1973) showed that the filtration rates of *M. edulis* decreased with increasing food concentration such that the bivalves could keep the number of filtered algae in unit time relatively constant within the range of 10×10^6 to 40×10^6 cells l^{-1}. Contrary results, however, were reported by Winter (1978) and Riisgård and Randløv (1981), that is, that filtration rates increased quickly with increasing particle concentration. Griffiths and Griffiths (1987) reviewed the relationship between food quality and quantity and filtration rate of various species of suspension-feeding bivalves and concluded that conflicting experimental results were largely attributed to differences in particle concentration. At low concentrations, a positive relationship between filtration rate and food quantity was established. When similar experiments were conducted at low to intermediate particle concentrations, and the concentration ranges were relatively narrow, no obvious relationship between filtration rate and particle concentration was observed. In the present study, four out of the five treatment groups had particle concentrations either equal to or lower than 10 mg l^{-1}. A reduction in filtration rate, therefore, is expected at higher particle concentrations when CR decreases.

Pseudofaeces production is regarded as one of the most important regulative processes in bivalves to organically enrich ingested matter by the selective rejection of inorganic matter versus organic matter and thus, as a consequence, to optimize energy uptake. The production of pseudofaeces is strongly related to both the density and organic content of suspended seston in the water (e.g., Foster-Smith 1975; Bacon et al. 1998; Baker et al. 1998; Beninger et al. 1999). *Septifer virgatus* started to produce pseudofaeces when TPM was ~10 mg l^{-1}; its production rate was also highly correlated with TPM and FR. Ingestion rate, therefore, increased across the full range of food availability. This agrees with the observations of Kiørboe at al. (1980) and Hawkins et al. (1996) on *Mytilus edulis* but is not consistent with those of Widdows et al. (1979) who demonstrated that maximum IR coincided with the threshold TPM above which pseudofaeces were produced. Hawkins et al. (1996) anticipated that IR would reach maximal values in association with reduced CR and/or an increase in the ratio RR/FR, as observed for *M. edulis* feeding upon pure strains of cultured algae (Foster-Smith 1975).

The SEo index represents the efficiency with which bivalves can organically enrich ingested matter by selectively rejecting inorganic matter via the palps. For both *C. edule* (Iglesias et al. 1992, 1996) and *P. viridis* (Wong & Cheung 1999), SEo was a curvilinear function of f whereas in another study on *C. edule*, SEo was positively related to f and negatively related to seston concentration (Navarro & Widdows 1997). In *S. virgatus*, SEo varied from 0.74 to 1.0 and was negatively correlated with TPM but not significantly correlated with f. Such high values of SEo in *S. virgatus* can probably be attributed to low seston concentrations and it is expected that SEo would decrease when seston concentration increased beyond that experienced by the individuals used in this study. A maximum selection efficiency of 0.60 was obtained for *C. edule* when fed at low seston concentrations, and this decreased to the lowest value of 0.10 when seston concentration increased to 600 mg l^{-1} (Navarro & Widdows 1997). The SEo of *Perna viridis* was comparable to *S. virgatus*, with a maximum efficiency of 0.75 (Wong & Cheung 1999).

The present study demonstrates inter-specific differences in pre-ingestive feeding behaviour between two mussels in Hong Kong. *S. virgatus* is a dominant species on exposed rocky shores in the eastern waters of Hong Kong characterized by low TPM values (Morton & Morton 1983). Seasonal variations in TPM at Cape d'Aguilar, Hong Kong, where the animals used in the present study were collected from, have been studied for one year (unpublished data). TPM varied from 4.5 to 36 mg l^{-1} with an annual mean of 9.5 mg l^{-1}. With the relative independence of clearance rate from particle concentration, and positive relationships between RR and FR and between IR and FR, the ingestion rate of organic particulate matter, therefore, could be enhanced under the low food concentrations which prevail in this environment. In contrast to *S. virgatus*, *P. viridis* occurs predominantly in sheltered environments in which the water is often turbid and sometimes heavily polluted (Lee 1985; Cheung 1993). This species possesses large labial palps with strong ciliary rejection tracts (Morton 1987; Seed & Richardson 1999) to cope with the high sediment loadings often associated with sheltered, low energy habitats. Ingestion of particulate organic matter by *P. viridis* was regulated through pseudofaeces production, as herein demonstrated for *S. virgatus*, although the rate was much higher at ~9 mg h^{-1} (Wong & Cheung 1999) as compared with *S. virgatus* of a similar size (~1.6 mg h^{-1}). Regulation was further enhanced by controlling clearance rate which has not been observed in *S. virgatus*.

Absorption and Gut Passage Time

The absorption efficiency of suspension-feeding bivalves has been shown to change over time scales according to variability in seston characteristics (Bayne & Newell 1983) and is mainly controlled by organic food quantity and/or quality when feeding on either natural seston or on suspensions resembling natural conditions (Bricelj & Malouf 1984). In the present study, the AE of *S. virgatus* was negative quadratic functions of both POM and OIR. Digestion in bivalves is biphasic involving the stomach and digestive diverticula as compartments for extra- and intra-cellular digestion, respectively (Purchon 1968). Food may undergo extracellular digestion in the stomach followed by intestinal absorption and is voided as "intestinal faeces". Some of the food may then also undergo intra-cellular digestion and absorption within the digestive diverticula and eliminated as "glandular faeces" (Bricelj & Malouf 1984). With higher rates of food processing, the proportion of particles by-passing the digestive diverticula would increase and result in reductions in both GPT and AE (Navarro & Iglesias 1993). In models combining gut passage time and feeding behaviour. Willows (1992) also showed that GPT generally decreased with an increase in the quality of food at high levels of food availability. These observations agree with the present study, i.e., as food concentration increased (TPM), the GPT of *S. virgatus* remained at high levels and was relatively constant when OIR was low (<0.4 mg h^{-1}). Further increases in OIR resulted in a reduction in GPT. The high and constant values of AE under relatively low OIR (up to 0.4 mg h^{-1}), therefore, might be attributed to the prolonged GPT and resulted in a rapid increase in AR from 0.1 to 0.3. Further increases in OIR, however, did not cause significant increases in AR. Similar observations were also reported upon for *Placopecten magellanicus* (Brillant & MacDonald 2000) and *Aulacomya ater* (Griffiths & King 1979) that AE of the latter species decreased rapidly with increasing algal concentration and AE approached zero when algal concentrations were $>32 \times 10^6$ cells l^{-1}. Using algal concentrations ranging from 50 to 100×10^6 cells l^{-1} (equivalent to 1.25 – 2.5 mg l^{-1} POM), Gerdes (1983), however, found that AE of the Pacific Oyster, *Crassostrea gigas*, was independent of ration with AE of ~75% being obtained for all three kinds of diet with different TPM and POM. As the range of POM used in our study on *S. virgatus* varied from 1 to 6 mg l^{-1} as compared to a narrower range (1.25 – 2.5 mg l^{-1}) used by Gerdes (1983), AE of *C. gigas* is expected to decrease, as what has been observed in *S. virgatus* and other bivalves, when POM increases further.

The ranges of seston quantity (TPM) and quality (f) used in this study were 20 mg l^{-1} and 0.4, respectively, and within the ranges recorded for the habitat where *S. virgatus* was collected for this study. AR reached asymptote when OIR was only one third that of the highest value. This suggests that *S. virgatus* is particularly well-adapted to a low seston concentration environment. Food quality was also an important factor controlling AR. For example, AR is a positive quadratic function of POM in *P. viridis* (Wong & Cheung 1999) and is positively linearly related to the different measures of diet quality in *Placopecten magellanicus*, even when the organic content of seston (f) was as high as 80% (Cranford 1995). This agrees with the results obtained for *S. virgatus* in this study.

The present study demonstrated regulative mechanisms in the subtropical mussel *S. virgatus* which is dominant on locally clean and wave-exposed habitats characterized by low seston concentrations. As food concentration increases, particulate organic matter ingestion is enhanced through pseudofaeces production with preferential ingestion of particulate organic matter, although clearance rate is relatively independent of food quantity. GPT was a negative function of TPM and OIR such that AE is relatively constant and absorption rate reaches asymptote at low seston concentrations.

COMPARATIVE SETTLEMENT DEPTHS OF *MYTILUS EDULIS* C. LINNAEUS, 1758 AND *M. TROSSULUS* GOULD, 1850: I. A MESOCOSM STUDY

K. R. FREEMAN,[1,*] E. KENCHINGTON,[1] AND S. P. MACQUARRIE[2]
[1]Department of Fisheries & Oceans, Bedford Institute of Oceanography, P.O. Box 1006, Dartmouth, Nova Scotia B2Y 4A2, Canada; [2]Department of Biology, Dalhousie University, 1355 Oxford Street, Halifax, Nova Scotia B3H 4J1, Canada

ABSTRACT Production on many commercial mussel farms in Eastern Canada is hampered by the presence of *Mytilus trossulus*, a comparatively thin-shelled but close relative of *M. edulis*, the principal species collected and grown. Exploitation of a species-based difference in depth preference could potentially increase the collection of *M. edulis* at mixed species sites. As a first step in the investigation, larval cultures of each species were reared to settlement in replicated mesocosms in a study conducted at Dalhousie University's Aquatron facility in Halifax, Nova Scotia. Depth preference for settlement was examined with and without a thermocline. Both *M. edulis* and *M. trossulus* had the largest percentage of larvae settling at the surface. Settlement occurred below the thermocline at 6 m in both species, although in significantly lower proportions. In mixed water, a significant species–depth interaction was detected. This was driven by a significantly large number of *M. edulis* spat settling at 8 m, a pattern not found in *M. trossulus*.

KEY WORDS: *Mytilus edulis*, *M. trossulus*, settlement, depth, mesocosms

INTRODUCTION

Farm recruitment [1]of mussels in Eastern Canada depends on the timing and inter-relationship of a number of natural events combined with judiciously applied husbandry practices. The deployment of a suitable settlement medium, at an appropriate time, is key to maintaining an uninterrupted cycle of spat collection, growout, and harvest. Traditionally, spat collecting is performed on the farm site, usually by deploying plastic mesh (Vexar™) on headropes near the surface several days before the anticipated onset of settlement. This technique has proven successful over the relatively short history of Eastern Canadian mussel farming. Nevertheless, spat collections at some farms comprise two species (*Mytilus trossulus* Gould, 1850 and *M. edulis* C. Linneaus 1758) and the presence of the former is cause for concern to many growers (Freeman 1996).

Although it was realized early in the industry that certain farms often produced mussels of varying quality, it was not initially appreciated, at least in certain cases, that the problem was species-based. After this had been demonstrated (Koehn et al. 1984), investigations into distributions of the two species showed that Eastern Canadian *Mytilus* populations vary from purely one or the other species to varying proportions of each (Penney & Hart 1999; Mallet & Carver 1999). Although the two are often superficially similar, *M. trossulus* is characterized by comparatively fragile shells and generally lower meat weight per shell length. For example, it has been found that the initial number of *M. trossulus* farmed would have to be multiplied 1.7 times to achieve the same economic return as with *M. edulis* alone (Mallet & Carver 1995). Furthermore, anecdotal reports suggest that on some farms the proportion of *M. trossulus* to *M. edulis* is gradually increasing (Freeman 1996). Importation of pure *M. edulis* seed has been the sole means producers have to overcome production shortcomings associated with farm-collected *M. trossulus*, however, researchers have been looking for other options. It had been believed, for example, that comparison of early life events of both species might suggest alternate husbandry strategies at sites with both species, where growers might wish to harvest only the more commercially desirable *M. edulis* (Freeman 1996)

Examination of spawning times and duration of larval phases revealed close synchrony between *M. edulis* and *M. trossulus* (Freeman et al. 1994), indicating that any separation technique employed as part of routine husbandry would have to be based on some other criterion. Anecdotal references to different settlement depths for each suggested that looking for larval depth variations between the two would be an appropriate first step. It is presumed that initial settlement would "preferentially" occur at a depth chosen by the larvae upon their attainment of competence, assuming the larvae had immediate accessibility to a suitable substrate at that depth. Following recent success of mesocosm studies of *Placopecten magellanicus* larvae at the Dalhousie University Aquatron in Halifax, Nova Scotia (e.g., Manuel et al. 1996; Gallagher et al. 1996), additional experiments were performed at the same facility using laboratory-reared larvae of *M. edulis* and *M. trossulus* (MacQuarrie 1995; Freeman & MacQuarrie 1999).

Here we present data on depth settlement preferences of both *M. edulis* and *M. trossulus* as observed in the laboratory. Settlement behavior was examined in columns of mixed water, and when a thermocline was present at 6 m.

METHODS

Broodstock Selection

Naturally conditioned broodstock animals were obtained from a commercial mussel farm near Lunenburg, Nova Scotia. The collection was made in early June 1995, a time corresponding to peak natural spawning at this site. Animals were selected on the basis of apparent shell weight (a completely subjective judgment) combined with shell length to shell height ratio derived from direct measurements. Those animals with a shell length to shell height ratio >2.2 and deemed 'light weight' for their length, were considered *M. trossulus*, whereas those animals with a ratio of <2.0 and deemed 'heavy' for their length were regarded as *M. edulis*. Subsequent isoenzyme analysis in earlier work confirmed the accuracy of this visual identification method at this site (Freeman et al. 1994). Furthermore, a more recent shell analysis of mature, DNA-identified mussels has indicated that the length-to-height

proportions, as a guide to species identification at Corkums Island, remain valid. Greater assurance of species identification was attained by selecting animals toward the extreme ends of the shell length/shell height scale, which at this site, ranged from approximately 1.75 to 2.50. One hundred putative *M. edulis* and 92 *M. trossulus* were chosen from several dozens of specimens examined. These animals were taken to the former Halifax Fisheries Research Laboratory, Halifax, Nova Scotia.

Spawning and Fertilization

Animals were held in ultraviolet-irradiated, 1-μm filtered ambient temperature (<10°C) seawater to encourage gut content release prior to spawning attempts. On spawning occasions, mussels were brushed clean of epiphytic growth, wiped with dilute bleach solution, rinsed in 1-μm filtered seawater, and then placed in 500-mL containers, one animal per container. Seawater (20°C) was added to each container and changed after the first 30 min if spawning had not commenced; any mussel not spawning after this first rewarming was discarded. Sperm–seawater mixtures from several *M. edulis* males were combined in one labeled container, and egg–seawater mixtures from several females of the same species were combined in a second labeled container. To remove fecal matter and other detritus, all the eggs were passed through a 100-μm filter, and the sperm mixtures were passed through a 40-μm filter. Gametes from *M. trossulus* were treated similarly. *M. edulis* broodstock was spawned on June 13, and *M. trossulus* on June 20, 1995.

Within species, pooled sperm was well mixed and 25 mL of the mixture were added to the pooled eggs in a 20-L bucket and gently mixed again. Egg–sperm mixtures were examined microscopically to ensure that the sperm concentration was not excessive; further sperm additions were made if concentrations appeared low. Two hours following fertilization, a well-stirred sample of each batch of eggs was examined microscopically and the percentage of fertilization was estimated by noting the proportion of intact eggs to embryos having attained at least the first division. Within 3 h of fertilization, each batch of fertilized eggs was separated into seven roughly equal lots, placed into seven 135-L plastic containers, filled with treated (20°C, 1 μm) seawater, and left standing. One day later, the upper 80% of each container was carefully siphoned off and retained. The final 20% containing detritus, unfertilized eggs, and many substandard trochophores, was discarded. The 135-L containers were sanitized, the retained larvae replaced in them, and refilled with treated seawater. At 48 h, the entire contents of the 135-L tubs, now containing straight-hinge (veliger) larvae, were siphoned through 40-μm filters, and rinsed with, then resuspended in treated seawater. At this stage, the *M. trossulus* larvae were enumerated using a Coulter Counter, then equally divided among four sanitized, covered, 20-L buckets and transported to the 10-m-deep tower tank at Dalhousie University (for a complete description of the facility, see Gallagher et al. 1996). For logistic reasons, *M. edulis* larvae were held for 5 days at the Department of Fisheries Laboratory before final counting, separation into four lots, and being transported to the tower tank. While being held at the Fisheries laboratory, *M. edulis* larvae were fed Tahitian *Isochrysis* daily, and the water was changed at 2 and 4 days.

Tower Tank Procedure

Each mesocosm was a 8.5-m-deep by 0.6-m-diameter polyethylene cylinder sealed at the bottom, supported at the surface by a

styrofoam floatation collar, and filled with 2.40 m^3 of 1.0-μm filtered water. Hot and cold water circulating in vertically adjustable piping circling the inside walls of the tank maintained a thermocline, in this instance at 6 m. The temperature above the thermocline was 19°C; below it 9°C. Of the *M. edulis* larvae, 1.43×10^6 were placed in each of four mesocosms suspended in the tower tank. For *M. trossulus*, two mesocosms were charged with 1.65×10^6 larvae and two others with 1.70×10^6 larvae. One of the latter *M. trossulus* and one *M. edulis* mesocosm was fitted with an outer polyethylene bag containing water and an airlift system, which kept the water stirred. This system eliminated the thermocline in these two mesocosms, and held their internal temperatures at 12°C, top to bottom. Logistic constraints eliminated the possibility of replicating the nonthermocline mesocosms. A 12-h day/night photoperiod established during the larval stages was continued to the end of the settlement experiment. The feeding regime established by the mid-larval period was also continued. Mixtures of Tahitian *Isochysis* and *Chaetoceros gracilis* were distributed throughout the depths of each mesocosm by use of perforated hoses. Final concentrations of 5.0×10^3 cells/mL of each algal species were maintained to the end of the experiment. Algal counts were assessed and adjusted every 2 days.

Collectors

Duplicate, preconditioned, 13-mm diameter, 25-cm lengths of polypropylene rope were suspended by weighted monofilament lines in all eight mesocosms. The portions of rope were positioned more or less horizontally, at 1-m depth intervals, from the surface to 8.0 m. The use of fine-diameter, smooth-surfaced monofilament line was intended to discourage newly settled spat from migrating vertically. The collectors were installed in the *M. edulis* mesocosms when these larvae were 24 days old, and in the *M. trossulus* mesocosms when these larvae were 21 days old. In each case, settlement began about 5 days after collector installation.

On July 31, the 25-cm segments of polypropylene rope from these collectors with their attached spat were retrieved, placed in a container of 80% ethyl alcohol, and labeled by species, replicate, and depth. *M. edulis* collectors were removed at 48 days of age; those of *M. trossulus* were removed at 41 days. Spat were subsequently separated from the rope segments with a light brushing, then counts of the total number of spat per segment were done microscopically. The chronology of events is shown in Table 1.

Data Treatment

Thermocline at 6 m

Spat counts from the collectors (two replicates for each mesocosm with a thermocline) were converted to percentages settled at each depth per collector, $\log_{10}$ transformed, then tested for normality using the Shapiro-Wilk W test. Normal Q–Q plots of the residuals were visually inspected for deviations. For each factor, homogeneity of variance was assessed with Levene's test. Data were then subjected to analysis of variance (ANOVA). All analyses were computed with JMP® version 3.1 software. The initial analysis was designed to test the hypothesis that there was no significant difference between species in settlement depth distribution in the presence of a thermocline at 6 m. The mesocosms were nested within each species. The model is expressed as

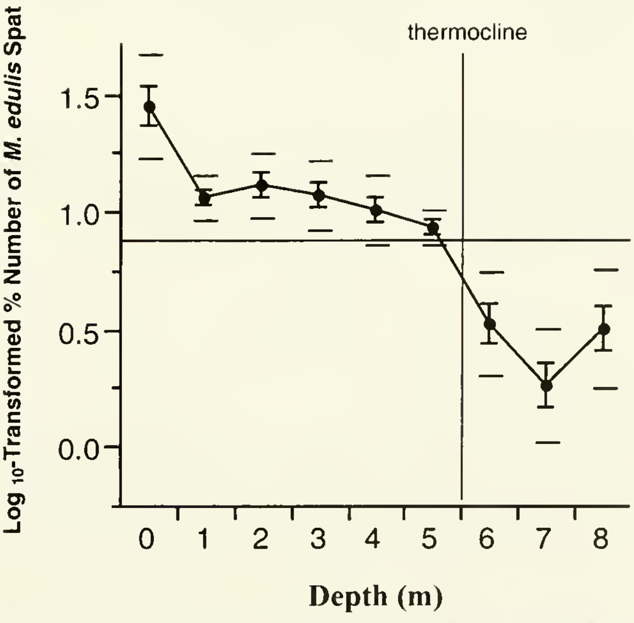

Figure 1. Log_{10}**-transformed percent number of** *M. edulis* **spat. Mean, standard error, and standard deviation are indicated for each depth (0–8 m). The mean across all depths is also indicated (solid line). A thermocline was present at 6 m in this experiment.**

Positive values show pairs of means that are significantly different at $\alpha = 0.05$.
A thermocline was present at 6 m.
Depths are ordered to position significantly different pairs together.

$$X_{ijkl} = \mu + A_i + B_j + AB_{ij} + C(B)_{k(j)} + AC(B)_{jk(i)} + \varepsilon_{l(ijk)}$$

where A is depth with nine levels (0, 1, 2, 3, 4, 5, 6, 7, and 8 m) treated as an ordinal value, B is species with two levels (*M. edulis* and *M. trossulus*), and C is mesocosm with three levels nested within species. Depth was orthogonal to both factors.

Tukey-Kramer honestly significant difference (HSD) tests were performed in post-hoc analyses of all ANOVA results. Multiple comparisons of all pairs of means were performed. The significance level (alpha) in the one-way ANOVA for all comparisons was set at 0.05. The mean values of the $\log_{10}$-transformed percentages were plotted for each depth and species along with descriptive statistics.

No Thermocline

A second model was used to test the hypothesis of no difference in the percent of spat of each species settling at depth, in the absence of a thermocline. Because there was only one mesocosm per species, a two-way ANOVA model was used:

$$X_{ijk} = \mu + A_i + B_j + AB_{ij} + \varepsilon_{ijk}$$

where A is depth with nine levels (0, 1, 2, 3, 4, 5, 6, 7, and 8 m), B is species code with two levels (*M. edulis* and *M. trossulus*), and AB is the interaction term. The data were converted to percentage settled at each depth per collector rope and $\log_{10}$ transformed. Normality, homogeneity of variance, and post-hoc tests were performed as above.

RESULTS

Spawning and Fertilization

Of the putative *M. edulis* subjected to spawning inducement, 28 females and 27 males (55%) spawned. Of the putative *M. trossulus* subjected to spawning inducement, 18 females plus 22 males (43%) spawned. Two hours after batch fertilization, 84% of the *M. edulis* eggs had progressed to at least first divisions and for *M. trossulus*, 86%. From past experience with broodstock from the same farm, the percentage spawning and the subsequent progress of fertilization and embryo development fell well within expectations. Approximately 5.72×10^6 *M. edulis* larvae and 6.60×10^6 *M. trossulus* 2-day-old veliger larvae were taken to the Dalhousie University tower tank.

Analyses of Spat Settlement, Thermocline Present at 6 m

The transformed data produced a distribution that was not significantly different from normal at $P = 0.01$ (Shapiro-Wilk W test). Untransformed percentages did not meet the assumptions of the tests. The variances were homogeneous within depth and species according to Levene's test ($P = 0.45$ and 0.74, respectively). Normal Q–Q plots of the residuals indicated that the residuals were normally distributed.

The ANOVA model explained approximately 80% of the variance in the data set (adjusted $R^2 = 0.81$). Table 2 provides the test results. These indicate that both species had significantly different numbers of spat settling at different depths and that those distributions differed according to mesocosm. The spat were not uniformly distributed by depth, however, no significant differences between the species were observed.

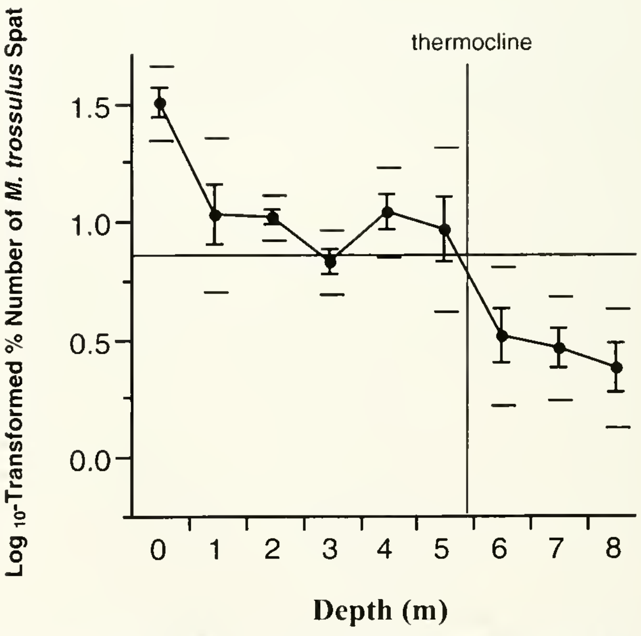

Figure 2. $\log_{10}$-transformed percent number of *M. trassulus* spat. Mean, standard error, and standard deviation are indicated for each depth (0–8 m). The mean across all depths is also indicated (solid line). A thermocline was present at 6 m in this experiment.

TABLE 5.

Two-way ANOVA of the transformed percentage of spat settled at depth by species.

Source	DF	Sum of Squares	*F* Ratio	Probability > *F*	Power
Sp. Code	1	0.007876	0.3184	0.5795	0.083
Depth	8	0.947826	4.7893	0.0028	0.877
Sp. Code * Depth	8	0.609815	3.0814	0.0225	0.559

No thermocline was present.

Post-hoc analyses of the depth distributions of spat of each species in the presence of a thermocline at 6 m depth were performed. For *M. edulis*, the number of spat settling at the surface (depth 0 m) was significantly greater than those settling at any other depth except 2 m. All collections taken above 6 m were significantly greater than those settling below 6 m, where the thermocline was positioned (Table 3). The mean values of the transformed data are illustrated in Figure 1 for each depth. The general pattern is seen quite clearly. These results are mirrored in the depth settlement distribution of *M. trossulus*, however, the significance of the pattern is not as strong (Table 4, Fig. 2). In this species the surface samples (0 m) had significantly more spat than any other depth, whereas the shallower depths generally had significantly more spat than those below the 6 m thermocline.

Analyses of Spat Settlement, No Thermocline

The transformed data produced a distribution that was not significantly different from normal (Shapiro-Wilk *W* test, P = 0.873). The variances were homogeneous within depth and species according to Levene's test (P = 0.06 and 0.098, respectively). Normal *Q–Q* plots of the residuals indicated that the residuals were normally distributed. The results of this analysis are summarized in Table 5. Once again, there is a significant effect of depth, but no difference between the species. The interaction term is also significant and appears to be influenced by the differences in the means of each species below 6 m (see Figs. 3 and 4).

Post-hoc analyses were performed on the data. *M. edulis* had large percentages of spat setting at the surface and also on the deepest collectors (8 m). This suggests that the thermocline was a barrier to settlement (Table 6, Fig. 3), because there was low settlement below 6 m when the thermocline was present, but high numbers when the water was mixed. However, the only significantly different pair of depths was between 0 and 6 m (Table 6), with a greater percentage of spat at the surface. In contrast, *M. trossulus* did not show an increase in settlement with depth when the thermocline was removed. The only significantly different pairs of depths were between 0 and 8 m (Table 7, Fig. 4). This difference between the species at the 8-m depth accounts for the significant interaction term in the ANOVA (Table 5).

CONCLUSIONS

Larval depth distributions of *M. edulis* and *M. trossulus* have been examined with a similar experimental design to that used in our study (MacQuarrie 1995; Freeman & MacQuarrie 1999). Halfway through the larval stage, vertical distributions over time in larvae of both species were similar to each other, with major concentrations found just above the 6 m thermocline, with slightly lesser amounts at the surface, and lower numbers elsewhere. This

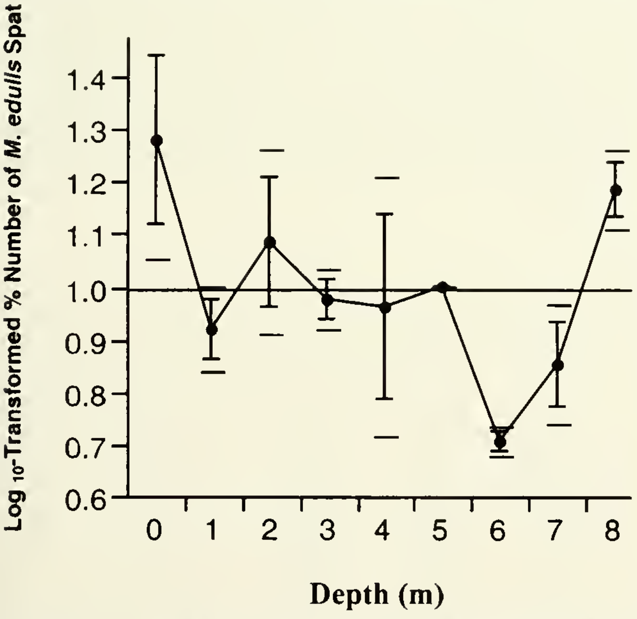

Figure 3. Log_{10}-transformed percent number of *M. edulis* spat. Mean, standard error, and standard deviation are plotted. The sample mean across all samples is illustrated (solid line). No thermocline was present in this experiment.

clustering of larvae at the thermocline was not surprising, because the behavior has been noted in field studies of lamellibranch larvae (e.g., Southward & Barrett 1983; Scrope-Howe & Jones 1986). In addition, *M. trossulus* larvae lack a diel migration (MacQuarrie 1995), although Freeman and MacQuarrie (1999) report a modest (1.6 m) mean diel migration in 11-day-old *M. edulis* larvae with a thermocline present. However, these diel migrations are unlikely to be statistically significant and are in contrast to observations made on scallop larvae (Manuel et al. 1996).

Although thermocline accumulations of larvae decreased as the veligers matured, the settlement patterns, as reported here (Figs. 1–4), are incongruous, because it was expected that a reflection of the earlier attraction to the thermocline would be clearly evident in the distribution of spat which were harvested immediately upon settling. *M. edulis* and *M. trossulus* showed similar patterns of spat distribution with depth in the presence of a thermocline. Spat of both species settled below the thermocline, but at lower numbers than above and the highest numbers were recorded at the surface. In mixed water, *M. edulis* showed a strong preference for settlement at depth (8 m), a feature not seen in *M. trossulus*, although both had high numbers settling at the surface. Reasons for these different patterns are currently speculative, but a recognized weakness in the experiment was that we did not obtain genetic data to support the status of broodstock used. This leaves open to question whether these laboratory observations might have been affected by species contamination. Nevertheless, in subsequent field experimentation (see Kenchington et al. in this issue), DNA markers on field-collected mussels support the observation of behavioral differences by species seen in the mesocosm work.

The industry custom of deploying spat collectors at or near the surface suggests that yields are better there, as was observed in this study. The high degree of similarity in the distribution of the spat of both species augurs little hope for growers wishing to preferentially select *M. edulis* over *M. trossulus* at mixed species sites. However, the significant species × depth interaction in the mixed water offers some basis for further hypothesis testing. Furthermore, the complexity of natural conditions may provoke disparities between the species that are not seen under the controlled conditions of the tower tank.

ACKNOWLEDGMENTS

The authors are grateful for technical assistance provided by Mr. Ron Duggan and Ms. Natalie Randall, and for the broodstock animals supplied by Mr. Dale Cook, Corkums Island Mussel Farm, Lunenburg, Nova Scotia. Prof. Ron O'Dor, Dalhousie University, provided funding and support for this project through the Interim Funding Research Program, an Atlantic Canada Opportunities Agency-funded program in collaboration with Dr. E. Kenchington. The authors thank Mr. Dale Roddick for his critical review of the manuscript.

COMPARATIVE SETTLEMENT DEPTHS OF *MYTILUS EDULIS* C. LINNAEUS, 1758 AND *M. TROSSULUS* GOULD, 1850: II. FIELD OBSERVATIONS

E. KENCHINGTON, K. R. FREEMAN, B. VERCAEMER, AND B. MACDONALD

ABSTRACT Controlled mesocosm experiments using larvae of *Mytilus edulis* and *M. trossulus* have shown that the two species have different settlement patterns with respect to depth, and that the presence of a thermocline can modify the depth distribution. A field program was conducted over 3 y at one site, and at two sites during the final year to determine the settlement patterns of these species in the wild. In all analyses, there was a greater percentage of *M. edulis* postlarvae settling at 5 m than of *M. trossulus*. In addition to opening up certain ecological questions, these results show promise for direct application to husbandry practices at mussel farms having both species, where preferential collection of the *M. edulis* is desirable.

KEY WORDS: *Mytilus edulis, M. trossulus,* settlement, depth, annual variability, spatial variation

INTRODUCTION

The relative depth at which *Mytilus edulis* C. Linnaeus, 1758 and *M. trossulus* Gould, 1850 settle is of direct concern to aquaculturists in Atlantic Canada, and elsewhere, most of whom depend upon the collection of spat from the wild. Although similar in morphology, the lower yield and propensity for shell breakage observed in *M. trossulus* can cause significant production losses on mixed species farms (Mallet & Carver 1995).

The possibility of using ecological information to preferentially collect *M. edulis* postlarvae over *M. trossulus* has been explored (e.g., Freeman et al. 1994). Freeman et al. (2002) have shown that in experiments conducted an indoor tank at Dalhousie University (Halifax, Nova Scotia, Canada), the two species have different depth preferences for settlement. Both species had high percentages of postlarvae settling at the surface, however, in the absence of a thermocline, *M. edulis* showed a strong preference for settling at 8 m depth, which was not seen in *M. trossulus*. Should these results be confirmed in the field, they offer a practical solution to growers who have traditionally deployed surface collectors.

In designing our experiment, we were particularly concerned with identifying patterns that were stable in time and space in order to generate advice to the mussel industry. Although our field experiments were limited in many ways, we were able to examine postlarval settlement patterns in *M. edulis* and *M. trossulus* with depth through the spawning season, across 3 y at one site, and between sites in 1 y.

MATERIALS AND METHODS

Study Sites

Two study sites were chosen to examine temporal and spatial variability in the depth preferences of the mussel spat. One site was located in St. Margarets Bay and the other in Ship Harbour, Nova Scotia (Fig. 1). Both sites were associated with mussel farms that collect, as part of their operation, wild spat for culture, and were known to have both *M. edulis* and *M. trossulus*. Although both sites were located in coastal inlets, the oceanography of the two sites is quite different.

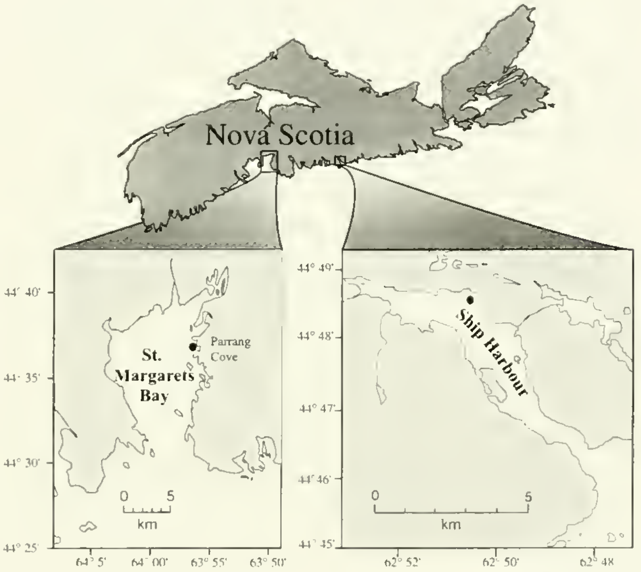

Figure 1. Location of sampling sites at Parrang Cove in St. Margarets Bay and at Ship Harbour, Nova Scotia.

Parrang Cove, St. Margarets Bay

St. Margarets Bay is situated approximately 40 km west of Halifax, Nova Scotia. Our study site was located near the head of the bay at Parrang Cove (44°37′N, 65°56′W) on the eastern shoreline (Fig. 1). St. Margarets Bay is one of the larger bays along the Nova Scotian Atlantic coast and has an axis length of 23.7 km, a surface area of 138.0 km^2, a total volume of 5191 × 10^6 m^3, and an opening of the sea that is ~5 km wide. The bay is subjected to freshwater input from a watershed of 819.1 km^2 (Gregory et al. 1993). In addition to direct runoff, freshwater inputs come from five rivers and the tidal/freshwater volume ratio is 416.32 (Gregory et al. 1993). There is a large, deepwater basin of 80 m maximum depth, and there is a sill at a depth of 35 m (Platt et al. 1972).

As with all coastal inlets in Nova Scotia, the water in winter is well mixed. A thermocline establishes in late spring or early summer between 4 m and 10 m, but in summer the warm surface layer may extend to 30–36 m, depending on direction and strength of winds (Platt et al. 1972). The thermocline can be destroyed through sustained SE or NW winds and can also be pushed offshore by the summer southwesterlies resulting in a cold upwelled nearshore area.

Ship Harbour

Located 90 km east of Halifax, the much smaller Ship Harbour has an axis length of 8.3 km, a surface area of 6.6 km^2, a total volume of 47×10^6 m^3, and an opening to the sea at the mouth of 0.6 km. It is subjected to freshwater input from a watershed of 444.7 km^2 (Gregory et al. 1993), including two rivers and two brooks. The tidal/freshwater volume ratio is 23.87 (Gregory et al. 1993). There is a small, deepwater basin of 27 m and an extensive sill at 7 m.

As with other inlets along the coast, in Ship Harbour the water column turns over in the fall, with a thermocline reestablishing according to wind direction and velocity, the next spring. Thermoclines are strongest in the summer months, establishing around 5 m (Strain 2002). Within Ship Harbour, the study site was located near the head of the harbour at 44°48.65′N, 62°50.53′W, along the northeastern shoreline (Fig. 1).

Sampling Design

Mussel growers at each site reported settlement beginning in mid- to late July and continuing through August and into September. Settlement very late in the year occasionally occurs (December), and may be attributed to either a second fall spawning or to a protracted spawning period. In the first year of sampling (1998), replicate collector ropes were deployed at Parrang Cove on July 24. These were removed on July 31 and replaced with a new pair of collectors. Spat collection continued through the spawning season (Table 1). The schedule for the deployment and retrieval of collectors is given in Table 1. Sampling continued at Parrang Cove at a reduced frequency in 1999 and 2000, according to the schedule in Table 2. In 2000, replicate collectors were also placed at Ship Harbour in order to examine geographic variation in the observed setting pattern. These were deployed and retrieved on the same dates as the Parrang Cove collectors (Table 2).

During 1998, a small experiment was run to determine whether the active postlarval mussels would move along the collector rope after settlement. Two collectors were left in the water from July 24 until October 16 (85 days) at Parrang Cove, in order to compare the depth distribution of older mussels with that of newly settled spat.

Spat Collection

Spat were collected using 5-m lengths of 13-mm-diameter yellow polypropylene rope, weighted at the lower end and suspended at each site from buoyed, surface headropes. Prior to deployment, all collectors were soaked for 2 wk in running seawater to remove any chemicals that might inhibit settlement.

As collectors were retrieved, they were cut into 1-m lengths and placed in polyethylene bags and sealed. Care was taken to avoid cross-contamination of the sample segments. In the laboratory, spat were preserved by adding 85% ethanol to each bag. Subsequently, each 1-m rope portion was removed and the attached spat were separated from the rope by a gentle brushing, and then placed in vials with 80% ethanol. Although mussels from all five 1-m lengths were saved, only those from 0–1, 2–3, and 4–5 m were analyzed (hereafter referred to as 1, 3, and 5 m), with one exception. All five 1-m rope segments were analyzed from the two collectors which were deployed at Parrang Cove on July 24, 1998, and left in the water until the fall. The number of spat at 1, 3, and 5 m were recorded for two time periods at each of two sites in 2000.

Species Determination

Approximately 30 individual spat from each sample depth replicate/time/site were subsequently decanted and examined under the microscope to ensure that the shell contained tissue. In some cases, there were too few animals to meet the sample size objective, in which case all available animals were sampled. For the two collectors left in the water for 85 days, only animals greater than 9 mm were analyzed in order to ensure sampling of animals from the earliest settlement period.

Individuals were then separately picked, crushed, and rinsed with high TE (1 M Tris 0.5 M ethylenediaminetetraacetic acid [EDTA], pH 8) and ddH$_2$O three subsequent times (Heath et al. 1995). Tissue was resuspended directly in a 20.4-μL extraction solution (19 μL H$_2$O, 1 μL 10 × SFG buffer, 0.4 μL proteinase K) and digested overnight at 37°C. The reaction was stopped by boiling samples for 10 min before performing polymerase chain reaction (PCR) amplification. The internal transcribed spacer (ITS) region of the nuclear DNA was used as a species-specific marker (Heath et al. 1995). ITS primers were purchased from Operon Technologies, Inc. Twenty-two microliters of reaction mixture containing 1 × PCR buffer, 2 mM MgCl$_2$, 0.5 μM of each primer, 0.2 mM dNTP, and 1.0 U Taq polymerase were added to 2 μL of DNA solution. The thermal cycling protocol was used as described in Heath et al. (1995). PCR-amplified ITS fragments (approximately 1250 bp) were verified by running 8 μL of the amplification product on 1% agarose gels. Successfully amplified ITS fragments were digested with the endonuclease *HhaI* (MBI Fermentas). Ten microliters of digestion mixture containing 10× enzyme buffer and 5.0 U of *HhaI* was added to 15 μl of amplification product. The *Mytilus* species-specific restriction fragment length polymorphisms (RFLPs) were then visualized on 2% agarose gels and samples were identified as *M. edulis*, *M. trossulus*, or hybrid.

Statistical Analyses

The percentage of *M. edulis* spat was determined for each of the rope segments. Hybrids were rare and were not included in the percentage calculations. Arcsin-transformed data were tested for normality with the Kolmogorov-Smirnov (K-S) test. Levene's test was used to test the homogeneity of the error variance. Normal *Q–Q* plots of the residuals were visually inspected for deviations. Transformed data were subject to analysis of variance (ANOVA).

A full factorial ANOVA was calculated from the 1998 data series collected at Parrang Cove (Table 1) with two factors, Time (six consecutive sampling periods) and Depth (1, 3, and 5 m), using a type III sums of squares. For the two collectors which were left in the water from July 24 through to October 16, a one-way ANOVA with Depth as a factor (1, 2, 3, 4, and 5 m) was performed. The results of these analyses inspired the subsequent field program to determine the temporal and spatial stability of our observations.

To determine whether there were annual variations in the species-specific settlement patterns of *Mytilus*, a three-factor, full-factorial ANOVA was calculated using type III sums of squares. Specifically, the data collected from Parrang Cove (Table 2) were analyzed to examine whether the percentage of *M. edulis* spat varied in response to Year of collection (1998, 1999, 2000), Time of collection during the spawning season (three periods of collection) and/or depth (1, 3, and 5 m). Including the 1998 data created a lack of independence between this analysis and the previous ANOVA; however, excluding the 1998 results did not change the significance of the terms and so the full analysis is presented here for its greater interpretive value.

A similar three-way ANOVA was calculated to examine whether the percentage of *M. edulis* spat varied in response to the Site of collection (i.e., Parrang Cove or Ship Harbour), Time during the season, and Depth (Table 2). Data for this analysis were collected in only 1 y, 2000.

All interaction terms and main effects were tested, however, the three-way interaction term in the last two analyses was nonsignificant and so this term was removed from the equation and the analyses were rerun, testing only main and two-way effects. Tukey-Kramer honestly significant difference (HSD) pairwise multiple comparison tests between each pair of means were performed in post-hoc analyses of all ANOVA results with a significance level of 0.05.

RESULTS

The 1998 data from Parrang Cove were analyzed prior to the 1999 field season in order to determine the design of subsequent fieldwork. The 1998 field season was designed to test the hypothesis, with higher power, that there was no significant difference in the percentage of *M. edulis* spat settling at different depths.

The arcsin-transformed percentage of *M. edulis* spat data distribution was not significantly different from a normal distribution (K-S $Z = 0.628$; $P = 0.825$). The variances were homogeneous and the residual plots supported a random distribution of the error term. The two-way ANOVA model explained 71% of the variance in the data set (adjusted $R^2 = 0.711$; $F = 5.92$; $P = 0.00$). There was no significant interaction between Depth and Time, however, the factors Depth and Time of collection were both highly significant (Table 3).

Post-hoc analyses of the data using Tukey's HSD multiple comparisons test revealed highly significant differences between the transformed percentage of *M. edulis* spat settling at 1 m depth and the percentage settling at 3 and 5 m ($P = 0.004$ and 0.000, respectively). There was no significant difference between the percentage of *M. edulis* spat settling at 3 and 5 m ($P = 0.102$). Examination of the mean values for each depth shows that there are significantly fewer *M. edulis* at 1 m, or conversely, that there are more *M. trossulus*. The nonsignificant interaction term indicates that this pattern did not change during the course of the setting season.

The percentage of *M. edulis* spat settling also showed a significant difference with Time (Table 3). The post-hoc analyses (Table 4) did not have any clear pattern in these differences other than period 4 (deployed September 4th and retrieved on the 18th) which had a significantly lower percentage of *M. edulis* across all depths than most other sampling periods (except period 2). Although no pattern of species-specific spat settlement was known to exist during the setting season, a significant Time factor causing higher percentages of one species over the other through the season can be explained by events such as differential spawning time, larval periods, and/or current changes.

Did mussel spat change their position along the ropes when allowed to stay in the water for longer periods? As in the above analysis, depth was a significant factor in the one-way ANOVA ($F = 11.95$; $P = 0.009$; power 0.93). Post-hoc analyses using Tukey's HSD test indicated that there was no significant difference ($\alpha = 0.05$) between the percentage of *M. edulis* at 1, 2, 3, or 4 m, but that significantly more *M. edulis* were found at 5 m than at these depths ($P = 0.032$, 0.008, 0.14, and 0.47, respectively). These animals were all over 9 mm in length, indicating that they had settled on the collectors early in the season. Therefore, the preference of *M. edulis* to settle at 5 m depth as observed in the newly settled spat, persists through 85 days to at least 9 mm shell length.

Annual Variation in Setting Pattern

The results from the 1998 program indicated that in the field, *M. edulis* prefers to settle at 3 and 5 m depth, while *M. trossulus* is dominant near the surface to 1 m. However, we felt that such results could not be generalized until the annual stability of the

TABLE 3.

pattern could be determined. Annual differences in the percentage of *M. edulis* spat setting at depth during three time periods in each of 3 y were examined.

The three-factor ANOVA model explained 70% of the variance in the data set (adjusted R^2 = 0.702; F = 7.66; P = 0.00) and identified a significant interaction between Year of collection and Time of collection during the spawning season (Table 5). When the adjusted mean values of the transformed data are plotted (Fig. 2), it can be seen that this interaction effect is due to a much higher percentage of *M. edulis* sampled in 1998 during the first collection period (July 14–August 15) than in a similar time period in 1999 and 2000. The second time period (sampled between August 7 and September 12) showed relatively high percentages of *M. edulis* each year, whereas in the third time period (September 4–October 10) the percentage of *M. edulis* was very low in 1998 but remained high in 1999 and 2000. These results indicate that the percentage of *M. edulis* vs. *M. trossulus* spat varies through the season and is not predicted from year to year.

Depth was the only significant main effect in this analysis (Table 5), but was never significant in an interaction. Figure 3 shows the strong change in the median value of the transformed data with depth. Post-hoc analysis using Tukey's HSD identified significant differences between all pairs of means of each depth, with the greatest percentage of *M. edulis* spat settling at the 5 m depth and the least at 1 m.

TABLE 5.

Three-way ANOVA of the arcsin-transformed percentage of *M. edulis* spat settling at Parrang Cove, Nova Scotia, by year (1998, 1999, 2000), time (three periods during set), and depth (1, 3, 5 m) with two-way interactions.

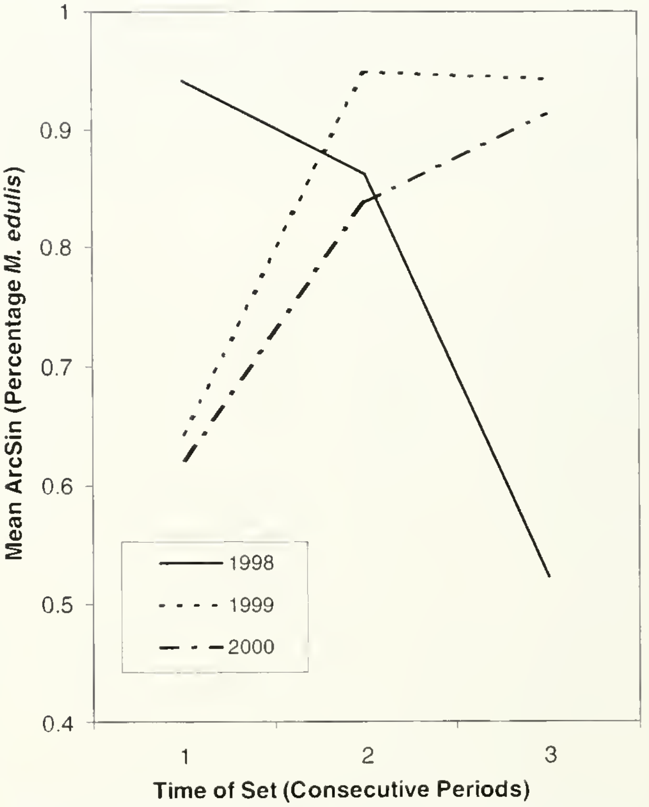

Figure 2. The interaction between year (1998, 1999, and 2000) with sampling period in the transformed adjusted mean percentage of *M. edulis* spat collected at Parrang Cove, St. Margarets Bay, Nova Scotia.

Geographic Differences

The above-described analyses confirmed that the observations first documented at Parrang Cove in 1998 were repeated in 1999 and 2000, with a greater percentage of *M. edulis* occurring at depth (5 m) and a greater percentage of *M. trossulus* occurring at the surface (1 m). The final analysis was designed to determine whether this pattern was particular to Parrang Cove, or whether it also occurred at other locations.

The three-factor ANOVA model explained 66% of the variance in the data set (adjusted R^2 = 0.660; F = 6.23; P = 0.00) and identified a significant interaction between the Site of collection and Time of collection during the season (Table 6). In all cases, there is a greater percentage of *M. edulis* spat at Parrang Cove than at Ship Harbour. However, in the first sampling period and in the last (third) sampling period, the relative difference between the sites is the same, whereas in the second period there are fewer *M. edulis* postlarvae (and therefore more *M. trossulus*) at Ship Harbour relative to Parrang Cove (Fig. 4).

Unlike the previous ANOVA, all three main effects were significant. The boxplots of the median values by depth and site are illustrated in Figure 5. As in the previous analysis, there is sig-

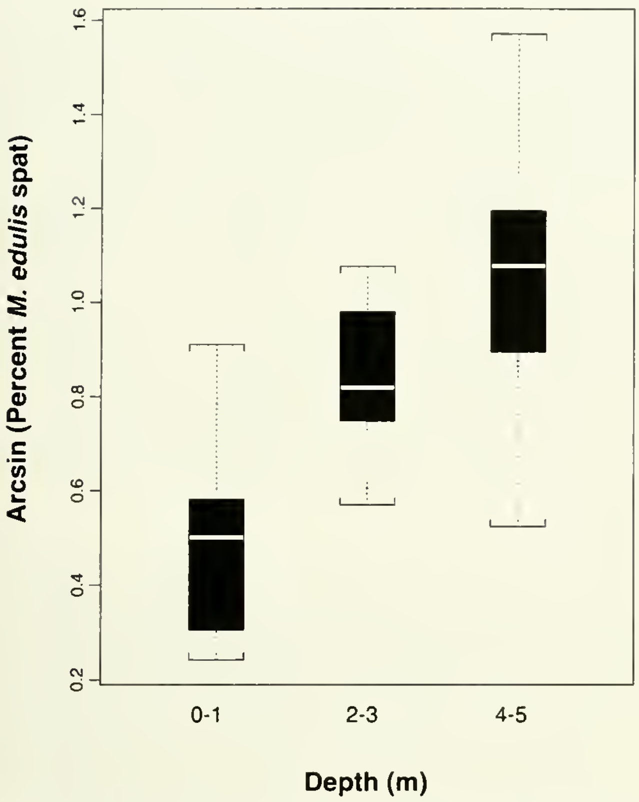

Figure 3. Boxplots (median bar, upper and lower quartiles, and outer fences marking extent of data beyond the quartiles) of the arcsin-transformed percentage of *M. edulis* spat settling at Parrang Cove, St. Margarets Bay, Nova Scotia, at three depth intervals.

nificantly more *M. edulis* spat settling at 5 m depth than at the surface meter (Fig. 5). The third time period had the largest percentage of *M. edulis* spat across all sites and depths. Therefore, as in the previous analysis, depth is an important factor in determining the percentage of *M. edulis* spat, regardless of site or time period, or year of collection.

The total numbers of postlarvae at the 1, 3 and 5 m depth intervals from a single collector rope from each site on two dates are provided in Table 7 in order to place the percentage data in perspective. As expected the total number of mussels collected was highly variable and ranged from 134 to over 10,000 per metre. The experimental design was not adequate to statistically analyze these data and so additional counts were not completed. However, it can be seen that large numbers of postlarvae did settle below the surface and that the total numbers of *M. edulis* collected at depth was consistently higher than the number setting at the surface (Table 7). *M. trossulus* was more variable being present in the highest numbers at the surface in two collections, at 5 m in one and

The absolute number of mussel postlarvae per 1 m rope at 1, 3 and 5 m depths collected at Parrange Cove and Sheet Harbour, Nova Scotia at two sampling dates in 2000. The percentage of mussels identified as *M. edulis* using DNA markers is indicated, as well as the estimated numbers of *M. edulis* ($N_{M\ edulis}$) and *M. trossulus* ($N_{M\ trossulus}$) postlarvae.

Date	Location	Depth (m)	N	% *M. edulis*	$N_{(M.\ edulis)}$	$N_{(M.\ trossulus)}$
Aug. 15, 2000	Parrang Cove	1	476	31.3	149	327
		3	184	61.9	114	70
		5	367	60.7	223	144

homogenously distributed through the depth range in the fourth sample (Table 7).

Hybrids

Of the 2485 animals scored using the DNA technique, 8.4% (208) were hybrids. The hybrids were not present in sufficiently high numbers to permit a robust analysis of their distribution. However, hybrids were relatively abundant in the October 2 replicates sampled at Parrang Cove in 1998 (Table 1), with the percentages ranging from 5% to 58%. In these two samples, the greatest percentage of hybrids was at the surface.

DISCUSSION

The mixing of seawater due to tides, winds, currents, and upwelling, and the seasonal establishment of thermoclines, characterize inshore marine waters around Eastern Canada and in similar temperate waters elsewhere in the world where *Mytilus* is found. The larval period is therefore one of great uncertainty, where the dynamic environment must be contended with while simultaneously searching for food and avoiding predators. Under these conditions, it is remarkable that we were able to observe a consistently and significantly higher percentage of *M. edulis* postlarvae at 5 m depth. This depth preference observed in the newly settled spat persists through 85 days to at least 9 mm shell length, despite the fact that postlarval mussels are very active and have an ability to repeatedly attach themselves to various substrata prior to choosing a final settlement location (e.g., Bayne 1964; Dare & Davies 1975). Further, the total number of *M. edulis* collected at depth was greater than at the surface, to the extent that this was examined.

Pineda (2000) identified three processes affecting larval settlement in invertebrates: (1) processes influencing the larval pool; (2) physical transport; and (3) microhydrodynamics, substrate availability, and behavior. Larger-scale processes governing physical transport, and coupled to the onset and duration of spawning, likely explain the variation in the relative percentage of each species through the spawning season, across years, and between sites, observed here and elsewhere (e.g., Seed & Suchanek 1992). However, the significant difference in postlarval depth distribution between the species is consistent with a behavioral differences.

Freeman et al. (2002) observed the settlement of *M. edulis* and *M. trossulus* separately in the laboratory, under mixed water conditions and with a thermocline. In all cases the greatest percentage of postlarvae settled at the surface, however, under mixed water conditions the postlarvae of *M. edulis* also had a large settlement at 8 m, a pattern not seen in *M. trossulus*. These data support an innate behavior as opposed to a response created through interspecific competition (e.g., Petersen 1984). Furthermore, the limited data that we obtained on hybrids identified a settlement pattern similar to *M. trossulus*. We were unable to determine which species dammed these hybrids, however, the possibility of maternal inheritance of setting depth is intriguing.

Mussel larvae are known to show behavioral responses to light, gravity, pressure, and substratum (e.g., Bayne 1976; Seed & Suchanek 1992; Young 1995). To cite only a few examples: competent larvae of *M. edulis* migrate to deeper water in the North Sea (Bayne 1976) and prefer to settle subtidally below 3 m in the Wadden Sea (Pulfrich & Ruth 1993), although Dobretsov and Miron (2001) observed the opposite in the White Sea, with pediveligers migrating toward the surface to set primarily at 1.5 m. *M. galloprovincialis* Lamark, 1819 is more homogeneously distributed with depth than *M. edulis* and *M. trossulus* (as observed in this study). However *M. galloprovincialis* shows greater settlement at 5 and 10 m depth in northwest Spain (Caceres-Martinez & Figueras 1998), reflecting the pattern seen in *M. edulis*. In addition, variation in settlement depth preference of mytilid species can be influenced by the presence of phytoplankton and predators. With the literature confounded by difficulties with species identification (cf. Johannesson et al. 1990), it is premature to determine whether the observations reported here are representative of the two species.

Miron et al. (1999) have suggested that competent barnacle larvae position themselves at a depth in the water column corresponding to the position where they might settle on shore. If this were true for mussels, then photonegative and geopositive behavior would ensure a greater depth with less exposure when setting on a fixed substrate (e.g., shore, pilings). Conversely, the photopositive and geonegative behavior hypothesized for *M. trossulus* would ensure a distribution above mean low water spring tide (MLWS), with greater exposure to desiccation, freshwater, and temperature fluctuations associated with life in the upper intertidal environment. This tolerance is consistent with the more euryhaline nature of *M. trossulus*.

For aquaculturists, positioning mussel collectors on the bottom or at 5 m depth would ensure the preferential collection of *M. edulis* over *M. trossulus*, at least in Nova Scotian waters. This is in contrast to the current practice of deploying plastic mesh on headropes near the surface for several days before the anticipated onset of settlement, a practice which may favor the collection of *M. trossulus* and increase the relative proportion of this species on the lease sites over time. The absolute numbers of spat were not recorded for all collectors and density is expected to be much more variable because of large-scale processes and microhydrodynamic conditions. However, in the collectors examined, placing the collectors below the surface rarely resulted in reduced settlement, although the total number of post larvae was highly variable with respect to depth of collection. Nevertheless, we encourage mussel growers to experiment with subsurface and bottom deployment of collectors at sites where both *M. edulis* and *M. trossulus* occur.

ACKNOWLEDGMENTS

We thank Yonghong Shi, Melissa Cox, Angela Glass, Amy Chisholm, Shawn Roach, Amanda Ginnish, and Liqin Cao for their assistance in the laboratory; Amy Thompson for her help in the field. We thank Dr. Gareth Harding (Bedford Institute of Oceanography, Dartmouth, N.S.) for reviewing this manuscript. This work could not have been done without the co-operation and assistance of the mussel growers, Mr. Joe Levy (Parrang Cove), and Mr. John Stairs (Ship Harbour). This project was supported by the Department of Fisheries and Oceans, Canada, the Human Resources Canada Science and Technology Youth Internship program, and an NSERC research grant to EK.

ROUTES OF INTRODUCTION OF THE MEDITERRANEAN MUSSEL (*MYTILUS GALLOPROVINCIALIS*) TO PUGET SOUND AND HOOD CANAL

ANTHONY S. ANDERSON, A. LELANIA BILODEAU,* MATTHEW R. GILG, AND THOMAS J. HILBISH**

Department of Biological Sciences, University of South Carolina, Columbia, South Carolina 29208

ABSTRACT To test alternative routes of introduction we describe the distribution of *Mytilus galloprovincialis*, *M. trossulus*, and their hybrids in Puget Sound and Hood Canal. Native mussels, *Mytilus trossulus*, dominate the blue mussel communities of Puget Sound and Hood Canal; at most sites *M. galloprovincialis* alleles were rare or absent. *M. galloprovincialis* alleles were present but uncommon (~5%) in mussel populations in the southern portion of Puget Sound, and were nearly absent in populations in the northern Puget Sound and the Hood Canal. The only locations where *M. galloprovincialis* alleles are locally common are sites where they are likely to have been repeatedly introduced. These include sites near mussel farming operations and near the Port of Seattle and Bremerton Naval Shipyards. The results indicate that both aquaculture and shipping activities have been responsible for the repeated introduction of *M. galloprovincialis* to Puget Sound. Although hybridization between *M. galloprovincialis* and *M. trossulus* occurs, there was little evidence for advanced introgression between these two species.

KEY WORDS: introductions, mussels, *Mytilus galloprovincialis*

INTRODUCTION

The invasion of nonindigenous species has become of ecological and economic concern in the last few decades (Schmitz & Simberloff 1997). The effects of species introduction range from localized and limited to those that severely degrade native ecosystems and have immense economic consequences (Geller et al. 1994; Ruiz et al. 1997; Ruiz et al. 2000). The unpredictable ecological consequence of introducing nonnative species makes such introductions generally undesirable.

Global commerce is responsible for the majority of both intentional and unintentional species introductions. In marine systems a major route of species introduction has been through the transport and discharge of ballast water from ships (Geller et al. 1994; Ruiz et al. 1997; Ruiz et al. 2000). For example, Carlton and Geller (1993) found that the ballast water from 159 cargo ships in Coos Bay, Oregon, contained a minimum of 367 marine species. A second, potentially major, source of species introductions is aquaculture endeavors, particularly farms and fisheries. The decline of traditional fisheries has lead to a rapid increase in aquaculture as a source of aquatic products (Johnson 1998); presently 20% of the world's seafood comes from aquaculture. The commercial culture of aquatic organisms has led to the intentional and accidental introduction of nonnative species in many parts of the world (Bartley & Subasinghe 1996).

One marine species that has been both intentionally and accidentally introduced by these activities is the mussel *Mytilus galloprovincialis*. This mussel has been unintentionally introduced to South Africa (Grant & Cherry 1985), the Sea of Japan (Wilkins et al. 1983), and California (McDonald & Koehn 1988). Larvae of *M. galloprovincialis* are commonly found in ballast water of transport ships (Geller et al. 1994), making unintentional introductions likely. *M. galloprovincialis* is also the subject of large aquaculture farms in Europe and has been intentionally introduced to Puget Sound and the Georgia Straits as part of culture efforts in the northeastern Pacific (Heath et al. 1995).

Mytilus galloprovincialis is a member of a complex containing two other species of blue mussel, *M. edulis* and *M. trossulus*. *M. galloprovincialis* is native to the Mediterranean and the Atlantic coast of southern Europe. *M. edulis* is native to temperate Atlantic waters of Europe and North America, and *M. trossulus* is native to cold-temperate waters of the northern Pacific and Atlantic (Gosling 1992). *M. galloprovincialis* is the most warm-adapted of the three species (Hilbish et al. 1994), which perhaps contributes to its propensity for introduction. All members of the blue mussel species complex will hybridize in nature. In particular, extensive hybridization between *M. galloprovincialis* and *M. trossulus* occurs in California (Rawson et al. 1999) and between *M. galloprovincialis* and *M. edulis* in Europe (Skibinski et al. 1983). The capacity to interbreed with congeneric species expands the possible consequences of introducing non-native species; they may genetically contaminate native species as well as ecologically displace them. The fate of hybrids, however, is uncertain. In Europe hybridization between *M. galloprovincialis* and *M. edulis* is extensive resulting in high levels of introgression between the species (Quesada et al. 1998; Rawson & Hilbish 1998). In contrast, hybridization between *M. galloprovincialis* and *M. trossulus* is prevalent, but results in very limited introgression (Rawson et al. 1999).

This study describes the distribution of *Mytilus galloprovincialis*, *M. trossulus*, and their hybrids in Puget Sound. *M. galloprovincialis* has been intentionally introduced to Puget Sound through aquaculture efforts, but also may have been repeatedly introduced via shipping activities. If *M. galloprovincialis* is present in Puget Sound as a result of shipping activities, we expect high concentrations of *M. galloprovincialis* alleles to be present around major shipping ports, particularly in the vicinity of Seattle. Alternatively, if aquaculture activities are responsible for the presence of *M. galloprovincialis*, we expect to find alleles indicative of this species in the vicinity of culture operations. In this study we also have used molecular markers that distinguish *M. galloprovincialis* and *M. trossulus* to determine whether genetic contamination of native mussels is occurring in Puget Sound and to infer the possible fate of hybrid mussels.

METHODS AND MATERIALS

Mussels were collected in the summer of 1997 and 1998 from 28 locations in Puget Sound and Juan de Fuca Strait and five locations in the Hood Canal (Fig. 1).

Shell length of each mussel was measured from the anterior to posterior margin to the nearest 0.1 mm. We attempted to analyze both small and large mussels from each location, but this was not always possible because the size structure of the mussels varied widely among sites. We analyzed between 16 and 64 mussels from each location. Each mussel was dissected and a section from the margin of the mantle was removed and preserved in 95% ethanol. Total cellular DNA was extracted from each tissue sample as described by Rawson et al. (1999). The Glu-5′ gene was amplified using the polymerase chain reaction (PCR) as described by Rawson et al. (1996) using the primers of Inoue et al. (1995). PCR amplification of the Glu-5′ marker produces species-specific products which differ in size for *Mytilus edulis*, *M. trossulus*, and *M. galloprovinicialis* (Rawson et al. 1999). A second locus, internal transcribed spacer (ITS), was amplified using the procedures described by Rawson et al. (1999), cut with the restriction enzyme *Sau96*, and run on a 1.5% agarose gel. This produces a species-specific restriction pattern that distinguishes *M. trossulus* from *M. galloprovincialis* (Rawson et al. 1996). Mussels from three locations (Silverdale, Totten Inlet, and Edmonds) were also assayed at a third nuclear locus, Mal-I, according to the protocol given by Rawson et al. (1999).

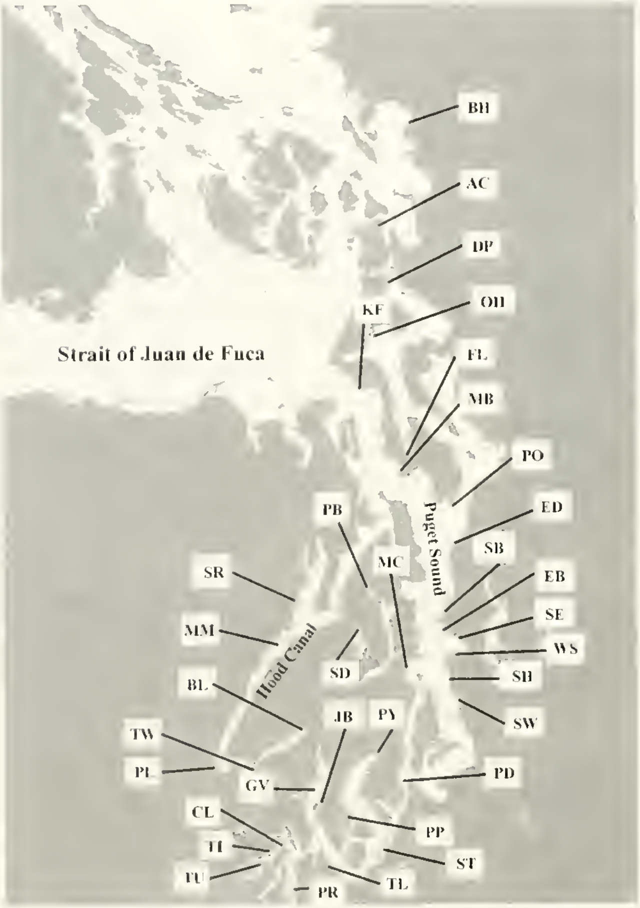

Figure 1. Location of sampling sites in Puget Sound and Strait of Juan de Fuca: Bellingham Bay = BH, Anacortes = AC, Deception Pass Marina= DP, Oak Harbor = OH, Keystone Ferry = KF, Freeland = FL, Mutiny Bay=MB, Possession Point = PO, Edmonds = ED, Poulsbo = PB, Silverdale = SD, Shilshole Bay = SB, Elliot Bay Marina = EB, Seattle Pier 91 = SE, West Seattle = WS, Manchester State Park = MC, Seahurst County Park = SH, Purdy = PY, Saltwater State Park = SW, Point Defiance = PD, Grapeview Marina = GV, Penrose Point State Park = PP, Joemma Beach State Park = JB, Carlyon = CL, Totten Inlet = TI, Taylor United = TU, Steilacoom Marina = ST, Tolmie State Park = TL, and Priest Point = PR. Location of sampling sites in Hood Canal: Seal Rock = SR, Mike's Marina = MM, Potlatch State Park = PL, Twanoh State Park = TW, and Belfair State Park = BL.

RESULTS

The *M. galloprovincialis* allele frequency for the Glu-5′ and ITS genes at each site is presented in Table 1. Alleles specific to *M. galloprovincialis* are not generally very abundant in Puget Sound. Outside of the Totten Inlet (where Taylor United, Inc., cultivates *M. galloprovincialis*) the average frequency of the *M. galloprovincialis* allele was 0.032 for Glu-5′ and 0.019 for ITS (counting only sites for which both genes were scored). The frequency of *M. galloprovincialis* alleles at Glu-5′ and ITS was highly correlated ($r = 0.775$, $P < 0.05$, sites without *M. galloprovincialis* alleles at both loci and the Taylor United site were excluded). In the central and southern Puget Sound, *M. galloprovincialis* alleles are relatively common in three locations. The Totten Inlet contained relatively high frequencies of *M. galloprovincialis* alleles. Mussels farmed by Taylor United in the Totten Inlet contained only *M. galloprovincialis* alleles at both loci. Wild mussels from a floating dock near the middle of the inlet (Totten Inlet) also had relatively high frequencies of *M. galloprovincialis* alleles. Mussels from the Carlyon Marina near the mouth of Totten Inlet, however, had low frequencies on *M. galloprovincialis* alleles, similar to that observed in other mussel populations in the southern Puget Sound (Table 1). Alleles specific to *M. galloprovincialis* were also common at Silverdale and at sites north and south of Seattle (Edmonds, Shilshole Bay, and Seahurst) (Table 1, Fig. 1). Silverdale is near the Bremerton Naval Shipyards, whereas the other three sites are near the Port of Seattle at Elliot Bay. Surprisingly, *M. galloprovincialis* alleles were absent from samples collected within Elliot Bay (Elliot Bay Marina, Seattle Pier 91, and West Seattle) (Table 1). Mussels with *M. galloprovincialis* alleles were absent from samples collected in the Hood Canal and from the northern portion of Puget Sound and Juan de Fuca Strait (Table 1).

To evaluate the extent of introgression between the two species mussels from the three sites with the highest frequency of *Mytilus galloprovincialis* alleles (Silverdale, Totten Inlet, and Edmonds) were assayed at all three genetic markers and pooled into multilocus genotypic classes. Mussels homozygous for *M. trossulus* alleles at all three loci were designated *M. trossulus*. Those homozygous for *M. galloprovincialis* alleles at all three loci were designated *M. galloprovincialis*. Mussels heterozygous for *M. trossulus* and *M. galloprovincialis* alleles at all three loci were designated F1 hybrids. Those homozygous for *M. trossulus* alleles at one locus and *M. galloprovincialis* alleles at another locus were designated F2 hybrids. Of the remaining possible genotypes, those that contained four or five *M. trossulus* alleles were designated as *M. trossulus* back-crosses and those that contained one or two *M. trossulus* alleles were designated *M. galloprovincialis* back-crosses. Sorting individuals into the categories listed above does not necessarily indicate their genealogical origin; genuine F2 and back-cross matings should generate a wide variety of multilocus

TABLE 1.

Allele frequency of Glu-5′ and ITS at each sample site in the Puget Sound and Hood Canal: Sample size (*n*) for each locus and the size range and habitat sampled are also indicated.

genotypes, including individuals that are homozygous for alleles from one species at all three loci and mussels that are heterozygous at all three loci. It is important to note, however, that mussels homozygous for *M. trossulus* alleles at one gene and homozygous for *M. galloprovincialis* alleles at another can only be the product of F2 or other advanced introgressive crosses; they can not be the progeny of either F1 hybridization or first-generation back-crossing.

Of the 55 mussels from Silverdale, Edmonds, and Totten Inlet assayed for all three genetic markers, 51% had genotypes consistent with pure *Mytilus trossulus* and 22% appeared to be pure *M. galloprovincialis* (Table 2). Putative F1 hybrids were rare, comprising only 9% of these samples. Putative back-crosses to *M. trossulus* appear to be about four times more common than back-crosses to *M. galloprovincialis* (15% versus 4%, Table 2). No individual was observed, in either the overall sample (Table 1) or this subsample (Table 2), that had a genotype exclusively compatible with F2 or other advanced hybridization.

Silverdale was the only site with a high frequency of *M. galloprovincialis* alleles where a wide range of size classes was available for analysis (Table 2). Mussels between 5 and 60 mm shell length were similar in genetic composition; the frequency of *M. trossulus* alleles was between 0.73 and 1, depending on locus, and *M. trossulus* genotypes predominated. Mussels >60 mm shell length were dominated by *M. galloprovincialis* genotypes and allele frequencies (0.75–0.77, depending on locus) (Table 2). *M. galloprovincialis* may either grow faster or attain a larger size than *M. trossulus*, be selectively favored, or historical variation in recruitment success may have favored *M. galloprovincialis* sometime in the past, but not more recently. The presence of putative F1 and *M. galloprovincialis* back-cross genotypes among the largest mussels at Silverdale suggests the observed relationship between size and allele frequency is a long-term and recurring feature at this location and not the result of historical variation in recruitment.

DISCUSSION

Native mussels, *Mytilus trossulus*, dominate the blue mussel community in Puget Sound; at most sites *M. galloprovincialis*

TABLE 2.

Multilocus genotypes of mussels from Silverdale, Edmonds, and Totten Inlet: The number of mussels of each genotype is indicated.

	Genotype				
	Trossulus	**Back-tross**	**F1**	**Back-gallo**	**Gallo**
Silverdale, length (mm)					
0–20	3	2	0	0	0
20–40	4	3	0	0	0
40–60	7	2	1	0	1
>60	1	0	3	2	6
Edmonds	8	1	0	0	2
Totten Inlet	5	0	1	0	3

Trossulus = mussels homozygous for *M. trossulus* alleles at Glu-5′, ITS, and Mal-I, Gallo = mussels homozygous for *M. galloprovincialis* alleles at all three loci; and F1 = mussels heterozygous at all three loci. Back-tross and Back-gallo indicate mussels with genotypes consistent with *M. trossulus* back-crosses and *M. galloprovincialis* back-crosses, respectively, as specified in the text. No mussels were observed that were homozygous for *M. trossulus* alleles at one locus and homozygous for *M. galloprovincialis* alleles at another (i.e., F2 genotypes).

alleles were rare or absent. The distribution of *M. galloprovincialis* alleles varies regionally within Puget Sound. *M. galloprovincialis* alleles are present but uncommon (~5%) in mussel populations in the southern portion of Puget Sound, and appear to be nearly absent in populations in the northern Puget Sound and the Hood Canal. The only locations where *M. galloprovincialis* alleles are locally common appear to be sites where they are likely to have been repeatedly introduced. These include the Totten Inlet where Taylor United, Inc., maintains a mussel farm, and sites near the Port of Seattle and Bremerton Naval Shipyards.

Aquaculture operations appear to be the source of the high frequency of *M. galloprovincialis* alleles in mussel populations from the Totten Inlet. Taylor United, Inc., maintains a grow-out facility in the inlet that produces 1–1.5 million pounds (live weight) of *M. galloprovincialis* per year (Gordon King, pers. comm.). The frequency of alleles specific to *M. galloprovincialis* among "wild" mussels within the inlet ranged between 21% and 33%, depending on the locus assayed. However, the impact of the aquaculture operation is highly restricted; mussels sampled at the mouth of the inlet (Carlyon Beach) had a low frequency of *M. galloprovincialis* alleles that was not readily distinguished from the background frequency of these alleles found in other mussel populations in the southern Puget Sound. This result is surprising because the Totten Inlet is about 12 km long and mussel larvae could potentially disperse over much greater distances during their development in the plankton of several weeks. These results suggest that the circulation patterns in Totten Inlet retain larvae within the inlet.

Two additional lines of evidence suggest that the genetic impact of aquaculture operations on the genetics of indigenous mussel populations may be minimal. First, Taylor United has previously cultured *M. galloprovincialis* at Freeland, on Whidby Island in the northern Puget Sound from 1992 to 1998. No *M. galloprovincialis* alleles were found among wild mussels at Freeland or at any other location on Whidby Island in 1997. Second, Taylor United maintains hatchery and nursery operations for the culture of *M. galloprovincialis* in Dabob Bay at the northern end of the Hood Canal. *M. galloprovincialis* alleles were virtually absent from all sites sampled within the Hood Canal. These results indicate that either cultured mussels are unlikely to escape aquaculture operations or, if they do, they have relatively little impact on resident populations of *M. trossulus*. Surveys conducted by Taylor United indicate that in 1996 and 1997, the frequency of *M. galloprovincialis* alleles among mussels on the shore near their mussel farm on Whidby Island was 2.8% and 1.3%, respectively (Gordon King, pers. comm.). Taylor United's mussel farming operations on Whidby Island were discontinued due to high mortality rates among *M. galloprovincialis*. These results all suggest that *M. galloprovincialis* is only marginally successful in northern Puget Sound.

It is worth noting that 100% of the mussels obtained from Taylor United's grow-out operation in the Totten Inlet were homozygotes for *M. galloprovincialis* alleles at both Glu-5′ and ITS. This result indicates that Taylor United has been highly successful at maintaining pure cultures of *M. galloprovincialis* for several generations, despite the presence of resident populations of *M. trossulus* as potential sources of contamination at both the grow-out and the hatchery/nursery locations.

Shipping also appears to be an important vector for the release of *M. galloprovincialis* into Puget Sound. The two greatest concentrations of *M. galloprovincialis* alleles outside of the Totten Inlet are near major shipping areas. The highest frequencies of *M. galloprovincialis* alleles outside of the Totten Inlet were observed at the Edmonds and Shilshole Bay Marinas north of Seattle, Seahurst County Park south of Seattle, and Silverdale, near the Bremerton Naval Base. Shipping appears to be the primary mechanism responsible for the introduction of nonnative marine species throughout the world (Carlton & Geller 1993; Ruiz et al. 1997; Ruiz et al. 2000). Geller et al. (1994) documented that larvae of *M. galloprovincialis* may be transported in ballast water of ships. The occurrence of *M. galloprovincialis* alleles near major shipping terminals in Puget Sound suggests that shipping may be responsible for the repeated introduction of this species to Puget Sound. It is also suggestive that *M. galloprovincialis* alleles are absent from the Hood Canal, which does not have any major shipping activity. Notably, *M. galloprovincialis* alleles were absent from within Elliot Bay near the Port of Seattle (Elliot Bay Marina, Pier 91 and West Seattle), which may indicate that ships release their ballast water before entering Elliot Bay.

Although *M. galloprovincialis* appears to have been repeatedly introduced into Puget Sound by both aquaculture and shipping activities, the fate of these introductions is tenuous. Mussels from the southern Puget Sound with *M. galloprovincialis* alleles appear to mostly be the result of back-crosses with *M. trossulus*. There was little evidence for pure *M. galloprovincialis* mussels outside of Totten Inlet and Dyes Inlet (Silverdale). Even in the three areas with the highest frequency of *M. galloprovincialis* alleles there was no evidence for advanced introgression, as indicated by the presence of genotypes that are exclusively compatible with being the progeny of F2 hybridization. These results indicate that when pure *M. galloprovincialis* are introduced, they occasionally hybridize with *M. trossulus* and then F1 hybrids may subsequently back-cross to *M. trossulus*. Continued hybridization is not apparent within Puget Sound. Rawson et al. (1999) examined hybridization between *M. galloprovincialis* and *M. trossulus* in California. They also found that even though mussel assemblages often contained high frequencies of both species, hybrids were relatively uncommon and there was little evidence for advanced levels of introgression. Although the mechanism is presently unclear, the results of

Rawson et al. (1999) and of this study indicate that the "genetic pollution" of native populations of *M. trossulus* by introduced *M. galloprovincialis* is limited. Further work is necessary to examine the mechanism(s) that determine the genetic fate of *M. galloprovincialis* alleles introduced by hybridization to resident populations of *M. trossulus*. It should also be noted that although introgression between these two species appears to be limited, *M. galloprovincialis* has been successfully introduced in California and in the Sea of Japan, and the ecological impact of these introductions on native mussel populations is presently unclear.

ACKNOWLEDGMENTS

We thank Gordon King and Taylor United, Inc., for providing samples and information on local mussel farming operation. We acknowledge the support of NSF grants DEB-9807055 and OCE-9731277 to T.J.H.

TEMPORAL AND SPATIAL VARIABILITY IN DREDGING INDUCED STRESS IN THE GREAT SCALLOP *PECTEN MAXIMUS* (L.)

JULIE A. MAGUIRE,[1] MAURICE O'DONOGHUE,[2] STUART JENKINS,[3] ANDREW BRAND,[3] AND GAVIN M. BURNELL[1]

[1]*Aquaculture Development Centre, Dept., of Zoology and Animal Ecology, University College Cork, Lee Maltings, Prospect Row, Cork, Ireland;* [2]*Department of Microbiology, University College Cork, Cork, Ireland;* [3]*Port Erin Marine Laboratory, University of Liverpool, Port Erin, Isle of Man, United Kingdom*

ABSTRACT Temporal and spatial variability in the stress caused to the great scallop *Pecten maximus* by dredge capture was determined using the adenylic energetic charge (AEC) of the striated muscle as an index. Samples were taken on a seasonal basis from dredge captured scallops of a single fishing ground in the north Irish Sea. All samples were taken from individuals under the minimum legal landing size. On one date samples were taken from scallops from three separate grounds with contrasting bottom characteristics. At all dates dredge captured scallops had a significantly reduced level of AEC compared to control scallops. This reduction was greatest in February when glycogen levels in the muscle tissue were shown to be at a minimum. There was little or no variability among fishing grounds in the effect of dredge capture on AEC levels. An additional aim of this study was to determine if scallops that encounter dredges but are not captured suffer a reduction in AEC levels. Scallops collected from dredge tracks immediately following the passage of dredges showed a significant reduction in AEC compared to control, scallops collected from outside the tracks. However, the reduction in AEC was not as great as in captured scallops.

KEY WORDS: scallop, *Pecten maximus*, dredging effects, adenylic energetic charge, seasonal effects, glycogen

INTRODUCTION

Most fishing techniques aim to capture a single or limited number of target species over a minimum size. This size may be dictated by markets or by government legislation. In scallop dredging, as in many other fisheries, a proportion of the captured target species is discarded owing to their small size. These undersized discards may be damaged during capture, for example suffering chipped valve margins or separation of the hinges, or may suffer stress from fatigue and desiccation. The level of mortality of these discarded scallops is unknown but may be considerable. Several studies have speculated on the levels of dredging induced mortality in relation to scallop size, sorting time and conditions on deck (Medcof & Bourne 1964), substrate type (Naidu 1988), catch weight (Chapman et al. 1977) and type and performance of gear (Gruffydd 1972).

Damaged scallops that are left on the seabed, or are discarded, are likely to show high mortality owing to the aggregation of predators to dredge tracks (e.g., Caddy 1973; Kaiser 1994; Medcof 1964) and to damaged bycatch (Veale et al. 2000). However, the majority of undersized discarded scallops show no signs of external physical damage. In the Irish Sea Jenkins et al. (2001) showed that less than 10% of scallops (*Pecten maximus*) encountering dredges showed any signs of damage while Shepard and Auster (1991) estimated that damage to the scallop *Placopecten magellanicus*, that encounter dredges but are not captured, can vary between 7% and 25% depending on substrate type. Although discarded scallops may have low levels of damage, they are likely to be highly stressed from the process of capture. Little is known regarding the effects of fishing induced stress on subsequent survival of scallops.

Dredging induced stress can be assessed in scallops using a variety of biochemical indicators. Maguire et al. (in press, a) discussed the usefulness of various techniques for stress assessment in scallops and found Adenylic Energetic Charge (AEC) to be the most effective in the measurement of acute dredging stress. AEC was first proposed as a stress index by Atkinson (1968) and is defined by the ratio:

$$\mathrm{AEC} = (\mathrm{ATP} + 0.5\mathrm{ADP}) \div (\mathrm{ATP} + \mathrm{ADP} + \mathrm{AMP})$$

where: ATP = adenosine tri-phosphate, ADP = adenosine diphosphate and AMP = adenosine mono-phosphate.

The AEC ratio varied from 0 to 1 i.e., 0 (all nucleotides were energy deficient AMP molecules) or 1 (all nucleotides were energy rich ATP molecules). In optimal conditions animals typically displayed AEC levels >0.8 while under stress conditions values ranged from 0.5 to 0.75. Such animals had a reduced growth rate and did not reproduce, but recovered when returned to optimal conditions. Severely stressed animals yielded values of <0.5 and these animals had a negative scope for growth and did not recover (Duncan 1993; Ivanovici 1980). Subsequently many studies have been carried out using AEC as a stress index in scallops, for example *P. magellanicus* (de Zwaan et al. 1980; Livingstone et al. 1981) and *P. maximus* (Fleury et al. 1997; Maguire et al. 1999a; Maguire et al. 1999b). Maguire et al. (in press a) used AEC as a stress index to investigate the effect of dredge capture on undersized scallops. They found no difference in AEC levels between different lengths of tow (15, 30 or 45 minutes) but found that emersion following dredging had an added stress effect. In this study we aimed to investigate different aspects of dredging on scallops i.e., effects of different seasons, ground types and to assess the stress caused to scallops that come in contact with dredges but remain uncaught on the seabed.

We aimed to examine dredging induced stress in the great scallop *Pecten maximus* on a seasonal basis to determine if seasonal reproductive cycle in this species affected the extent to which it is negatively affected by dredge capture. Seasonal variability in AEC levels has been examined in a number of invertebrate species including the crayfish, *Procambarus acutus acutus*

(Dickson & Giesy 1982), the oysters *Ostrea edulis* and *Crassostrea gigas* (Moal et al. 1989b; Moal et al. 1991), the mussel *Mytilus edulis* (Zaroogian et al. 1982) and the clam *Cardium* sp. (Picado et al. 1988). Such variability has generally been associated with the reproductive cycle. Seasonal changes in biochemical composition of the scallop *P. maximus* have been well documented (Ansell 1978; Maguire & Burnell 2001). Carbohydrate reserves are built up during periods of greater food availability during the summer and used up in the winter. In *P. maximus* the main period for gonadal proliferation takes place between November and February by the mobilization of glycogen and protein reserves from the adductor muscle and lipid from the digestive gland. *P. maximus* may spawn over a long period from spring to autumn (Ansell 1978). Gametogenesis represents a period of high-energy demand in scallops and when external food supplies are limited, gamete production occurs at the expense of biochemical components in somatic tissues (Calow 1985). In this study on each sampling day we measured the glycogen content of both the striated adductor muscle and the gonad in order to assess the reproductive state of the scallops. Brokordt et al. (2000) showed that the reproductive state of the scallop *Chlamys islandica* affected its ability to escape, presumably as a result of changes in the energetic state of the individual. Therefore, it would be reasonable to hypothesize that seasonal variability in the energetic state of scallops would affect the degree to which they are negatively affected by dredging.

In addition to the major aim of this study, the determination of temporal variability in dredging induced stress, two further objectives were pursued. Initially, field trials were conducted at three different fishing grounds to assess the degree to which dredging induced stress varies spatially. Fishing grounds were specifically chosen with contrasting bottom characteristics. Diving was undertaken to collect scallops that encountered dredges but were not captured. AEC was measured to determine the extent to which these scallops were negatively affected by this experience.

MATERIALS AND METHODS

Seasonal Field Trial

The field trial was carried out on the commercial scallop ground known as the Chickens, off the south west of the Isle of Man in the North Irish Sea (53°58.75'N, 04°52.71'W). The scallops were caught using a Newhaven type spring-loaded dredge (width – 75 cm) with a toothed cross bar (tooth spacing – 66 mm; tooth length – 100 mm), a collecting bag made from case hardened steel rings (diameter – 70 mm) and a net mesh cover (mesh size – 100mm). Eight dredges were towed at a speed of 5 kph for forty-five minutes on 4 dates, March 15th, June 5th, October 6th (2000), and February 14th 2001. On each date two tows were made. At the end of each tow at least 15 scallops below the minimum legal landing size (<110 mm shell height) were taken from two random dredges and samples of muscle and gonad taken for AEC and glycogen analysis. Each scallop was opened and two small portions of the striated adductor muscle and one portion of gonad weighing approximately 0.2 g were removed using a scalpel. Samples were wrapped separately in foil and immediately placed in liquid nitrogen.

On each date 10 undersized scallops were taken from the dredges and transferred alive to Port Erin Marine Laboratory and placed in tanks containing running seawater. Samples of muscle were taken one week later as described above. These samples acted as controls for AEC analysis. A preliminary experiment showed that the AEC levels of post-dredged scallops returned to normal after 24 hours (at most) of recovery in seawater (Maguire et al., in press b). Scallops placed in tanks for a full week had made a complete recovery and thus this protocol was adopted for the control animals in this study.

Comparison of Scallops from Different Grounds

This field trial was carried out in June 2000 on three commercial scallop fishing grounds off the Isle of Man (Fig. 1); Chickens (53°58.75'N, 04°52.71'W), Laxey (54°13.50'N, 04°21.38'W) and Bradda Inshore (54°06.5'N, 04°47.76'W). The substratum on all grounds was generally coarse sand or gravel, often overlain with pebbles, cobbles and dead shell. The abundance of pebbles and cobbles, as indicated by the number caught during dredging varied greatly among the three grounds sampled. At Laxey there were relatively few and the substratum was predominantly sandy with areas of dead maerl. The Chickens and Bradda Inshore grounds were both made up of variable gravel sediment with large numbers of pebbles and cobbles at Bradda Inshore and intermediate amounts at Chickens.

Scallops were caught using the same method as above. Samples of muscle for AEC analysis were taken from 15 undersized scallops from random dredges from two tows.

Stress in Non-Captured Scallops

In June 2000 dredging was undertaken on the Bradda Inshore scallop ground as part of a study into the impacts of dredging on benthic megafauna (see Jenkins et al. 2001 for details). Divers collected scallops that had encountered dredges but had not been captured by following the tracks on the seabed formed from the passage of the dredge. Forty-two scallops from within the dredge tracks (impacted scallops) and 14 scallops from outside the tracks (control scallops) were collected between 15 and 45 minutes after the passage of the dredges. Dredging also took place and two tows were carried out. For each tow, 15 undersized animals were removed from the dredge bags. On surfacing all scallops were im-

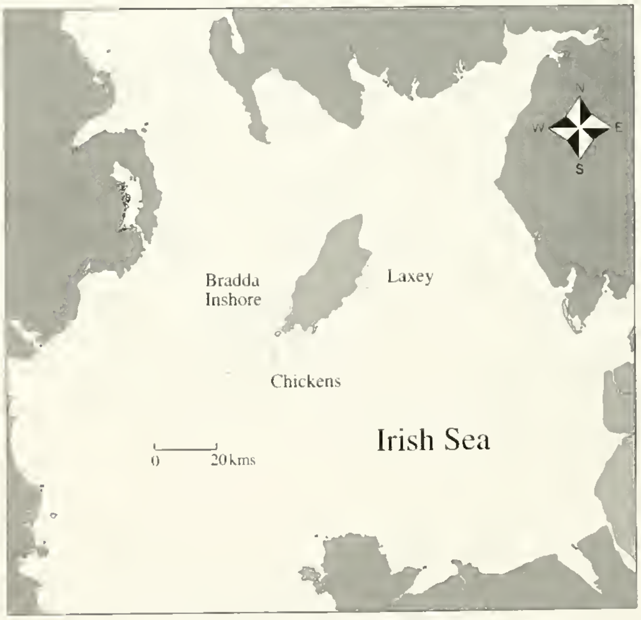

Figure 1. Map of dredged sites.

mediately opened and samples of striated adductor muscle taken for AEC analysis.

Biochemical Analyses

All samples were stored in liquid nitrogen until analysis. Adenylic Energetic Charge (AEC) of the striated adductor muscle was determined using the technique of Moal et al. (1989a). Maguire et al. (1999b) conducted an experiment to assess the effect of stress on the AEC level of both the smooth and striated muscle of the king scallop. A greater significant AEC decline was shown between treatments in the striated muscle. For glycogen analysis samples were withdrawn from the liquid nitrogen and freeze dried using a HETOSICC CD 53-1 freeze dryer. The glycogen content was analyzed using a miniaturization of the Dubois et al. (1956) method.

Statistical Analyses

After testing for normality, non-parametric data were normalized by log transformation or arcsine square root transformation. One-way analyses of variance (ANOVAs) were used to test significant differences between treatments and *a posteriori* Tukey test was used to contrast treatments. The level of significance was set at 0.05.

RESULTS

Seasonal Field Trial

Figure 2 shows the effect of dredging on the AEC level of scallops from the Chickens scallop fishing ground off the coast of the Isle of Man. The AEC level decreased significantly in the dredged scallops from the control samples at each sampling period ($P < 0.001$). However, the AEC levels of the control samples varied throughout the year but not significantly. The highest AEC levels in the control animals were found in October (0.90 ± 0.01) and the lowest levels were found in February (0.77 ± 0.05). Because of this seasonal AEC variation in the control animals the % AEC decrease from the control to dredged scallops was calculated for each season. The AEC reduction was highest in February (44.8% ± 3.3) and June (43.4% ± 2.9) and significantly less ($F_{136,3} = 3.476$, $P < 0.05$) in March (33.6% ± 2.8). The lowest absolute value of AEC in the striated muscle of scallops following dredging was also in February (0.43 ± 0.03) and the highest was in October (0.53 ± 0.01). The AEC level reached in scallops sampled in February was significantly different ($F_{136,3} = 4.942$, $P < 0.05$) from all the other dates sampled except for June. No difference in the AEC levels of dredged scallops was found between any of the other sampling dates.

The percentage of glycogen content in the striated muscle of the animals showed a similar pattern to the AEC results found in the control animals (Fig. 3). The lowest glycogen levels were found in the scallops sampled in February (4.38% ± 0.27), with levels over three times higher in October ($F_{165,3} = 83.32$, $P < 0.001$). The % glycogen content in the gonad also varied significantly throughout the year ($F_{156,3} = 331.42$, $P < 0.001$). The glycogen levels in the gonad ranged from a minimum in October (0.30% ± 0.05) to a maximum in June (10.33% ± 0.43).

Sea water temperatures decreased from a maximum on August 29th 2000 (15.7°C) to a minimum value on the 17th of January 2001 (7.3°C). On the specific sampling days the temperatures are shown on Figure 2.

Comparison of Scallops from Different Grounds

There was no difference in the AEC levels of scallops dredged at different sites in June (Fig. 4). The AEC level varied in scallops from 0.46 to 0.48 on all three grounds.

Stress in Non-captured Scallops

Scallops that came in contact with the dredge but remained uncaught had a significantly lower AEC level than the control scallops ($t_{69} = 7.401$, $P < 0.001$). However, the reduction in AEC was not as great as in captured scallops. Figure 5 showed that the AEC level in captured scallops was significantly lower ($t_{55} = 6.869$, $P < 0.001$) than in the non- captured scallops.

DISCUSSION

The results from this study suggest that the AEC response to dredging of undersized scallops is different according to the season of the year. Lowest AEC levels in dredged and control scallops

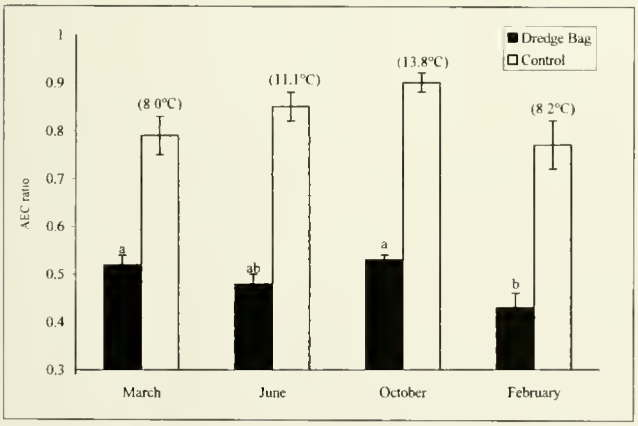

Figure 2. The seasonal effects of dredging on the AEC level (mean ± s.e) of scallops from Chickens (March 2000 to February 2001). Sea water temperatures shown in parenthesis. Any two means sharing a common letter between each treatment are not significantly different at $P < 0.05$ (Tukey test).

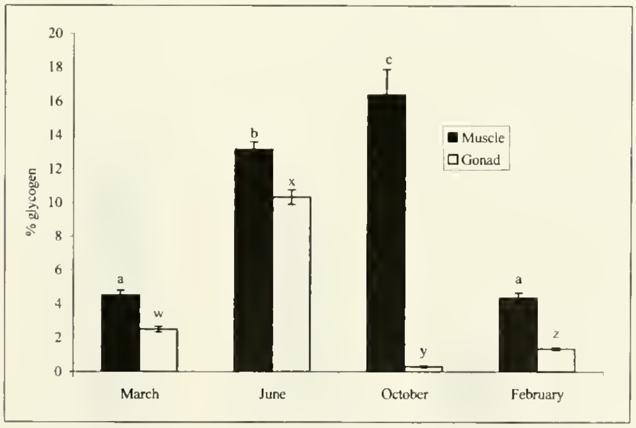

Figure 3. The seasonal % glycogen content (mean ± s.e) of scallops from Chickens (March 2000 to February 2001). Any two means sharing a common letter between each treatment are not significantly different at $P < 0.05$ (Tukey test).

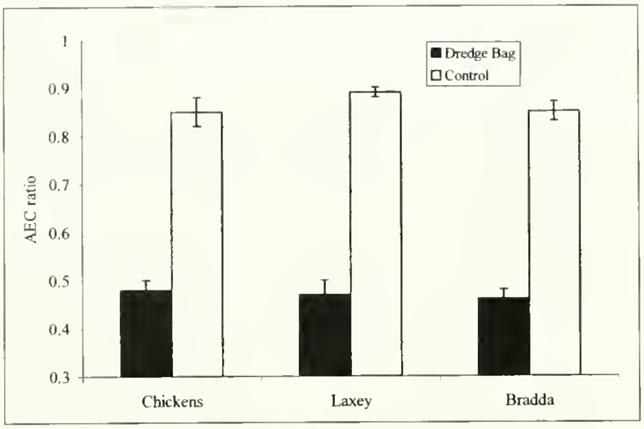

Figure 4. The effects of dredging on the AEC ratio (mean ± s.e) of scallops from three sites off the Isle of Man (June 2001).

were found in February and highest levels in October. This coincided with the troughs and peaks of the glycogen content in the adductor muscle of the test animals. Reserves are built up during periods of greater food availability in the summer. However, energy requirements for maintenance are high therefore rapid utilization of reserves takes place during the winter. Many demands are placed on the metabolism of scallops during the winter from the stresses imposed from internal physiological drives such as gonadal proliferation. However, during unfavorable winter conditions these energy demands may be insufficient to support gonadal development (Ansell 1978). The greatest percentage of AEC decrease from control to dredged scallops was also in February (44.8%). Therefore, the additional stress effect of dredging at the end of winter had a greater negative effect on the AEC level of scallops whose energy reserves were already low. Similarly, Brokordt et al. (2000) showed that the mobilization of reserves had a detrimental impact on the escape response of the Iceland scallop, *Chlamys islandica*.

Moal et al. (1989b), also found that the AEC response to the stressor aerial exposure was different according to the time of year in the oyster *Crassostrea gigas*. The animals were subjected to a three hour emersion period in January, May, and July. Lowest AEC values were found in July and these levels were inversely correlated with temperature. Similarly, in our study a large % AEC decrease from control to dredged animals was recorded in June (43.4%) and October (41.1%) when temperatures were highest. The June sample coincided with the spawning season of the scallop population in the Isle of Man. Moal et al. (1991), also found low AEC levels during the summer in the farmed oysters *C. gigas* and correlated this decrease with the reproductive state of the oysters.

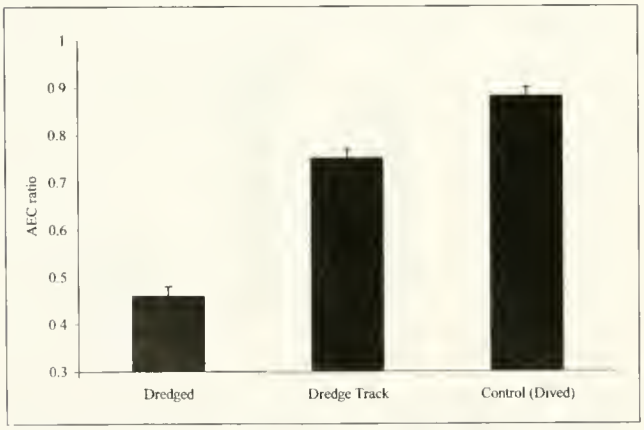

Figure 5. Comparison of the AEC levels (mean ± s.e) of dredged scallops and scallops left behind on the dredge track from Bradda in June.

Many authors have suggested that AEC levels in molluscs below a value of 0.5 result in a negative scope for growth, which would eventually lead to mortality even if the animals were transferred to optimal conditions (Ivanovici 1980; Duncan 1993). However, in this study scallops dredged in February and June had AEC levels <0.5. However, no mortality was recorded in the control scallops. Similarly in a previous study by Maguire et al. (1999a), juvenile scallops were transported in polystyrene boxes for 12 hours and the AEC level of the spat decreased form 0.88 to 0.42. Recovery of these animals was initially rapid and AEC levels had increased to 0.68 after only two hours in optimal conditions and had returned to normal after 24 hours. In addition dredge captured scallops that are returned to the laboratory and maintained in running seawater showed consistently low levels of mortality (Jenkins, unpublished data). Although the stress and subsequent reduction in AEC levels in dredge captured scallops may not lead directly to mortality, such scallops may be more susceptible to predation (Thompson et al. 1980) through a reduction in their escape response or inability to recess (Minchin et al. 2000). Maguire et al. (in press a) found that the AEC levels of dredged scallops (30 minute tow length) had returned to normal after 3 days of recovery but had not recessed into the sediment in that time period. Jenkins and Brand (in press) have shown that the escape response in *P. maximus* was significantly reduced following simulation of dredging for up to 24 hours. Such observations suggest that predator induced mortality may be significant for stressed discards.

In general, the percentage of glycogen content of these Isle of Man scallops was quite low in the striated adductor muscle ranging from 4.4% to 16.4%. In a study of a population of scallops in Bantry Bay, Ireland the glycogen content ranged from 16.5% to 45.9% (Maguire & Burnell 2001). Ansell (1978) studied the storage of reserves in the adductor muscle of some scallop populations in the U.K. and found that the % glycogen content generally varied from 2.2% to 24.0%, but in one population the glycogen content was as high as 39%. He also suggested that glycogen content could vary between sites and between different years.

There was no difference in the AEC values between the three different sites studied. The effect of the dredging process was the dominant stressor on the animals so much so that the subtle differences between the sites had little added impact on the AEC decrease. Similarly, Verschraegen et al. (1985) found no difference in the AEC levels of the polychaete species *Nereis diversicolor* and *Nephtys* sp. between sites in the Western Scheldt estuary, Belgium. Also, Zaroogian et al. (1982) found no difference in AEC levels of the mussel *Mytilus edulis* in two sites.

Scallops that came in contact with the dredge but remained uncaught and were found on the dredge track were stressed (AEC level = 0.75). Although the AEC level was not as low as in captured scallops it is important to demonstrate that the impact of dredging is not confined solely to those scallops landed on deck. Owing to the relatively low efficiency of scallop dredges (Dare et al. 1993) far more scallops will encounter dredges and remain on the seabed than are captured. These non captured animals which include all sizes, may suffer enhanced mortality due to dredge induced stress in the same way as undersized discards. Also, it was interesting to note that the collection and transportation of scallops from the sea-bottom to the surface did not induce stress in the control animals.

CONCLUSIONS

1. AEC levels in dredged and control animals, and % glycogen in the striated muscle of dredged scallops, were lowest in February and highest in October.
2. The largest % AEC decrease from control to dredged scallops was also in February and the smallest decrease was in March.
3. There was no difference in the AEC level of dredged scallops from three sites with different ground types around the Isle of Man.
4. Scallops that came in contact with the dredge but remained uncaptured on the dredge track had a reduced AEC level but this level was significantly higher than the AEC level of captured animals.

REDUCED GROWTH OF ICELAND SCALLOPS *CHLAMYS ISLANDICA* (O.F. MÜLLER) CULTURED NEAR THE BOTTOM: A MODELLING STUDY OF ALTERNATIVE HYPOTHESES

MARCEL FRÉCHETTE[1] AND GAÉTAN DAIGLE[2]

ABSTRACT Slow growth of *Chlamys islandica* held in pearl nets near the bottom is usually attributed to poor seston quality owing to higher concentration of resuspended inorganic particles near the bottom. In a recent contribution, we hypothesized that current speed variations in boundary layers and feeding behavior may also result in slower growth of Iceland scallops kept in pearl nets near the bottom, independently of resuspension effects. Here we present computer simulations of growth of scallops kept in pearl nets at two population densities and various heights above the bottom. Our simulations suggest that resuspension may account for experimental results but that food depletion within the pearl nets is required. Our simulations also suggest that a direct positive effect of current speed on clearance rate or physiological regulation of clearance rate, both coupled with seston depletion within pearl nets, may both explain experimental patterns. Based on the profile of growth across height, our results also provide a criterion for interpreting results of experiments designed to identify the actual control mechanism.

KEY WORDS: *Chlamys islandica*, density dependence, growth, scallop, seston quality

INTRODUCTION

Iceland scallops (*Chlamys islandica* O.F. Müller) cultured in pearl nets typically exhibit reduced growth rate near the bottom (Wallace & Reinsnes 1984; Wallace & Reinsnes 1985; Thorarinsdóttir 1994). Because reduced seston quality dramatically reduces assimilation efficiency of Iceland scallops (Vahl 1980), near-bottom growth reduction is usually attributed to low seston quality due to local resuspension. Resuspended particles indeed tend to be of poor trophic quality as compared to planktonic food, the stronger the resuspension forces the larger the difference (Demers et al. 1987; Thomsen & Gust 2000).

Boundary layers are zones of strong change in current speed with respect to distance from the interface between fluids and solid surfaces. They are universal features of flow near such discontinuities. Bottom resuspension results from shear in the benthic boundary layer (BBL; e.g., Muschenheim 1987; Thomsen & Gust 2000). Therefore if organisms are held across a resuspension gradient near the bottom, they will also experience a current speed gradient. It follows that the seston quality hypothesis cannot be invoked as the sole explanation to near-bottom vertical differences in scallop growth without implying that the scallops were also held across a current speed gradient and that current speed effects were negligible.

Fluid movement and associated physical processes are fundamental to the biology and ecology of aquatic organisms (Vogel 1981; Wildish & Kristmanson 1997). Trophic dynamics of scallops are no exception. For instance, Wildish et al. (1992) reported that current speed affects growth in a non-monotonous way through its effect on clearance rate. At low current speed, clearance rate increases with current speed until a maximum is reached at about 10 cm s^{-1}. Higher current speed results in clearance rate inhibition. These patterns are reflected in growth (e.g., Wildish et al. 1987; Cahalan et al. 1989; Eckman et al. 1989; Wildish et al. 1992; Wildish & Saulnier 1992) but in pearl net culture, they may interact with seston depletion within the pearl nets (Claereboudt et al. 1994b). Furthermore clearance rate may respond to temporal variability in phytoplankton concentration and current speed, indicating an effect of feeding history (Pilditch & Grant 1999). Therefore near-bottom effects may be ascribed to direct and indirect effects of current speed as much as to sediment resuspension.

In a recent study of growth and survival of Iceland scallops kept in pearl nets, we tested the effect of site, of height above the bottom (0.1 m versus 2.0 m) and of group size within the pearl nets (Fréchette & Daigle, in press). Our analysis also included fluctuating asymmetry as a proxy of individual effects. The group size treatment allowed testing for containment effects within the pearl nets. Available data showed no evidence of phytoplankton vertical depletion in the water column. However, we found slower growth near the bottom. This is similar to previous reports (Wallace & Reinsnes 1984; Wallace & Reinsnes 1985; Thorarinsdóttir 1994). We also found that at 2.0 m above the bottom there was a group size effect, but not at 0.1 m. High density groups grew slower than low density groups. This is consistent with food depletion within the pearl nets and has been observed repeatedly in growth experiments (Parsons & Dadswell 1992; Claereboudt et al. 1994a; Claereboudt et al. 1994b). The reasons for the absence of a group size effect at 0.1 m, however, are not clear. Food within the pearl nets was presumably more depleted at 0.1 m height, down in the BBL, where current speed is slower than at 2.0 m height. This should have generated a group size effect at 0.1 m as found at 2.0 m.

The goal of the present study was to explore three hypotheses for the group size*height interaction found in the growth experiment. We modeled growth according to various control factors: (1) with increasing inorganic particle concentration near the bed, due to resuspension; (2) with a direct positive effect of current speed on clearance rate; (3) with an indirect effect of current speed on clearance rate because of physiological regulation of clearance rate in response to more intense phytoplankton depletion in the pearl nets held near the bottom. To simplify matters, we modeled the effect of each factor separately.

METHODS

We modeled soft tissue growth of individual scallops contained in hypothetical pearl nets, as a function of non-dimensional current speed, U_z/U_2, with U_z and U_2 being respectively current speed at

---

Corresponding author. Marcel Fréchette, Institut Maurice-Lamontagne, Ministère des Pêches et Océans, C.P. 1000, Mont-Joli, QC, G5H 3Z4, Canada.

heights z and 2.0 m above the bottom. We assumed that the benthic boundary layer extended to 2.0 m above the bottom and that U_z increased logarithmically with height (Grant et al. 1984). A first set of simulations was made assuming that no seston depletion occurred in the pearl nets. In the second set of simulations, we assumed that seston depletion occurred in the pearl nets. Outside the pearl nets, phytoplankton concentration was assumed to be constant across heights (see Fréchette & Daigle, in press). We assumed that there were no interactions between individual scallops otherwise than through their effect on bulk food concentration in the pearl nets. We modeled flesh growth as the balance between energy intake and energy losses, based on the Scope for Growth approach (Bayne & Widdows 1978), although more mechanistic approaches to this problem are possible (e.g., van Haren & Kooijman 1993).

The numerical model has two state variables, scallop flesh mass (m, g) and phytoplankton concentration in the hypothetical pearl nets (P, J L^{-1}). We assumed that survivorship was 60% and 80% in pearl nets held at 0.1 m and 2.0 m, respectively (Fréchette & Daigle, in press). Mortality was spread evenly through time, one individual at a time. Flesh mass growth ($\mathrm{d}m/\mathrm{d}t$) is driven by net energy balance, with

$$\mathrm{dm/dt} = \mathrm{c_1} \cdot [(\mathrm{c_2} \cdot \mathrm{CR} \cdot \mathrm{P} \cdot \mathrm{AE}) - \mathrm{R}] \qquad (1)$$

where c_1 is a conversion factor from J to mass (c_1 = 0.00051; Dauvin & Joncourt 1989), c_2 is a parameter accounting for flow effects on clearance rate (see later), CR is clearance rate (L day^{-1}), AE is assimilation efficiency (dimensionless) and R is respiratory losses (J day^{-1}). To model phytoplankton in the pearl nets, we assumed that pearl nets were analogous to flow-through chambers, with flow rate being directly proportional to current speed. It is assumed finally that mixing is complete and that water displacement by scallops has negligible effect on residence time. Phytoplankton conservation in the pearl nets is given by

$$\mathrm{dP/dt} = (\mathrm{V} \cdot \mathrm{c_3})^{-1} \cdot [\mathrm{c_3} \cdot \mathrm{c_4} \cdot \mathrm{v} \cdot (\mathrm{P_i} - \mathrm{P_s}) - \mathrm{N} \cdot (\mathrm{P_s} \cdot \mathrm{c_2} \cdot \mathrm{CR})] \qquad (2)$$

where $\mathrm{d}P/\mathrm{d}t$ is the rate of change of phytoplankton concentration in the pearl nets, V is the volume of the hypothetical pearl nets, c_3 and c_4 are parameters (see later), P_i and P_s are phytoplankton concentration (J L^{-1}) at the inflow and the outflow of the pearl nets, respectively, N is the number of scallops in the pearl nets. In all simulations, P_i = 15.6 J L^{-1}. Assuming that the energy content of phytoplankton is 10.4 J mg^{-1} (Bayne & Widdows 1978, Thompson 1984), this specifies a particulate organic matter (POM) concentration equal to 1.5 mg l^{-1}, constant along the vertical. Under the assumption of complete mixing within the pearl nets, P is estimated by P_s (Northby 1976).

Growth was simulated for 360 days with no seasonal signal in P_i. Temperature was not taken into account. The values of V (40 L), c_2, c_3, c_4 and basic flow rate v (1000 L day^{-1}) were set arbitrarily to provide the desired conditions in the pearl nets–either seston depletion or no depletion, and flow rate variations as a function of height. The parameters c_2 and c_4 are the ratio of current speed at height z to current speed at 2 m above the bottom. c_2 and $c_4 \in \{0.1, 0.2, 0.3, \ldots, 1\}$, depending on the situation modeled. They are used to mimic the effect on flow rate of change in current speed with height in the benthic boundary layer.

In the first set of runs where phytoplankton depletion in the pearls nets is negligible, c_3 = 1000. In the second set of runs, where depletion occurs, c_3 = 1. To model the impact of a positive effect of current speed on CR, we assumed that c_2 and c_4 increase proportionally to current speed (Wildish et al. 1992) and ran the model with c_2 and c_4 equal to 0.1, 0.2, . . ., 1 successively. Clearance rate (l day^{-1} ind.$^{-1}$) was given by $CR = 24 \cdot 3.09 \cdot m^{0.60}$ after Vahl (1980).

To model the expected results of an indirect effect of current speed, we set c_2 = 1 and c_4 equal to 0.1, 0.2,. . ., 1 as above. Clearance rate was given by $CR = 24 \cdot (5 \cdot \exp(-0.4 \cdot P\ ) + 3.09 \cdot m^{0.60})$. The exponential part of the equation allows realistic mimicry of physiological regulation of clearance rate in response to phytoplankton concentration, at least as observed in *Placopecten magellanicus* (Bacon et al. 1998) and *Argopecten irradians* (Cahalan et al. 1989). In the cases of direct and indirect effects of current speed, AE = 0.5.

To model the effect of resuspension, we first constructed a suspended inorganic sediment (PIM) concentration profile above the bed, based on Rouse's theory, according to which we have $C = C_a \cdot (a/z)^q$, where C is sediment concentration (mg l^{-1}) at height z above the bed, C_a is a reference concentration at a reference height a (C_a = 1 mg l^{-1}; a = 200 cm), and $q = w_s/\kappa U_*$, where w_s is sediment mean fall velocity (w_s = 0.05 cm s^{-1}), κ is von Karman's constant (0.41) and U_* is friction velocity (U_* = 1 cm s^{-1}) (see e.g., Muschenheim 1987). Assuming that velocity above the scallop bed followed the law of the wall, with $U_z = U_* \kappa^{-1} \ln(z/z_0)$ (e.g., Grant et al. 1984), and estimating z_0 = 0.2 cm by means of Nikuradse's parameterization of bed roughness ($z_0 = k_b \cdot 30^{-1}$, where k_b = 7 cm, the approximate size of scallops and pebbles recovered from scallop dredge tows on the donor site of our growth experiment), we constructed an hypothetical flow profile above the bed. We then found the heights at which we had $U_z/U_2 \in \{0.1, 0.2, \ldots, 1\}$ and deduced the corresponding PIM concentration profile. Knowing PIM as a function of U_z/U_2 (POM is assumed to be constant across heights), we determined EA at height as $EA = \sin^2(139.6 - 2.14 \cdot \arcsin(1 - (PIM/(PIM + POM)))^{0.5})$, as modified from Vahl (1980). In all cases, respiration is given by $R = (155.2\ \mu\mathrm{l}\ \mathrm{O_2} \cdot \mathrm{m}^{0.80}) - 19.9 \cdot 10^{-3}\ \mathrm{J}\ \mu\mathrm{lO_2}^{-1}$ (Vahl 1978).

RESULTS

Results of the growth simulations with and without depletion in the hypothetical pearl nets are shown in Figure 1 and Figure 2, respectively. All results are reported as a function of U_z/U_2, which scales as ln z under the assumption of a logarithmic current profile above the bed. In all cases, growth at 2.0 m above bottom did not vary because this was the reference level, and was assumed to have constant current speed and suspended sediment concentration. Growth at height z, however, decreased with decreasing U_z/U_2. Without food depletion in the hypothetical pearl nets, growth decreased in a curvi-linear fashion with U_z/U_2, with upward concavity for both resuspension and a direct effect of current speed on clearance rate as control mechanisms. Because there was no food depletion to generate group size effects, data for different group sizes overlap in Figure 1. Therefore there was no interaction between height above bottom and group size. With food depletion in pearl nets, however, growth patterns were richer (Fig. 2). For U_z/U_2 = 1, growth at height z was higher than at 2.0 m because mortality at the lower level was more severe than at 2.0 m and therefore per capita food availability was higher. Resuspension and a direct effect of flow on clearance rate resulted in a curvilinear decrease of growth as U_z/U_2 decreased, with upward concavity

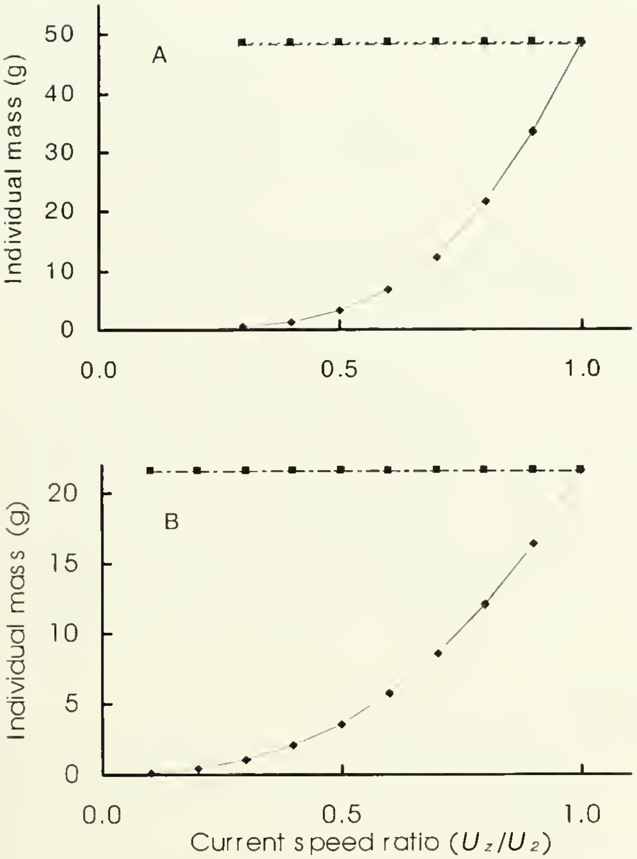

Figure 1. Simulated soft tissue growth without phytoplankton depletion in the hypothetical pearl nets. Diamonds: height z above bottom; squares: 2 m above bottom; solid symbols: 5 individuals per hypothetical pearl net; empty symbols: 10 individuals per hypothetical pearl net. Here empty symbols are hidden by solid symbols. A: effect of particle resuspension at the bottom. B: effect of positive relation between current speed and clearance rate.

(Fig. 2A, B). An indirect effect of current speed, however, generated a response with downward concavity (Fig. 2C). In all three cases, the difference between group sizes decreased with decreasing U_z/U_2.

DISCUSSION

Our simulations indicate that decreasing U_z/U_2 ratio resulted in a height effect on simulated growth. However, phytoplankton depletion within the hypothetical pearl nets was required to generate a height*group size interaction similar to that found in the actual growth experiment (Fréchette & Daigle, in press). The chances of occurrence of a significant height*group size interaction increased with decreasing height z because the effect of group size on scallop growth decreased with decreasing current speed. The lower the U_z/U_2 ratio, therefore, the better the simulations mimicked the experiment. The key factors implied here are seston depletion within the pearl nets and vertical differences in current speed owing to the BBL.

Our simulations show that the three mechanisms tested might have generated the height*group size interaction. Vahl (1980) reported that seston quality had a strong negative effect on growth of Iceland scallops. According to our simulations, higher *PIM* near the bottom, coupled with homogeneous *POM* concentration in the vertical and with phytoplankton depletion within the pearl nets (Claereboudt et al. 1994a; Claereboudt et al. 1994b), may have generated the height*group size interaction (Fig. 2A). Because within pearl net phytoplankton depletion is required, this mechanism is different from the hypothesis of a straightforward negative effect of poor seston quality on assimilation efficiency which is usually invoked to explain near-bottom effects on growth of Iceland scallops held in pearl nets (Wallace & Reinsnes 1984, 1985; Thorarinsdóttir 1994). Clearly different group sizes should be used routinely in growth experiments to test for containment effects.

The second mechanism tested, that is, a direct positive effect of higher current speed on clearance rate (Wildish et al. 1992), coupled with seston depletion within the pearl nets, also resulted in

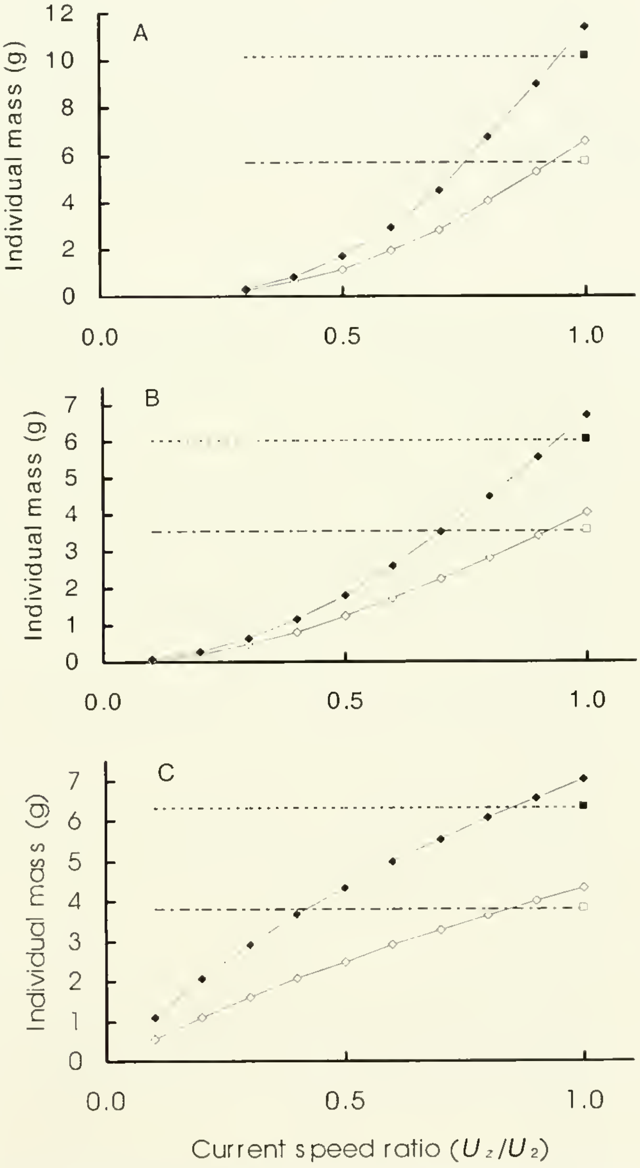

Figure 2. Simulated soft tissue growth with phytoplankton depletion in the hypothetical pearl nets. Symbols as in Figure 1. A: effect of particle resuspension at the bottom. B: effect of positive relation between current speed and clearance rate. C: effect of clearance rate regulation in response to seston concentration within the hypothetical pearl nets.

a height*group size interaction (Fig. 2B). It has been argued, however, that the positive relationship between clearance rate and current speed may be an artifact of flow removing seston depletion envelopes around individuals (Lenihan et al. 1996). There is indeed evidence that phytoplankton concentration may be structured in space (cm scale) by exhalent jets of suspension feeders (Monismith et al. 1990; O'Riordan et al. 1993; O'Riordan et al. 1995). In addition, Claereboudt et al. (1994b) found no evidence of positive effect of current speed on sea scallop growth. Although the ongoing considerations provide little support for a positive response of clearance rate to current speed, it should be noted that Butman et al. (1994) found such a positive response in a mussel population contained in a flume.

The third mechanism tested, that is, an indirect effect of flow mediated through changes in phytoplankton concentration within pearl nets coupled with clearance rate regulation (clearance rate is assumed to increase with decreasing phytoplankton concentration; e.g., Bacon et al. 1998), also resulted in a height*group size interaction. The relation between growth and U_r/U_2 was curvilinear, with downward curvature. In the case of resuspension and of a direct effect of flow, the relation was also curvilinear, but with upward curvature. Therefore, assuming that regulation of clearance rate in Iceland scallops resembles that of sea scallops and bay scallops, results of a growth experiment with different heights tested may provide information as to whether the height*group size interaction was attributable mainly to physiological regulation or to environmental forcing. We did not study the effect of inhibitory high flows on clearance rate (Eckman et al. 1989; Wildish et al. 1992) because it was inconsistent with lower growth near the bottom.

In summary, our simulations suggest that the original seston quality hypothesis alone is insufficient to account for the decrease in growth of scallops near the bottom. An additional factor is required, that is, seston depletion within the pearl nets and its interaction with the BBL. Furthermore, two other mechanisms, independent of resuspension, may explain the growth pattern in the BBL. Both require food depletion within the pearl nets and interaction with the BBL. The first mechanism is a direct positive effect of higher current speed on clearance rate and the second mechanism involves clearance regulation in response to food depletion. Because our simulations allow predictions about the profile of growth across height, growth experiments may provide evidence on the factor actually causing near bottom reduction in growth, provided that the processes simulated above act independently.

ULTRASTRUCTURAL CHARACTERISTICS OF SPERMATOGENESIS IN DIPLOID AND TRIPLOID CATARINA SCALLOP (*ARGOPECTEN VENTRICOSUS* SOWERBY II, 1842)

ROSALÍO MALDONADO-AMPARO AND ANA M. IBARRA
Aquacultural Genetics Laboratory, Centro de Investigaciones Biológicas del Noroeste, La Paz, México

ABSTRACT Spermatogenic stages in diploid and triploid catarina scallop (*Argopecten ventricosus*) were studied by light and electron microscopy at two different ages. In nine month old triploid scallops, a reduced number of spermatogonia and primary spermatocytes were seen in the male acini, and although no spermatids were found, a few spermatozoa were observed. All triploid spermatogenic stages and their nuclei were larger in diameter than those in diploids. Ultrastructure analysis reveled that spermatogenesis in triploids was almost completely arrested early, at the primary spermatocyte stage, indicating the halt occurs during the prophase stage of meiosis I, before the first reductional division. At age 12 months a large number of hemocytes invade some of the remaining male acini of triploids, which possibly have a trophic role after development is halted. At this age, the male part of the gonad in most analyzed scallops is completely replaced by female acini, with some developing oocytes. Checkpoint mechanisms recently described as "meiotic checkpoints" are proposed as possibly being involved in the partial or total sterility resulting from the triploid condition.

KEY WORDS: *Argopecten ventricosus*, sterility, EM, triploid, pectinid, spermatogenesis, meiotic-checkpoint

INTRODUCTION

Triploid sterility has been reported for a number of mollusk species, but in most cases the sterility is not reflected in a complete lack of gametogenic stages, but rather on a delayed process and a reduced number of fully developed gametes (Allen et al. 1986; Komaru & Wada 1989, 1990; Allen 1987; Allen & Downing 1990; Guo & Allen 1994b; Cox et al. 1996; Eversole et al. 1996; Kiyomoto et al. 1996; Ruiz-Verdugo et al. 2000). Whereas the most common characteristic in triploid mollusks has been reported to be the reduced development of the gonad and gametes, the reversal of gonad sex in a known functional hermaphrodite has been only reported to occur in catarina scallop (Ruiz-Verdugo et al. 2000).

In as much as several studies comparing diploids and triploids have been done on gametogenic stages by light microscopy, partial or total ultrastructure analysis of abnormal gametogenesis in polyploid mollusks has been done only for triploid Pacific oyster *Crassostrea gigas* (Komaru et al. 1994), triploid Sydney rock oyster *Saccostrea commercialis* (Cox et al. 1996), and triploid and tetraploid Mediterranean blue mussel *Mytilus galloprovincialis* (Komaru et al. 1995; Kiyomoto et al. 1996). Spermatogenesis in diploid catarina scallop *Argopecten ventricosus* at the ultrastructure level has not been studied before, although it has been done for other pectinid species, *Pecten maximus* (Dorange & Le Pennec 1989a; Beninger & Le Pennec 1991).

The catarina scallop, *Argopecten ventricosus*, is a functional hermaphrodite pectinid in which the gonad is divided into two parts, one female and one male. When triploidy is induced in this species, a gradual suppression of functional hermaphroditism has been noted to occur, with only female gametogenic stages developing in the male part of the gonad in one-year-old scallops (Ruiz-Verdugo et al. 2000). As reported for oysters (Guo & Allen 1994a) and Manila clams (Utting et al. 1996), as well as for this particular species (Ruiz-Verdugo et al. 2001), the number of oocytes formed was reduced when compared to diploids. In a continuance of those studies with triploid catarina scallop, we report here the effects of triploidy on spermatogenesis, studied as the comparative structure and ultrastructure of 9-month-old and 12-month-old diploid and triploid catarina scallops.

MATERIALS AND METHODS

Scallops

Diploid and triploid catarina scallops about nine months age (6 cm in shell length), kept in a growout area at Bahía Magdalena in Baja California Mexico, were transported to the Genetic Laboratory of CIBNOR (Centro de Investigaciones Biológicas del Noroeste), and placed under maturation conditioning for 20 days. A second group of scallops that were not conditioned for maturation in the laboratory was sampled from the field area at age12 months. The triploid scallops were produced using cytochalasin-B (0.5 mg/L) as described by Ruiz-Verdugo et al. (2001), and the diploids were from a control group the same age.

Maturation Conditioning

Each ploidy group was stocked (five scallops per 40-L tank) and kept under standardized controlled maturation conditions during 20 days (Ramírez et al. 1999). Feeding consisted of adding a mixture of *Isochrysis galbana*, *Monochrysis lutheri*, and *Chaetoceros muelleri* at a total concentration of 4×10^6 cells / scallop / day. Water temperature was kept at 19–20°C, salinity at 36‰, and dissolved oxygen from 7–9 mg / L. The maturation room was provided with a 12-hour light and 12-hour dark photoperiod.

Sampling and Histology for Light Microscopy

After the 20-day maturation-conditioning period, the gonads from 20 scallops per ploidy group were fixed in buffered formaldehyde (10%), dehydrated in a graded ethanol series, and embedded in paraffin. Duplicated sections, 5 μm thick, were obtained from each gonad, and stained with hematoxilin-eosin (H&E) and Feulgen.

Spermatogenic stages in diploid and triploid scallops were measured using image analyses. Images were taken with an Olympus BX-41 microscope, with an integrated camera (CoolSNAP-Pro). The images were analyzed with SigmaScan Pro 5, obtaining an area by digitalizing contours and estimating diameters from the

area for cytoplasm and nucleus of each spermatogenic stage. To correct for scale differences, for each microphotograph evaluated the image analysis program was calibrated accordingly to the microscope objective used for those images. For each ploidy group and stage (spermatogonium, spermatocyte, spermatid, and spermatozoa), 30 cells were measured.

Diameters of each spermatogenic stage for the two ploidy groups were analyzed with a single factor (ploidy) ANOVA, and mean differences tested with the F-test (Neter et al. 1985). Significance was set at $P < 0.05$.

To establish the impact of triploidy on both nuclei and cell size, a ratio between nucleus diameter and total cell diameter was estimated by dividing the nucleus diameter by the total cell diameter. Additionally, the increase in area (Area = 3.1416 × radius^2) in triploids was estimated for each cell and nuclei from the following relationship; [(Area in 3n × 100 / Area in 2n) − 100].

Electron Microscopy

Five gonad samples from each ploidy group were taken 20 days after laboratory conditioning (9-month old) as well as five from each ploidy group from 12-month-old field scallops.

The methodology described by Komaru et al. (1994) was followed for transmission electron microscopy (TEM). Gonad samples (2 mm^2) were fixed with a 4% gluteraldehyde solution in 0.1 M Sorensen's phosphate buffer, pH 7.5, for two hours at 4°C. The pieces were then washed in Sorensen's buffer solution three times for 30 minutes, and post-fixed in 1% osmium tetraoxide (OsO_4) in the same buffer for one hour, at 4°C. Samples were then dehydrated in ethanol (25, 50, 70, 95, and 100%) for 20 minutes in each concentration, and twice in 100% propylene oxide for 20 minutes. They were embedded according to the protocol of the commercial Kit Embed 812 Electron Microscopy Sciences (Luft 1961). Sections of 900Å were obtained with an ultramicrotome (Reicher, Model OMU3), mounted on a grid and stained with 2% uranyl acetate for 20 minutes and lead citrate for five minutes (Komaru et al. 1994). Photo microscopy was done using a JEOL JEM-1200EXII TEM.

Diameters of cell and nuclei of spermatogenic stages captured by photographic prints of TEM were measured after scanning the photomicrographs. To correct for amplifications, the size bar of each EM photomicrographs was used as a reference. All measurements were done using the image analyzer SigmaScan Pro 5. The number of stages measured varied, and depended on the number found in photomicrographs (6 spermatogonia, 15 spermatocytes and spermatids, 30 spermatozoa nucleus, mitochondria, and flagella, and 21 for acrosome length and invaginations in spermatozoa). The low number of captured spermatogenic stages in the triploids did not allow for measurement.

Scanning electron microscopy (SEM) gonad samples (4 mm^2) were fixed, post-fixed, and dehydrated in the same manner. Samples were dried in a SAMDRI-PVT-3P critical point dryer and coated with gold in an EDWARDS S150B sputter coating system (Komaru et al. 1994). Photo-microscopy was done using a JEOL JSM-5410LV SEM. All electron microscopy work was done at the Institute of Cellular Physiology in the National Autonomous University of Mexico (UNAM).

RESULTS

Gonad structure of nine-month diploid and triploid scallops are presented in Figure 1. In diploid scallops the characteristic synchronized development of sperm and oocytes in the gonad was seen (Fig. 1A). Compared to diploids (Fig. 1C), gametogenesis in triploids was retarded (Fig. 1B), and spermatogenesis was largely abnormal with only a reduced number of acini showing development of spermatogenic stages (Fig. 1D).

A summary of differences in mean size of spermatogenic stages between the two ploidy groups is in Table 1. The acini of triploid scallops were significantly larger (55%, $P = 0.01$) than those in diploids. There were also significant differences between ploidy groups in the diameter of all spermatogenic stages, as well as in their nucleus. Triploid scallops not only had larger nuclei area in spermatogonia and spermatocyte than diploid scallops (37% and 112% larger area in 3Ns, respectively), but also more cytoplasm area (78% and 119% more in 3Ns). Spermatids were not found in triploids, and comparative measurements between ploidy groups were not possible, but the few spermatozoa found indicated that triploids had a 50% larger area than diploids (Table 1). The nucleus/total cell ratio of spermatogonia was smaller for triploids (0.67) than diploids (0.76), whereas for spermatocytes it was approximately the same ratio for both ploidy groups (0.88 for 2Ns, 0.86 for 3Ns).

Diploid Male Gonad Structure and Ultrastructure

The details of the male part of the gonad of a diploid scallop are shown in Figure 2 and Figure 3. Male germinal cells were grouped in acini ranging from 120 to 200 μm in diameter. Each acinus contained a variety of developing stages distributed in a centripetal pattern from the inner acinus wall to the lumen (Fig. 2A). The spermatogonia (Spg) are oval shaped, and located nearest to the inner wall, whereas the spermatocytes (Spc) are smaller and loose from the acinus wall, positioned between the Spg and the lumen of the acinus. Mature spermatozoa (Spz) are almost exclusively confined to the central lumen of the acinus (Fig. 2A). The Spg had a diameter in ultrastructure measurements of 6.95 μm, and a nucleus 4.39 μm. The Spc appeared to be more numerous than the Spg (Fig. 2B), with a diameter approximately 3.92 μm, and a nucleus 2.93 μm. The Spc cytoplasm contained a complement of organelles, Golgi bodies (Gb) and mitochondria (Mi), very similar to those in the spermatogonia. The nucleus of primary spermatocytes (Spc1) exhibits scattered electron-dense chromatin (Fig. 2C), and its cytoplasm contains some Mi and Gb. Spermatids (Spm) in their early stages are spherical cells about 2.63 μm in diameter by ultrastructure measurements, with a dense nucleus, also spherical, about 1.95 μm in diameter (Fig. 2D). In the cytoplasm of the maturing Spm, Mi can be seen in what will be the basal pole of the future Spz.

The Spz have a proximal acrosome (Ac), nucleus (Nu), and a maximum of five cross-sectioned Mi in its distal part (Fig. 3A), where the flagellum (Fl) emerges. The anterior part of the spermatozoa, where the acrosome is, appears slightly denser than the nucleus. The ultrastructure of the spermatozoa in diploid *Argopecten ventricosus* can be divided into three main components: a sperm head consisting of the Ac and Nu, a middle piece consisting of two centrioles and the mitochondria, and a tail or flagella. The acrosome is invaginated toward the nuclear surface forming a conical structure about 0.51 μm in height, and it is composed of an outer layer with electron dense material and an inner layer of electron lucent material (Fig. 3A). The spherical electron-dense Nu is 1.82 μm in diameter and presents an anterior

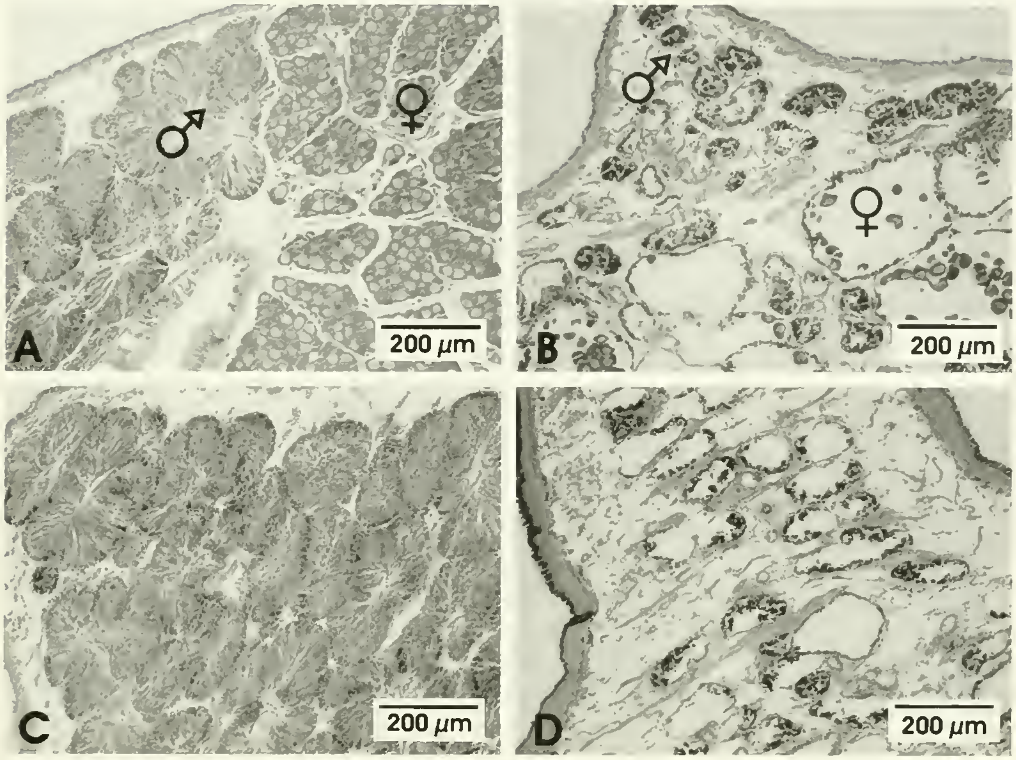

Figure 1. Diploid and triploid light photomicrographs. A. Diploid female and male gonads in advanced stages of gametogenesis. B. Triploid female and male parts of the gonad at 9 months old. C. Diploid male portion of the gonad in advanced stage of spermatogenesis. D. Triploid male part of the gonad with few spermatogenic stages developing.

invagination (Ai) 0.23 μm in depth (Fig. 3A), and a posterior invagination (Pi) 0.29 μm in depth (Fig. 3B). The distal mid-part of the spermatozoa head contains a ring of three to five cross-sections of mitochondria, each about 0.76 μm in diameter around two centrioles (Fig. 3B, 3C). The proximal centriole (Pc) is joined to the nuclear envelope by a satellite body (not shown) found in the post-nuclear fosse. The distal centriole (Dc) is joined and forms the basal body of the Fl, which has a diameter of 0.31 μm. Granules of glycogen (Gi) are detected between the mitochondria cross-section (Fig. 3B). Transversal cuts of the flagellum show the classical structure of nine external microtubule doublets (Md) and two internal single microtubules (Fig. 3D).

TABLE 1.

Mean diameter (SD) of spermatogenic stages ($n = 30$) in diploid and triploid catarina scallop *Argopecten ventricosus* measured by image analyses—light microscopy, and percent increase area in triploids with regard to diploids.

Spermatogenic stages	Diameter (μm) Diploid	Diameter (μm) Triploid	Percent area increase in 3N
Acinus^1	167 (36)^a	259 (47)^b	141
Spermatogonia^2	6.30 (0.43)^a	8.41 (1.64)^b	78
Spermatogonia nucleus^2	4.81 (0.36)^a	5.62 (1.11)^b	37
Spermatocyte^2	3.81 (0.31)^a	5.64 (0.44)^b	119
Spermatocyte nucleus^2	3.34 (0.32)^a	4.86 (0.36)^b	112
Spermatid^3	2.62 (0.25)	n.a.	
Spermatozoa^3 head	1.69 (0.08)^a	2.07 (0.15)^b	50
Number of sperm/ 1000 μm^2	250,000	2–3	

Superscript numbers in spermatogenic structures indicate magnification used for measurements: 1 = 4×; 2 = 10×; 3 = 100×. n.a. = not available for measurements. Different letters between ploidy groups indicate significant differences ($P < 0.05$).

Triploid Male Gonad Structure and Ultrastructure of Nine-Month-Old Scallops Conditioned in the Laboratory

Male acini of triploids were larger than in diploids, with a diameter varying from 197 to 387 μm. On the acinus wall dark colored cells representing Spg can be seen, and detached from the acinus wall some Spc were present. In some of the triploid scallops, Spz were seen sparsely distributed in the lumen of the acinus when using the Feulgen stain (Fig. 4A), and also when using scanning electron microscopy (Fig. 4B). The overall structure of the spermatozoa produced by a triploid catarina scallop appears to be similar to those produced by a diploid.

The spermatogonia were oval, and had the chromatin uniformly dispersed in small aggregations, with numerous mitochondria in the cytoplasm (Fig. 4C). As in diploids, the primary spermatocyte had a smaller size than the spermatogonia, and their cytoplasm contains a complement of organelles very similar to the spermatogonia (Fig. 4D). In the nucleus, the chromatin, set out in clusters, indicates the spermatocytes were in zygotene-pachytene stages of prophase I. There was no evidence in transmission electron microscopy of secondary spermatocytes and spermatids, although as already stated, some spermatozoa were observed by scanning electron microscopy (Fig. 4B).

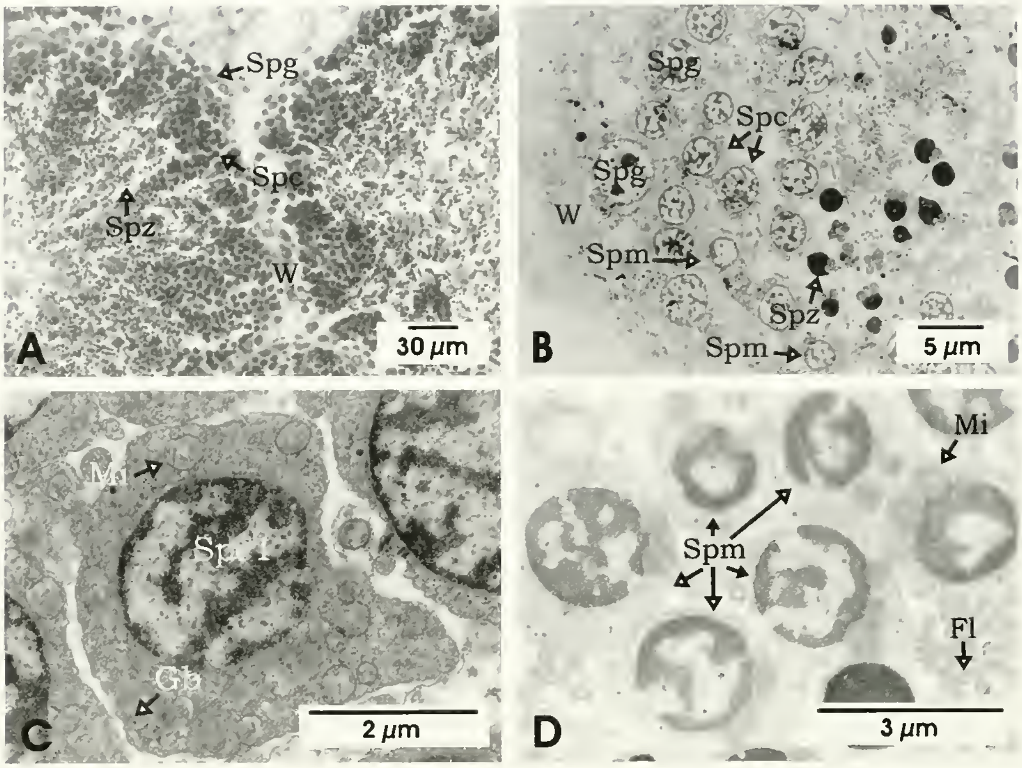

Figure 2. Diploid gonad structure and ultrastructure. A. Light microscopy (LM) of male acinus with spermatogonia (Spg) attached to the wall (W), spermatocytes (Spc), and spermatozoa (Spz). B. TEM of spermatogenic stages: Spg, Spc, spermatid (Spm), and Spz. C. TEM of primary spermatocyte with multiple mitochondria (Mi) and Golgi bodies (Gb). D. TEM of Spm with mitochondria at posterior pole, transversal cuts of flagella (Fl).

Triploid Male Gonad Structure and Ultrastructure of Field Scallops Sampled at 12 Months Old

The male part of the gonad in some triploid catarina scallops at age 12 months had a mixture of male and female acini, with both male and female gametogenic stages occurring in different acinus. However, most of the male germinal cells were in the process of degeneration. Large numbers of hemocytes were invading the male acini (Fig. 5A, 5B), which were characterized by the presence of degenerating spermatogonia and primary spermatocytes (Fig. 5C). The hemocytes were of the basophilic granulocyte type, with a not centrally positioned oval-rounded nucleus 4.5 μm in diameter, condensed chromatin, and an entire cell approximately 8 μm in diameter (Fig. 5D).

In most triploid scallops a gonad sex change occurred, as the male part of the gonad (the most distal part) was completely suppressed and female germinal structures were replacing the male germinal structures (Fig. 6A). Oocytes developing in the male part of the gonad of triploids (Fig. 6B) were similar to those found in the female part of the gonad of a diploid (Fig. 6C). They contained numerous vitelline inclusions, cortical granules and a vitelline coat.

DISCUSSION

The ultrastructure of diploid spermatogenesis was similar to that described by Dorange and Le Pennec (1989a) for *Pecten maximus*, with some size and morphology differences which is not surprising, as closely related species are known to have similar but not identical ultrastructure of gametic stages (Le Pennec & Beninger 1997).

Differences in cell size between triploid and diploid mollusks have been reported only for egg size (Guo & Allen 1994a, 1994c; Eversole et al. 1996; Utting et al. 1996; Ruiz-Verdugo et al. 2001) or sperm size (Komaru et al. 1994), but in triploid fish species an increase in size of different cell types has been reported (Valenti 1975; Ueno 1984; Small & Benfey 1987; Aliah et al. 1990). In the present study not only spermatogonia, but also all other spermatogenic stages measured indicated a larger cell size in triploids than diploids. Furthermore, an increase in spermatogenic stage size was not necessarily a correlate of increase in nucleus size. For example, there is an expected increase in the nucleus/total cell ratio of spermatocytes when compared to that same ratio in spermatogonia occurring as a consequence of nuclear distention (Dorange & Le Pennec 1989a). However, whereas the increased ratio in spermatocytes was observed in this study for both ploidy groups, the nucleus-total cell ratio in spermatogonia was smaller for triploids than diploids, and this occurred despite the larger nucleus in triploid spermatogonia than in diploids. This, as well as the increase in area estimated for triploid spermatogonia cell and nuclei indicates that a larger increase in cell size than nucleus size occurs in triploid spermatogonia of catarina scallop, and might be caused by a larger number of organelles (mitochondria, endoplasmic reticulum, ribosomes) than those found in diploids, as previously proposed by Guo and Allen (1994a) to explain the increased egg size of triploid oysters. These authors proposed that the increase egg size could be a consequence of a larger nucleus requiring a larger cytoplasm,

such that allocation of nutrients and organelles is in adequate proportions during cell divisions. Unfortunately, because of the few spermatogenic stages found in triploids when electron microscopy was done, quantification of the number of organelles could not be accomplished.

The spermatozoa of triploid catarina scallop was morphologically similar to that in diploids, although as shown by Komaru et al. (1994) for the Pacific oyster, it showed a larger head than that in diploids. The diameter differences observed between diploid and triploid spermatozoa of catarina scallop correspond to an area for triploid sperm of 1.5 times that of a diploid sperm, and is most probably a consequence of an increased amount of DNA in the sperm produced by triploids. Komaru et al. (1994) found an increase area of 1.4 times in sperm from triploids when compared with diploids, and the increase in area in triploid spermatozoa of the Pacific oyster has been shown to agree with an increased amount of DNA (1.5 of that in sperm from diploids) by flow cytometry (Allen 1987; Guo & Allen 1994a). In spite of the size increase, the spermatozoa of triploid catarina scallop had the same number of cross-sectioned mitochondria than diploids. A larger number of organelles in gametic cells have been demonstrated only for tetraploid Mediterranean blue mussel, but not for sperm produced by triploid Pacific oyster. That is, Komaru et al. (1995) found that spermatozoa from tetraploid Mediterranean blue mussels had from 5 to 7 mitochondria with a mode of 6, whereas that from diploids had 5. Contrary to that, spermatozoa from triploid Pacific oyster, although larger than that in diploids, had the same number of mitochondria as diploids (Komaru et al. 1994).

The observation of spermatozoa in triploid catarina scallop, even if in low numbers was important because previously, Ruiz-Verdugo et al. (2000) were unable to observe sperm in triploids from this same species, but their histology techniques were limited to H&E staining and light microscopy. In the present study, the use of the Feulgen stain for light microscopy allowed for the finding of some spermatozoa in isolated acinus, an observation that was corroborated when spermatozoa were also found by scanning electron microscopy. However, even if present, the rare occasions in which spermatozoa were found indicates that the triploid condition in catarina scallop results for the most part in an arrest of spermatogenesis early during the process of gamete formation, at the primary spermatocyte stage. That is, the arrest occurs at meiosis I, when the secondary spermatocyte would be produced by the first meiotic reduction (Beninger & Le Pennec 1991). The nearly complete arrest of meiosis at the primary spermatocyte stage has been previously noted by ultrastructure analysis in other bivalves such as *Saccostrea commercialis* (Cox et al. 1996) and *Mytilus galloprovincialis* (Kiyomoto et al. 1996). Contrary to that, in triploid *Crassostrea gigas* spermatogenesis has been reported to be reduced, but not arrested at the primary spermatocyte as spermatid and spermatozoa production occurs (Allen & Downing 1990), the last one being capable of fertilizing eggs (Guo & Allen 1994a).

The finding that in older triploid catarina scallop the male portion of the gonad was replaced with female acini is similar to that reported by Ruiz-Verdugo et al. (2000) after studying the annual gametogenic cycle of diploids and triploids for this scallop. The few gametic stages still present in the male acini of scallops

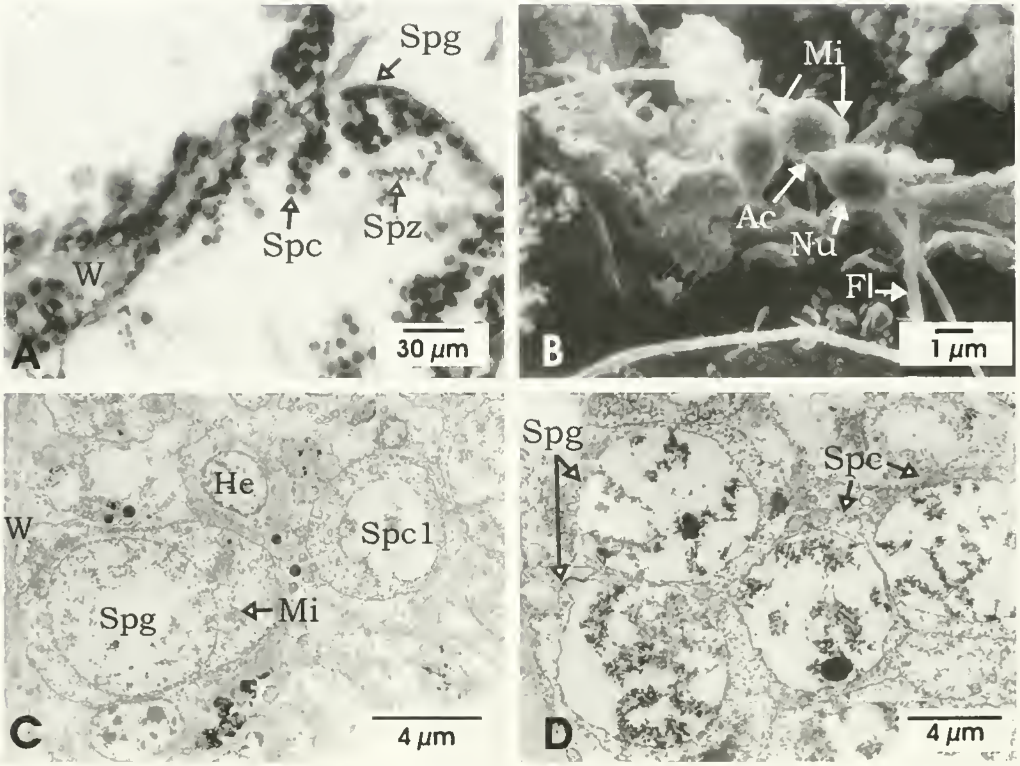

Figure 4. Triploid structure and ultrastructure of male part of the gonad. A. Scanning electron microscopy (SEM) of spermatozoa found in a male acinus, with electron dense nucleus (Nu), acrosome (Ac), mitochondria (Mi) at the base, and flagella (Fl). C–D. TEM of section through a male acinus with spermatocytes (Spc1), spermatogonia (Spg), and haemocyte (He).

12 months old were being lysed and possibly recycled through phagocytic activity, as demonstrated by the presence of large numbers of hemocytes, which are known to play a role in phagocytosis of degenerating pectinids gametogenic structures (Dorange & Le Pennec 1989a, 1989b; Beninger & Le Pennec 1991). The hemocytes were the typical ones described for other bivalves such as *Mya arenaria* and *Mytilus edulis* (Cheng 1981).

With this study we have demonstrated that the male gonad of triploid catarina scallop is almost but not completely sterile, as the lack of male gametes occurs until after spermatogenesis begins and is arrested, observing later oogenesis in male acini. The cause of the reversal of sex in male acini of catarina scallop is not known, but might be a consequence of the arrest of meiosis signaling, possibly through a neuroendocrine mechanism, an arrest of synthesis or release of some type of maleness factor required for spermatogenesis. Neuroendocrine factors are known to be necessary for development of male and female gonad in some mollusks (Feral et al. 1987), or only needed for development of the male gonad in functional hermaphrodites for which female gonad results from auto-differentiation (Gomot & Griffond 1993). The existence of those neuroendocrine factors has been demonstrated by isolation in other mollusks (van Minnen et al. 1989), but not in pectinids.

With regard to the arrest of meiosis, it has generally been presumed that the primary cause for triploid sterility, measured as inability to form viable and large number of gametes as in diploids, is the inability of chromosomes to pair and complete synapses because of multivalent formation. However, it has been demonstrated at least for one species that this is not the cause of sterility. Guo and Allen (1994a) established that for the Pacific oyster, *Crassostrea gigas*, the normal synapse of chromosomes and normal segregation was not a necessary event to obtain mature gametes in triploids, as they observed that the extra set of chromosomes segregated randomly in spawned eggs from triploids. To explain the sterility induced in triploids it is interesting to point to new research being done in the molecular genetic field. During the last decade a series of "housekeeping" mechanisms or "checkpoints" operating in the cell cycle during meiosis have been described for a number of experimental organisms. Their function is to detain further development when problems during replication, recombination, or segregation are present in a cell, and it is possible to explain some of the abnormal events occurring in triploids gametogenesis by considering them. These checkpoints act by means of protein complexes signaling abnormalities in chromosome behavior, and effector proteins acting on those signals to delay or arrest the meiotic process (Roeder & Bailis 2000). For example, among the described checkpoint mechanisms for meiosis is a "S-phase or premeiotic replication checkpoint," which functions on detecting chromosomal lesions after replication, but before recombination (Murakami & Nurse 1999). A second checkpoint mechanism, the "recombination or pachytene checkpoint," is known to act on gametogenic cells that have not completed correctly the recombination between sister chromatids during meiosis I, or in which the synaptotemal complex is defective, and it will arrest meiosis at pachytene (Murakami & Nurse 1999, 2000; Roeder & Bailis 2000; Tarsounas & Moens 2001). A third checkpoint mechanism, the "metaphase checkpoint," has been described for arresting meiosis in metaphase I, by blocking the metaphase to anaphase transition when chromosomes are misaligned on the spindle apparatus. An interesting aspect of this checkpoint mecha-

nism is that it is known to operate in mammalian males, halting spermatocytes at metaphase I, but oocyte formation is not affected or detained even when missegragation will result (for review see: Roeder & Bailis 2000). By considering the possible phenotypic effects of these three checkpoints on gametogenesis, we can parallel some of the known events in triploid gametogenesis. For example, the delay in the onset of gametogenesis known to occur in both sexes of triploids (Allen et al. 1986; Allen 1987; Allen & Downing 1990; Guo & Allen 1994b; Cox et al. 1996; Eversole et al. 1996; Kiyomoto et al. 1996; Komaru & Wada 1989, 1990; Ruiz-Verdugo et al. 2000) can be explained by the first checkpoint mechanism, the "replication checkpoint." If we can presume that DNA replication in triploids will have a larger probability of errors needing correction because more DNA is present, that could result in a delayed onset of gametogenesis. The delay reported to occur in triploid gametogenesis and not necessarily on their growth can be explained by a difference between meiosis and mitosis: the S-phase in meiosis usually takes from two to five times longer than the S-phase in mitosis (Murakami & Nurse 2000). The second checkpoint mechanism, the "pachytene checkpoint", agrees well with the observation that spermatogenesis is arrested at the pachytene-zygotene stage of prophase in meiosis I, at the primary spermatocyte, and also agrees with the fact that a lower number of vitellogenic and mature oocytes are formed in triploid catarina scallop than diploids (Ruiz-Verdugo et al. 2000, 2001), as it is known that in diploid scallops only oocytes that complete the pachytene stage and enter the diplotene stage will begin the process of vitellogenesis and become mature (Dorange & Le Pennec 1989b; Beninger & Le Pennec 1991). Further research on oocyte type frequencies in diploid and triploid mollusks are necessary to understand precisely at which stage oogenesis is halted.

In conclusion, this study has established spermatogenetic differences between diploid and triploid catarina scallop *Argopecten ventricosus*, pointing toward the halting of spermatogenesis occurring during prophase of the first meiotic division. Future studies are necessary to establish the level of ploidy and functionality of the few produced male gametes in triploids.

ACKNOWLEDGMENTS

This research was supported by CONACYT grant 28256-B to A. M. Ibarra. We thank Carmen Rodriguez-Jaramillo from CIBNOR for histology technical support, and Dr. Mark West, Rodolfo Paredes and Jorge Sepulveda from the Institute of Cellular Physiology of the UNAM for their support to carry out the ultrastructure analyses. We thank Dr. Elena Palacios for valuable suggestions on the manuscript. We also thank Dr. Alejandro Lopez-Cortes from CIBNOR for his advice on preserving tissues for ultrastructure analysis, and Sergio Rosas and Gerardo Hernández-García for the photography prints. The Scan Pro program used for the image analyses was that from Dr. Mario Monteforte at CIBNOR. The senior author is a CONACYT and SEP (DECYTM) Ph.D. fellow, and the results presented here are part of his thesis. Dr. Ellis Glazier edited the English language.

REPRODUCTIVE CYCLE OF *SPONDYLUS CALCIFER* CARPENTER, 1857 (BIVALVIA: SPONDYLIDAE) IN THE "BAHÍA DE LORETO" NATIONAL PARK, GULF OF CALIFORNIA, MEXICO

MARCIAL VILLALEJO-FUERTE, MARCIAL ARELLANO-MARTÍNEZ, BERTHA P. CEBALLOS-VÁZQUEZ, AND FEDERICO GARCÍA-DOMÍNGUEZ
Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional, Apartado Postal 592, La Paz, B.C.S. 23000, México

ABSTRACT The reproductive cycle of *Spondylus calcifer* from Bahía de Loreto, Gulf of California, was studied from January 1998 to March 1999. Microscopic analyses established that this species is gonochoric. The size at spawning occurred at 113-mm in shell height. *S. calcifer* exhibits a short spawning period from August to October followed by a long inactive period from November to February. Increase in water temperature initiates the gonadal maturation process, while decrease in water temperature inhibits gametogenesis. The threshold water temperature for spawning in *S. calcifer*, is 29 C. Nutrient reserves from the digestive gland are mobilized and used by the gonad during the developing stage. Meanwhile, reserves stored in the muscle are used only after gamete production has started, helping to support the energetic output during the ripe and spawning stages. In Bahía de Loreto, the period of highest phytoplankton abundance in bottom waters coincides with the onset of gametogenesis in *S. calcifer*. This suggests that *S. calcifer* also depends on food intake for oocyte growth.

KEY WORDS: spawning season, histology, energy transfer, *Spondylus calcifer*, Gulf of California

INTRODUCTION

Spondylus calcifer Carpenter, 1857 commonly named "Burra clam," belongs to the Spondylidae Family. It is geographically distributed from the Gulf of California to Peru. This clam can be found from intertidal to subtidal zones, attached by the right valve to exposed boulders or under rock ledges (Skoglund & Mulliner 1996). At present in Loreto, Baja California Sur, Mexico, this species is not commercially exploited; however divers capture it (only in small quantities) for human consumption year around.

This clam is the largest species of the genus *Spondylus*. *S. calcifer* is considered in danger of extinction (Baqueiro et al. 1982), and is currently protected by Mexican laws (Norma Oficial Mexicana 1994). Despite the above, there are no published records on its biology. Few articles have been published about the genus *Spondylus*, most focusing on the taxonomy, anatomy, morphology, habitat, and other topics (Yonge 1973; Dakin 1928 a,b; Mata et al. 1990; Parth 1990; Okutani 1991; Skoglund & Mulliner 1996). There is only one study about the reproductive cycle and spawning season of *Spondylus leucacanthus* (Villalejo-Fuerte & García-Domínguez 1998).

The present study describes the reproductive cycle throughout 15 months, and the spawning season of *S. calcifer*, from histological analysis and measurements of the volumetric fraction of oocyte. Additionally, the relation between the reproductive cycle and gonadic, digestive gland and muscle yield indexes is analyzed.

MATERIALS AND METHODS

Sampling was conducted in Bahía de Loreto, Gulf of California, Mexico (25°48′54″, 111°15′45″) (Fig. 1). Fifteen to 30 specimens of *S. calcifer* were collected monthly, from January 1998 to March 1999, by scuba diving at 10-m depth. Shell height and wet weight of the gonad, digestive gland, muscle and total soft body were recorded for each clam after fixation in a neutral 10% formalin solution prepared with sea water. Water temperature was recorded at each sampling time. The photosynthetic pigment concentration (mg chlorophyll/m^3) in Bahía de Loreto from January 1998 to March 1999 was obtained from Seawifs Project, NASA/Goddard Space Flight Center, and this was considered as an estimation of the food availability for the clams.

Because *S. calcifer* does not exhibit sexual dimorphism, individual sex was determined through histological analysis. The sex ratio for the total sample was obtained. The null hypothesis of a 1:1 sex ratio was established and its significance was tested using a chi-squared analysis (Sokal & Rohlf 1979).

For histological studies, gonads were dehydrated in an alcohol series and embedded in paraplast. Sections (7 μm) were placed on slides and stained with hematoxylin-eosin (Humason 1979).

The classification of gonadal development was similar to that of *S. leucacanthus* (Villalejo-Fuerte & García-Domínguez 1998), which includes five development stages: undifferentiated, developing, ripe, spawning, and spent. To facilitate the description of the reproductive cycle, the monthly relative frequencies for all gonadal development stages were calculated.

The size at spawning in the population is defined as the smallest length at which 50% of females and males are spawning (Somerton 1980). The size at spawning was estimated as the shell height at which the 50% of cumulative frequency of clams in the spawning stage was attained.

Three indexes were calculated: gonad index (GI), digestive gland index (DGI) and muscle yield index (MYI). Each index was calculated by dividing the gonad, digestive gland or muscle wet weight (respectively) by the total soft body wet weight, and expressing the results as a percentage (Sastry 1970).

Furthermore, the monthly proportion occupied by developing and mature oocytes combined (volume fractions) were estimated by stereology (Lowe et al. 1982; MacDonald & Thompson 1988). The gamete volume fraction (GVF) was obtained from point counts in a Weibel eyepiece graticule mounted in an ocular microscope and applied to a gonadal section (100X). Three replicates were done for each gonad. The algorithm of Lowe et al. (1982) was applied: GVF = No. of positive counts/total points

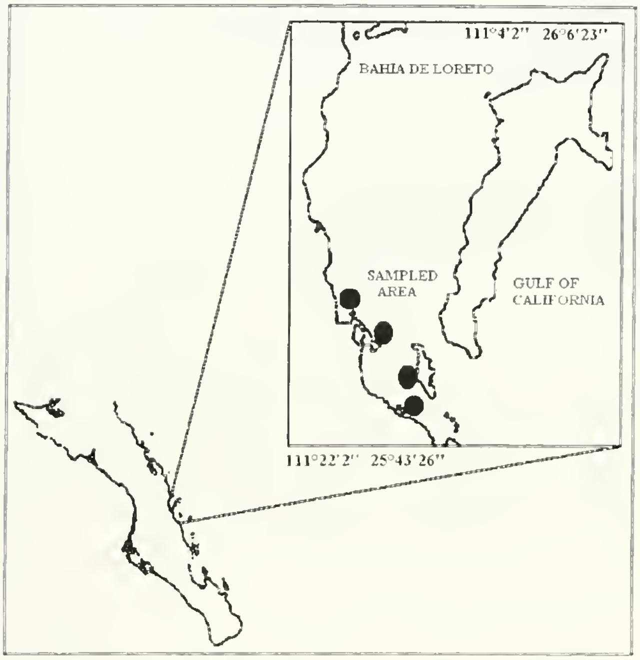

Figure 1. Location of sampling station in Bahía de Loreto, Gulf of California, Mexico.

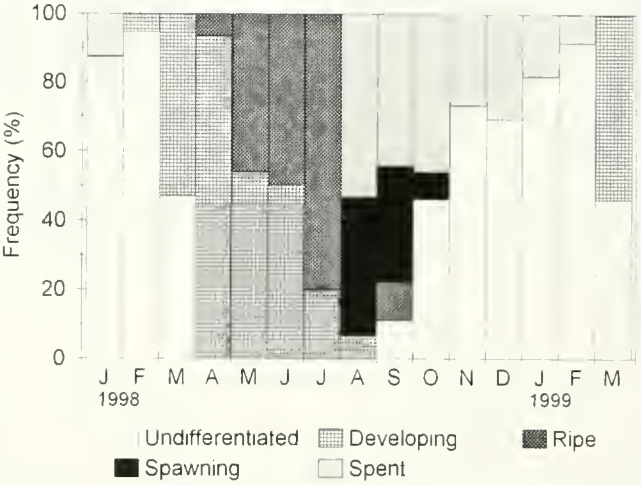

Figure 2. Reproductive cycle of *Spondylus calcifer* in Bahía de Loreto, Gulf of California. Relative frequency of gonadal stages between January 1998 and March 1999. Observations of males and females are combined.

counted X 100. GVF was calculated as the sum of the values for developing and mature oocytes in all females. The monthly mean GVF values were plotted.

A Spearman-rank correlation analysis was used to investigate the relationship between monthly mean values of GI, DGI, MYI, GVF, water temperature, and photosynthetic pigment concentration. As GI, DGI, and MYI are percentage values, the arcsine transformation (Sokal & Rohlf 1979) was used to attain data normality and homoscedasticity for statistical analysis.

RESULTS

A total of 223 clams were captured, of which 27% were females and 32% were males. The remaining (41%) were undifferentiated. The sex ratio for the total sample was 0.8 F:1 M and did not significantly differ from the expected ratio of 1:1 ($P > 0.05$). Shell height ranged from 70.5 mm to 165.2 mm, with the mode at 115 mm.

The reproductive cycle of *S. calcifer* was remarkably seasonal (Fig. 2). In January and February of both years, the majority of clams was inactive. Gametogenesis started in February in a small proportion (5.3%) of the clams. By March 52.9% of the clams were in the development stage. Development continued until August with the highest proportion occurring in April (93.7%). Ripe clams were found from April (6.2%) to July when the highest proportion was observed (80.0%). A small proportion of ripe clams was found in September (11.1%). Spawning was found in a higher proportion during August and September (40.0% and 33.3%, respectively) and dropped drastically in October (7.7%). From November to February, only undifferentiated and spent stages occurred.

Figure 3 shows that the size at spawning in the population of *S. calcifer* is 113-mm in shell height; however, individual organisms may begin spawning at 86 mm in shell height.

The GI shows its peak values during May, June, and July, coinciding with the occurrence of the highest frequencies of clams in the ripe stage. The GI declined from August to October, coinciding with the spawning season. A period of low values occurred from November to March, coinciding with the highest frequencies of spent and inactive stages (Fig. 4a).

The DGI shows high values in February, declining from March to June leave as is coinciding with the developing and ripe stages. In August and September (months in which the highest proportions of clams in spawning stage occur), the DGI values decrease. Afterwards, from October to March, DGI values start to rise again, coinciding with a reproductive inactivity of the specimens (Fig. 4b).

The MYI values decreased according to the maturation process, beginning the decrease in April, two months after the onset of gonadal development (February). The lowest MYI value was found in January 1999 and the higher value was found in March 1999 (Fig. 4c).

The volumetric fraction of gametes reflected the gonad devel-

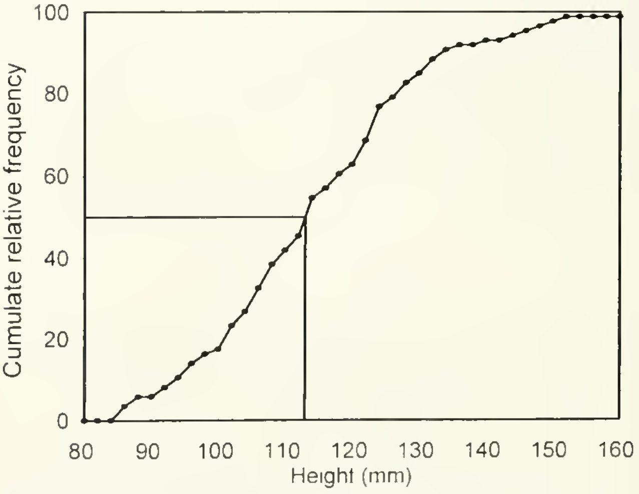

Figure 3. Size at spawning of 50% of the population of *Spondylus calcifer* in Bahía de Loreto, Gulf of California, Mexico.

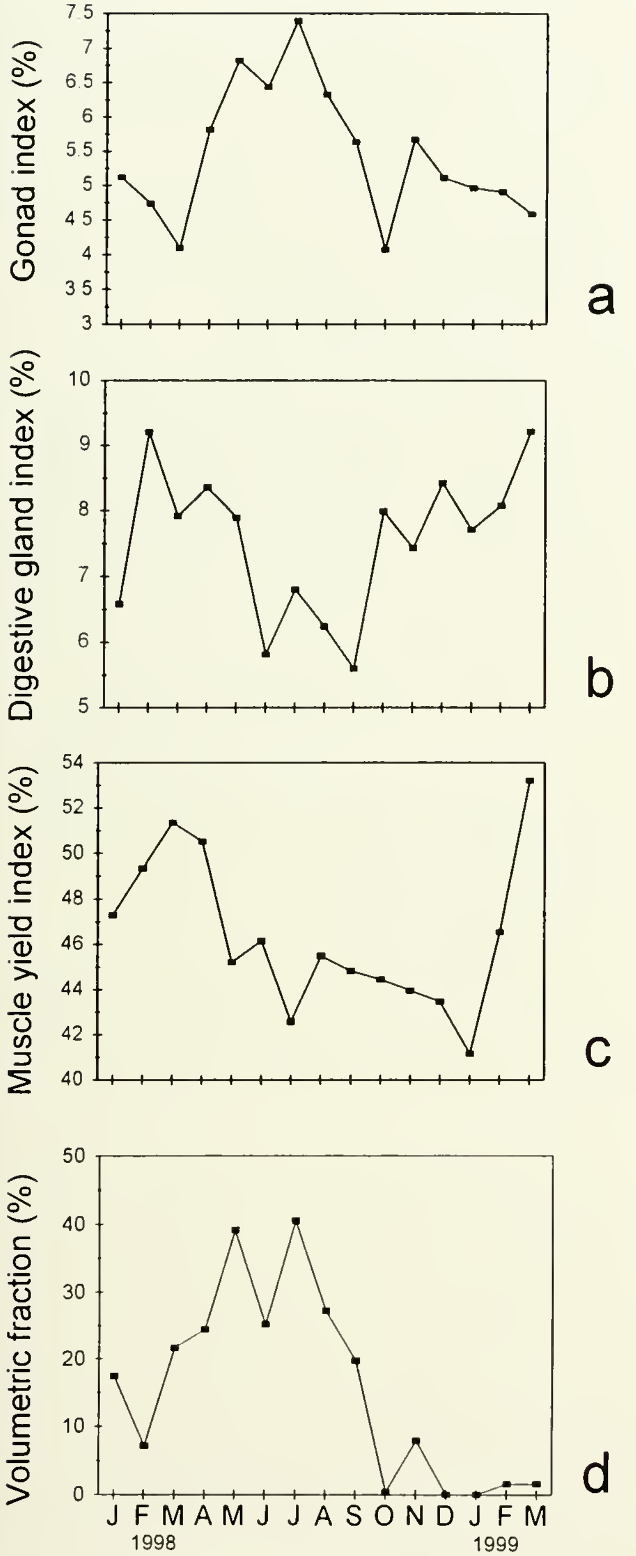

Figure 4. Variation in the mean values of a) gonad index, b) digestive gland index, c) muscle yield index, and d) oocyte volumetric fraction.

opment stages. Values increased when development and ripe stages were present, and they decreased concurrently with the spawning stage. Low values occurred when the inactivity and spent stages prevailed (Fig. 4d).

Seawater temperature varied seasonally from 19°C to 29°C during the study period. Temperature increased from March to August, reaching its peak (29°C) from August to October, then decreasing from November to February. The lowest temperature was recorded in February, both years (19.5°C and 19°C) (Fig. 5).

Photosynthetic pigment concentration (mg chlorophyll/m^3) in Bahía de Loreto was greater in the colder months than in the warmer ones. The maximum value was in March 99 (2.1 mg chlorophyll/m^3) and the minimum was in September (0.2 mg chlorophyll/m^3) (Fig. 6).

GI and GDI values were negatively correlated, with statistical significance ($P < 0.05$). GVF had a significant positive correlation ($P < 0.01$) with GI and a significant negative correlation with photosynthetic pigment concentration ($P < 0.05$). GDI showed a significant negative correlation with temperature ($P < 0.05$) and a significant positive correlation with photosynthetic pigment concentration ($P < 0.01$). The photosynthetic pigment concentration showed a significant negative correlation with temperature ($P < 0.01$). No significant correlation was found between MYI and any other variable ($P > 0.05$).

DISCUSSION

In the Gulf of California low densities of *S. calcifer* have been reported, ranging from 1 clam per 100 m^2 (from 1 to 25 m deep) to 1–5 clams per 25 m^2(>25 m depth) (Baqueiro et al. 1982). In this study, the number of organisms captured per month corresponds to these low population densities.

The histological analysis revealed that *S. calcifer* is a gonochoric species as no hermaphrodite or sex-reversal specimens were collected. However hermaphroditism has been reported in 3.8% of clams studied for *S. leucacanthus* from the same locality (Villalejo-Fuerte & García-Domínguez 1998). The sex ratio of *S. calcifer* was not different from 1:1, as also found for other bivalves like *Mercenaria mercenaria* (Heffernan et al. 1989), *Venus striatula* (Gaspar & Monteiro 1998), and *Megapitaria squalida* (Villalejo-Fuerte et al. 2000). No references regarding the sex ratio for this species were found in the literature. However, *S. leucacanthus*, a related and sympatric species, presents a sex ratio different from parity (Villalejo-Fuerte & García-Domínguez 1998).

The size at spawning in *S. calcifer* occurs at 113-mm in shell height, although specimens may start to spawn at 86-mm in shell height. In contrast, in the sympatric species *S. leucacanthus*, the size at spawning is 75-mm in shell height with some spawning specimens being as small as 40-mm in shell height. This difference in size at spawning may result from *S. calcifer* being a the larger species within the genus *Spondylus*.

The reproductive cycle of *S. calcifer* was remarkably seasonal. *S. calcifer* exhibits an annual reproductive cycle with a short spawning period from August to October followed by a long inactive period largely during the winter (November–February). The reproductive cycle of *S. calcifer* was similar to the one described for *S. leucacanthus* (Villalejo-Fuerte & García-Domínguez 1998). In both species, recruitment occurs once per year with a similar short spawning period. These characteristics correspond to a conservative reproductive strategy, similar to the one reported for *S. leucacanthus* (Villalejo-Fuerte & García-Domínguez 1998).

Gametogenic cycles are generally ruled by external environmental factors that may trigger and synchronize the "timing" of the different stages (Lubet 1983). The synchronization of the

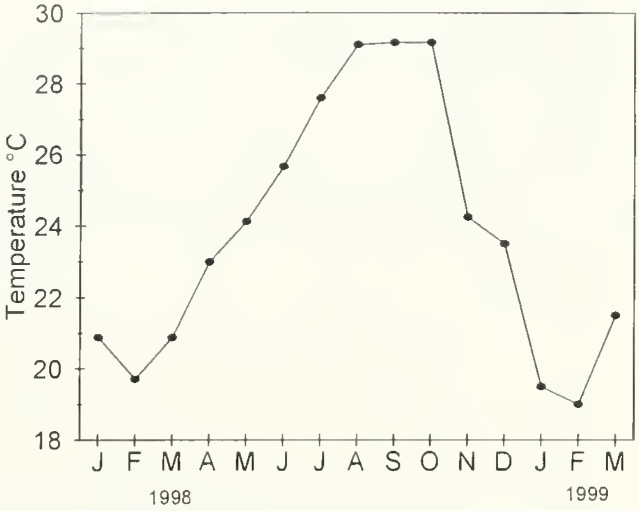

Figure 5. Variation of surface temperature from January 1998 to March 1999 in Bahía de Loreto, Gulf of California, Mexico.

gonadal cycles in a population is probably also the result of some kind of exogenous regulation (Gallardo 1989). Most studies consider that temperature is the important environmental factor in the regulation of bivalve reproduction (gametogenesis and spawning) (Giese and Pearse 1974; Sastry 1979; Barber & Blake 1981). However, in this study temperature was not correlated with GI. Nevertheless, the increase in water temperature coincided with the beginning of gametogenesis. The above suggests that the rise of water temperature may be responsible for triggering the gonad maturation process, however, laboratory studies are need to confirm it. In this respect, it had been previously observed that sudden increases in water temperature appear to be the final cue for stimulating maturation and ovulation in some fish species (Bye 1990).

In *S. calcifer* the inactive period (undifferentiated and spent stages) occurs from November to February, when water temperature drops (from 29°C in October to 19°C in February). Thus, it is reasonable to state that the decrease in water temperature inhibits gametogenesis, but newly laboratory studies are necessary to confirm this conclusion. Similarly, a cooler temperature inhibits gametogenesis in *Spisula solidissima* (Kanti et al. 1993). On the other hand, spawning in *S. calcifer*, only occurs when water temperature is at least 29°C (August to October). This fact suggests that 29°C is the threshold water temperature at which spawning occurs in *S. calcifer*. A threshold temperature for spawning has also been reported for some oyster species (Burrell 1985). In contrast, in other clam species, like *Paphies donacina* and *Cerastoderma edule* spawning occurs within a relatively wide temperature range (Navarro et al. 1989; Marsden 1999).

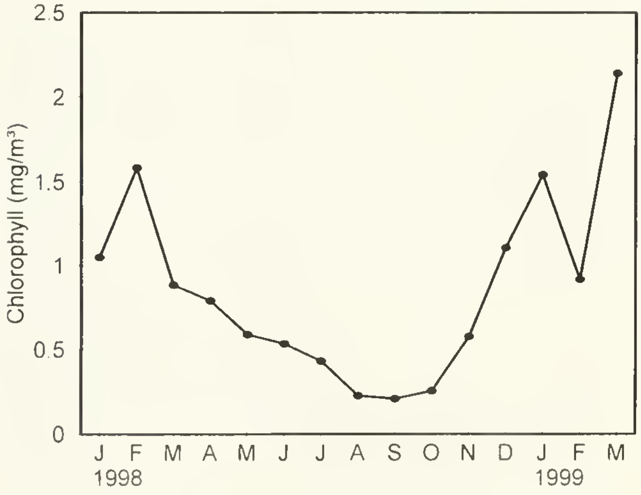

Figure 6. Variation of photosynthetic pigments concentration from January 1998 to March 1999 in Bahía de Loreto, Gulf of California, Mexico.

The bivalve gamete production is strongly influenced (set in a seasonal context) by environmental factors such as temperature but also by food availability (MacDonald & Thompson 1985). However, both factors may be strongly related. In this work, the photosynthetic pigments concentration was negatively correlated with temperature. Then the higher food availability for clams (expressed as photosynthetic pigment concentration) were during the cold months coinciding with the resting period. On the other hand, the spawning season of *S. calcifer* coincide with the lowest food availability (August to October). A relation of spawning time and food availability was found in *Chlamys amandi* (Jaramillo et al. 1993), whereas *Hinnites giganteus* showed no correlation between food availability and spawning (Malachowski 1988).

The DGI had a significant positive correlation with photosynthetic pigment concentration, then the higher food availability and the higher DGI values were during the inactive period of reproduction. The trend observed for DGI suggests that a period of accumulation of nutrient reserve in the digestive gland takes place during the inactive period. These nutrient reserves are mobilized and utilized by the gonad during the developing stage. The significant negative correlation between DGI and GI confirms the above for *S. calcifer*. In mollusks, it has been observed that the onset of the oocyte growth phase is dependent upon the accumulation and transfer of nutrient reserves from the digestive gland to the gonad (Sastry 1968; Gabbott & Bayne 1973).

Despite MYI and GI not being correlated, MYI values start to decrease in April, just two months after gametogenesis had started. This suggests that there is a delayed in energy transfer from muscle to gonad. The reserves accumulated in the muscle are used up after gamete production had started, helping to support the energetic output during the ripe and spawning stages. Similarly, in *Argopecten irradians* it appeared that lipids from the digestive gland were used to fuel the beginning of gametogenesis whilst adductor muscle reserves become important later on to complete gonadal development (Barber & Blake 1981). A relationship between MYI and GI has been observed in *Pecten maximus* (Comely 1974; Faveris & Lubet 1991), *Argopecten irradians* (Sastry 1966), *Patinopecten yessoensis* (Mori 1975), *Placopecten magellanicus* (Robinson et al. 1981), and *Argopecten circularis* (Villalejo-Fuerte & Ceballos-Vázquez 1996).

However, in pectinids and other bivalves, it has been proposed that oocyte growth is dependent on two factors: food intake and energetic storage in specialized organs (Sastry 1963, 1966, 1968; Barber & Blake 1983). In *P. magellanicus* and *A. circularis*, the energy for gamete maturation comes from both stored reserves and ingested food (Thompson 1977; Robinson et al. 1981; Luna-González et al. 2000).

ACKNOWLEDGMENTS

We are grateful to The Instituto Politécnico Nacional (IPN) for funding this work, and for the grants (EDI and COFFA) to the authors. We also wish to thank to Sofia Ortega for the data of photosynthetic pigments concentration and to María Elena Sánchez-Salazar for his editorial help on the English manuscript.

BACULOVIRUS-LIKE PARTICLES IN EPITHELIAL CELL OF DIGESTIVE DIVERTICULA OF THE SCALLOP, *PATINOPECTEN YESSOENSIS*

YOUNG JIN CHANG,[1]* MIN-DO HUH,[2] MYUNG-JOO OH,[3] AND YOSHIO SUGAWARA[4]

[1]Department of Aquaculture, Pukyong National University, Busan 608-737, Korea; [2]Department of Aquatic Life Medicine, Pukyong National University, Busan 608-737, Korea; [3]Department of Aqualife Medicine, Yosu National University, Yosu 550-749, Korea; [4]Department of Biotechnology, Senshu University of Ishinomaki, Ishinomaki 986, Japan

ABSTRACT Virus-like particles were encountered in one epithelial cell of digestive diverticulum in a clinically healthy scallop, *Patinopecten yessoensis*. Virions, showing typical rods, were found in the cytoplasm without marked cellular degenerative change and were recognized as ovoid or spherical bodies, depending on sectional orientations. The envelope was approximately 12 nm in thickness and the space between the envelope and nucleocapsid was about 10 nm. Average length and diameter of the complete virions were 520 and 130 nm, respectively. No occlusion bodies were observed. From this morphological evidence, it was considered that the virus particles observed in one epithelial cell of digestive diverticulum in the scallop are likely to be a species of nonoccluded, baculovirus type C, which are morphologically very similar to the baculovirus associated with white spot syndrome (WSS) and baculoviral mid-gut gland necrosis (BMN) in shrimp.

KEY WORDS: bivalve, *Patinopecten yessoensis*, baculovirus, white spot syndrome (WSS), baculoviral mid-gut gland necrosis (BMN)

INTRODUCTION

A number of infectious diseases have been observed in bivalves such as oysters, clams, mussels, and scallops. Because bivalve production represents a considerable proportion of fisheries industry in South Korea, much attention is now being paid to the cause of the massive deaths occurring in bivalve farms along the southern coast. To date, diseases have been reported from 63 species of parasites, 7 strains of bacteria, 2 strains of fungi, and 3 strains of rickettsia or chlamydia. More recently, five kinds of viral diseases were reported from oysters (Fisher 1988; Sindermann 1990; Couch & Fournie 1993; Faisal & Hetrick 1994; Woo 1995). There are two other kinds of diseases with unknown cause. For most of the diseases cited, little is known regarding pathologic effects on the host and methods of prevention and control.

Virus particles were, by chance, encountered in one epithelial cell of digestive diverticulum during a study on the relationship of histological structures in digestive diverticula to nutrient accumulation. The morphological characteristics of the particles are described in comparison with other virus particles and discussed with respect to pathogenic potential.

MATERIALS AND METHODS

Thirty scallops were sampled every month from March 1982 to December 1983 from a bottom culture farm in Abashiri waters of Hokkaido, Japan. Each individual, ranging from 8.5 to 11.2 cm in shell height and from 62.9 to 197.4 g in total weight, was clinically healthy. For transmission electron microscopy, all scallops were necropsied and their digestive diverticula were carefully removed, then diced into 1-mm cubes. All tissue cubes were prefixed with a 5% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4, 4°C). After postfixation with 0.2 M cacodylate buffered 2% OsO_4 for about an hour, tissue blocks were dehydrated in a graded series of ethanol and embedded with Epon 812. Ultrathin sections were obtained using an ultramicrotome (Porter Blum II, Agwam, Massachusetts, USA) and stained with uranyl acetate and lead citrate. The grids were examined with a transmission electron microscope (JEOL 100B, Tokyo, Japan) under an accelerating voltage of 80 kV.

RESULTS

As shown in Figure 1, one epithelial cell containing viral particles corresponded to type I of the 3 types of cells that have been classified by Chang et al. (1989). Because of the shortness of apico-basal length, it appears to be embedded between the other types of cells. Cytoplasm of the virus-containing cell was completely occupied basally by a densely packed mass of rough endoplasmic reticulum (RER) and apically by a round area containing a number of viral particles.

A great number of virions had a fence-like array, which again formed several layers, roughly in parallel. Virions showed typical rods in shape but, depending on the sectional orientation, they were ovoid or spherical (Fig. 2). Virions were present among a great number of small vacuoles that appeared to be a network of proliferated, tubular smooth endoplasmic reticulum (TER). A layer of variably sized, unidentified vacuoles surrounded the virus-containing area (Fig. 3). The vacuoles, ranging from 520 to 1050 nm in diameter, were spherical in shape and clearly limited by double membranes. They also had thread-like or fuzzy materials with high electron density. No other morphological abnormalities were found in this virus-infected cell.

Each virion had a nucleocapsid and an envelope of unit membrane that was quite similar morphologically to baculovirus (Fig. 4). The average thickness of the envelope was 12 nm and the average distance from the nucleocapsid was 10 nm. The average length and diameter of virions were 520 and 130 nm, respectively. No occlusion bodies were observed.

DISCUSSION

There have been few reports on viral diseases in bivalves, and most of these were reported for oysters. Since the first identification of birnavirus from clam, *Tellina tenuis* (Hill 1976), retrovirus-like particles from clam *Mya arenaria*, iridovirus-like particles from oyster *Crassostrea angulata*, and herpes-like particles from

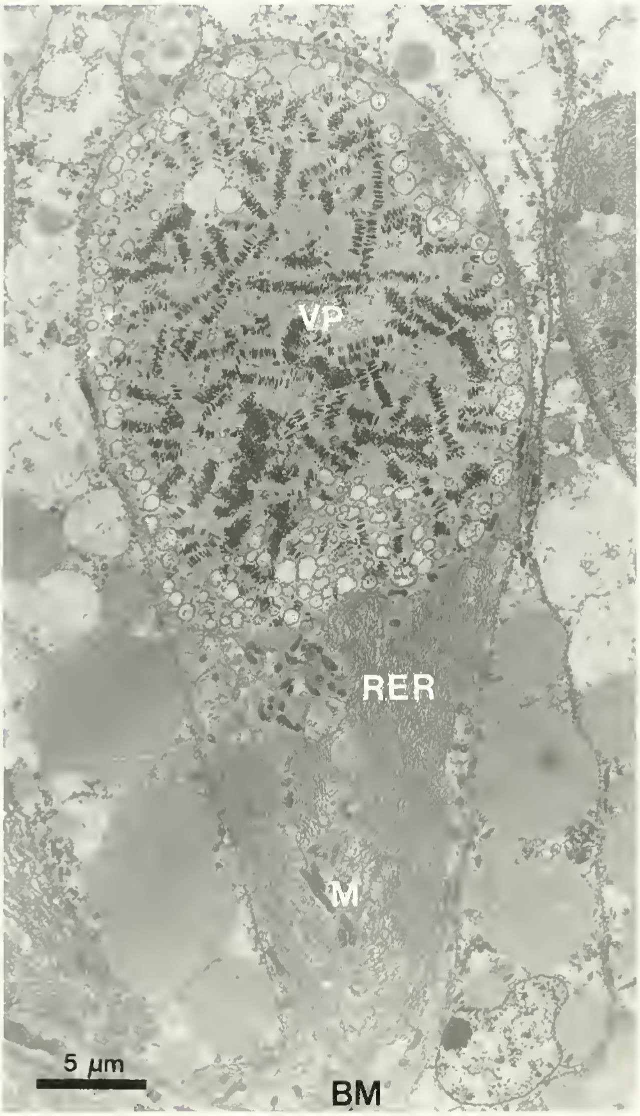

Figure 1. Virus-infected type I cell in digestive diverticula epithelium. This cell was very similar to pancreatic exocrine cells of mammalian pancreas. Cytoplasm near the basement membrane (BM) of the cell contained many large flattened cisternae of the rough-endoplasmic reticula (RER) and relatively few mitochondria (M). The apical part of the cytoplasm was without marked degenerative change, but the cell was filled with numerous viral particles (VP).

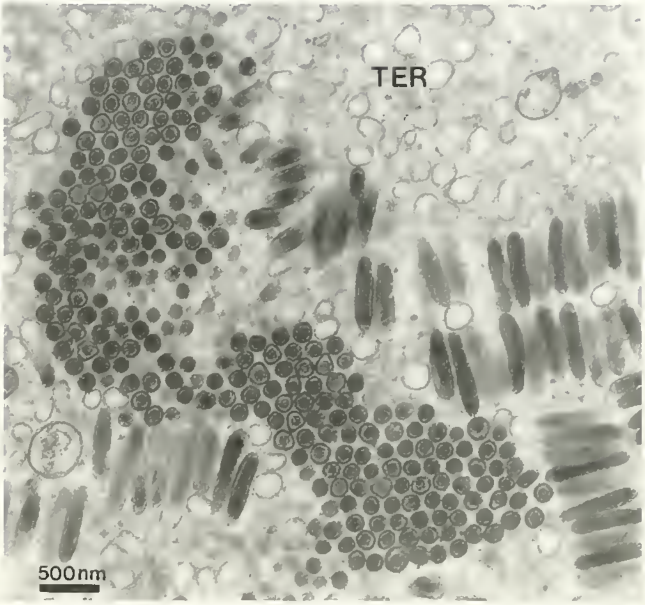

Figure 2. Fence-like array of viral particles. Numerous viral particles surrounded by tubular smooth endoplasmic reticula (TER) were rod-shaped, spherical, or ovoid in morphology, because of the difference in viewing orientation.

C. virginica have been reported (Perkins 1993). Since oyster velar virus disease (OVVD) caused by iridovirus was reported from farmed *C. gigas* (Elston & Wilkinson 1985; Sindermann & Lightner 1988; Bower et al. 1994), descriptions followed on small and nonenveloped virus particles from digestive diverticulum of pearl oyster *Pinctada maxima* (Pass et al. 1987), green lip mussel *Perna canaliculus* (Jones et al. 1966), herpes-like particles from hemocytes of flat oyster *Ostrea angasi* (Hine & Thorne 1977) and enterovirus or calicivirus-like particles from digestive diverticula of scallop *Pecten novaezelandiae* and toheroa *Paphies ventricosum* (Hine & Wesney 1977).

Virus particles in this study were morphologically different from those particles previously reported, but were quite similar to baculovirus that has not been described from bivalves. In general, baculoviruses are rod-shaped DNA viruses, which are known to be infective only in invertebrates. Baculoviruses are divided into the three subgroups of nuclear polyhedrosis virus (NPV, type A), granulosis virus (GV, type B), and nonoccluded virus (NOV, type C) (Sindermann & Lightner 1988; Faisal & Hetrick 1994; Levy et al. 1988).

From shrimps, six kinds of baculoviruses, including baculovirus penaei disease (BP virus disease), monodon baculovirus disease (MBVD), baculoviral mid-gut gland necrosis (BMN), plebejus baculovirus disease, and yellow-head disease (YHD), have been described, although their pathogenesis is still poorly understood (Faisal & Hetrick 1994). The causative agent responsible for white spot syndrome (WSS), which was responsible for mass mortality of shrimps in Taiwan during the last 7 years, was identified to be a species of baculovirus (Wang et al. 1997).

All baculoviruses reported in shrimps range from 150 to 310 nm in length and 33 to 74 nm in diameter. Virions in the scallop were very similar in size to causative viruses responsible for BMN and MBVD in shrimps. The finding that they did not form occlusion bodies is consistent with the viruses responsible for BMN and WSS in shrimps. The causative virus of BMN belongs to NOV type C that is found only within the hypertrophied nucleus. BMN frequently brings about mass mortality in an early larval stage of shrimp. Histologically, BMN is characterized by necrosis of epithelial cells in the hepatopancreas and mucosal membranes with a variety of nuclear changes, including severe hypertrophy, margination and loss of chromatin, and loss of nucleoli (Momoyama & Sano 1988; Momoyama & Sano 1989). In contrast, WSS is characterized by homogeneous nuclei with a variable degree of nuclear hypertrophy in nearly all kinds of tissue except for hepatopancreatic epithelium (Wang et al. 1997).

Even though grossly and microscopically no marked lesions were found in association with the presence of viral particles in the scallop, it was considered that the viral particles in this animal should be carefully monitored for the pathogenic potential.

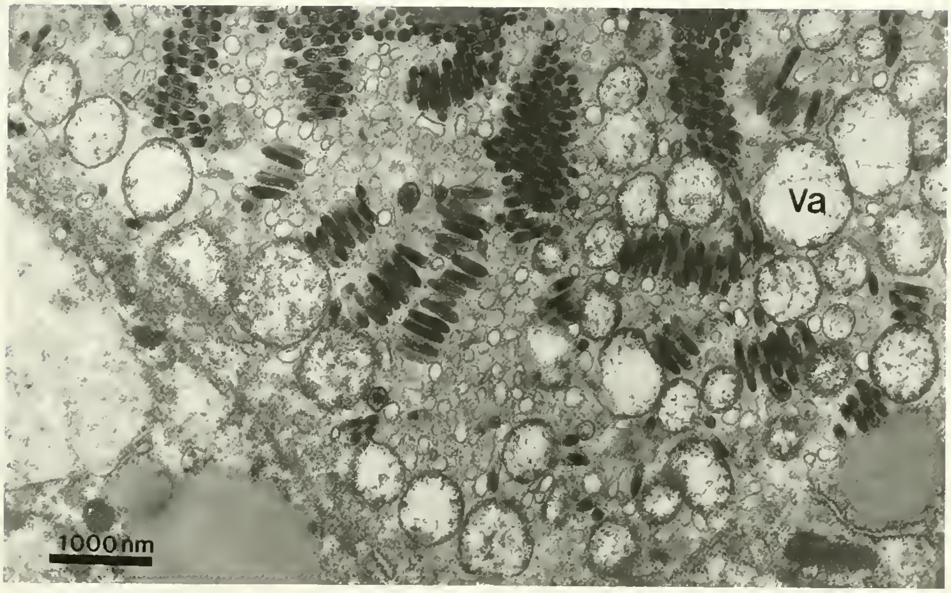

Figure 3. The cluster of viral particles was surrounded by unidentified vacuoles (Va).

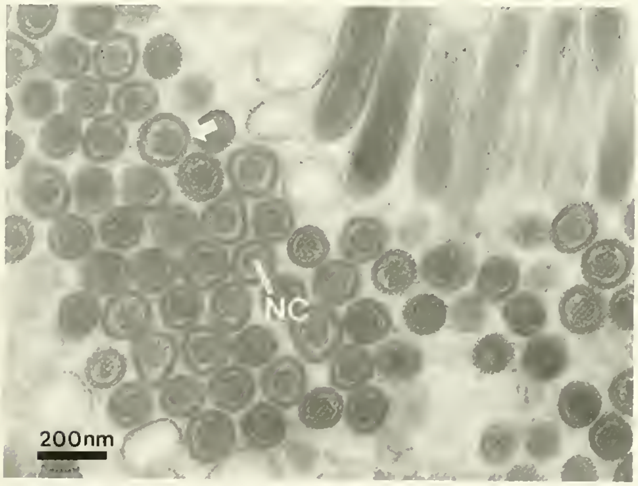

Figure 4. Higher magnification of Figure 2. Single envelope (arrow) and a central nucleocapsid (NC) were recognized in each viral particle. The clear spaces between envelopes and nucleocapsids were recognizable from all orientations of viral particles.

Box 1552, Oak Bluffs, Massachusetts 02557*

ABSTRACT A haplosporidian parasite, *Haplosporidium costale* (seaside organism or SSO), is associated with high mortalities of eastern oysters (*Crassostrea virginica*) in seaside bays of Virginia and Maryland. Its presence in Long Island Sound has been tentatively suggested in several publications for the last 50 y. Positive identification of *H. costale* and differentiation from another haplosporidian parasite, *Haplosporidium nelsoni* (MSX), from histological sections is difficult and requires the presence of spores. We detected *H. costale* spores in 4 out of 5010 (0.08%) oysters collected from Long Island Sound in 1997–1999. *In situ* hybridization using an oligonucleotide DNA probe designed to detect small subunit ribosomal DNA from Virginia's *H. costale* reacted positively with tentative *H. costale* plasmodia in 5 oysters from Long Island Sound. In each case there was a coinfection of *H. nelsoni*. In Virginia and Maryland, *H. costale* has historically sporulated in all infected animals in May–June. In Long Island Sound, the rare sporulating cases were detected in October–December, suggesting a different infection cycle.

KEY WORDS: *Haplosporidium costale*, eastern oyster, *Crassostrea virginica*, *in situ* hybridization, Long Island Sound

INTRODUCTION

A haplosporidian parasite, *Haplosporidium costale*, was identified as the causative agent of seaside organism (SSO) disease, resulting in high mortalities of eastern oysters (*Crassostrea virginica*) on the Atlantic coast of Virginia (Wood & Andrews 1962). Prevalence, mortality and infection cycle of *H. costale* have been thoroughly studied in Virginia and Maryland, but information from other geographical locations is scarce. In seaside bays of the Delmarva Peninsula, the first plasmodia can be detected in the epithelia of digestive tubules in April–May. Plasmodia rapidly proliferate in May and sporulate synchronously. Peak mortality of the oysters is in May–June, when dying oysters release spores in seawater to initiate a new infection cycle. New infections remain subpotent until spring of the following year. Mortality of oysters has been 20% to 50% annually in the seaside bays of Virginia (Andrews 1988; Andrews & Castagna 1978).

Reports of *H. costale* distribution north of Virginia's Atlantic coast are inconsistent. Several reports suggest the presence of plasmodia resembling *H. costale* in eastern oysters in Long Island Sound. According to Andrews (1984, 1988), SSO disease ranges from Cape Charles, Virginia, to Maine, but is important only in high-salinity bays (>25‰) from Cape Henlopen, Delaware, to the Virginia capes. He stated that the pathogen is regularly present from New York to Massachusetts, but mortality has not been a serious problem. However, a mortality event in Long Island Sound in 1953 may have been caused by *H. costale* (Andrews 1988). Sampling locations, dates, prevalences, or possible presence of spores were not mentioned in these reports.

Newman (1971) studied 1,337 oysters from New Haven Harbor, Connecticut, from 1966 to 1967. He found five specimens (0.4%) infected with plasmodia morphologically similar to *H. costale*, with one of the oysters moribund with heavy infection. No sporulation was detected. Meyers (1981) described haplosporidia-like plasmodia (4%) in juvenile oysters ($n = 68$) collected from Oyster Bay, north shore of Long Island, New York, from 1975 to 1976. He did not find similar organisms in adult oysters ($n = 145$). No effort was made to distinguish between different haplosporidian species because sporulating stages were not present. In addition, plasmodia morphologically identical to *H. costale* were observed in oysters transplanted from the vicinity of New Haven, Connecticut, to Tomales Bay, California, in 1967–1968 (Katkansky & Warner 1970). Six specimens with tentative *H. costale* infection (four moribund and two living) were reported, one with spores. Total number of oysters studied was not mentioned.

Reports of tentative *H. costale* infections in Long Island Sound reviewed above are based on histological examinations. Reliable diagnosis of *H. costale* on histological sections is nearly impossible when sporulating forms are not present. *H. costale* plasmodia can be easily misdiagnosed as *Haplosporidium nelsoni* (MSX), another haplosporidian oyster parasite enzootic to the area (for review, see Ford & Tripp 1996). During routine monitoring for oyster diseases in Connecticut, we found several oysters with spores and plasmodia consistent with descriptions of *H. costale*. We used a DNA probe, designed to detect *H. costale* from Virginia as the *in situ* hybridization (ISH) probe for these specimens to verify the presence of *H. costale* in Long Island Sound.

MATERIAL AND METHODS

The State of Connecticut, Department of Agriculture, Bureau of Aquaculture routinely receives oyster samples for histological diagnosis from Connecticut's commercial oyster companies. Most of the seed originates from natural seed beds, though some hatchery-raised seed is also used. Every oyster is transplanted an average of four times before it is marketed, which exposes it to possible parasitic infections in several different sites. Seventeen oyster samples were studied in 1997, 63 in 1998, and 87 in 1999. Each sample consisted of 30 oysters, for a total of 5,010 oysters. Samples represented the entire Connecticut shoreline and the north shore of Long Island, New York. Of the 167 samples, 20 originated from New York. Fifty-six of the samples originated from oyster nursery systems (5 from upwellers, 51 from suspended cultures), 30 from off bottom cultures, and 81 from natural oyster beds. Tissues were fixed in Davidson's fixative in 20‰ artificial seawater. Six-micrometer-thick paraffin sections were stained with hematoxylin-eosin. Samples with *H. costale* or *H. nelsoni* prespores and spores were stained also with Ziehl and Harris' hematoxylin according to Farley (1965).

The ISH procedure was conducted with 27 oysters, two with presumed *H. costale* spores and 25 oysters with haplosporidian plasmodia. Specimens were selected for ISH as follows: (1) specimens with haplosporidian plasmodia from samples in which *H. costale* spores were detected; (2) specimens with small plasmodia with central nucleoli, morphology that is considered to be characteristic for *H. costale*; and (3) specimens with plasmodia in the stomach, intestine, or digestive tubule epithelia, locations that are considered to be characteristic for *H. costale*. For the ISH procedure, 6-μm-thick sections from these oysters were deparaffinized and ISH was performed on consecutive sections as previously described (Stokes & Burreson 1995; Stokes & Burreson 2001). Two commercially synthesized digoxigenin-labeled oligonucleotide DNA probes were used: a 22-base oligonucleotide (SSO1318) specific for *H. costale* (Stokes & Burreson 2001) and a 21-base oligonucleotide (MSX1347) specific for *H. nelsoni* (Stokes & Burreson 1995). A negative control was performed by substituting DNA probes with distilled water during hybridization.

RESULTS

Haplosporidium costale was detected in three locations on Connecticut's shoreline: Norwalk, Branford, and Clinton (Fig. 1). *H. costale* was diagnosed in seven different specimens either by the presence of spores or by a positive ISH result. There were 17 oysters with haplosporidian spores among the 5,010 oysters studied (0.3%). Four oysters had a mixture of *H. costale* and *H. nelsoni* spores (0.08%). The remaining 13 contained only *H. nelsoni* spores. Locations, dates, and seed origin of oysters with spores are listed in Table 1.

H. costale and *H. nelsoni* spores differed in size, form, and location in oyster tissues. *H. costale* spores (3 × 4 μm), the sporoplasm of which stained bright red with acid-fast stain, were detected throughout the connective tissue. Prespores, which did not retain acid-fast stain, occurred inside sporocysts throughout the tissues. *H. costale* spores were found between vesicular connective tissue cells surrounding the digestive diverticula (Fig. 2A), in connective tissue of the gills, in the adductor muscle, in the heart, between neurosecretory cells in the ganglia, and between kidney tubules. On rare occasions, *H. costale* spores were detected inside digestive tubule or digestive duct cells, in the lumens of the digestive tubules and intestine, in epithelial cells of the intestine, or in the follicles.

H. nelsoni spores (5 × 7 μm), which also stained bright red with acid-fast stain, were in most cases restricted to digestive epithelial cells (Fig. 2B). However, during intense sporulation in four specimens there was an overspill to digestive duct cells and the connective tissue surrounding the digestive tubules. In cases with

extremely heavy sporulation, phagocytosed *H. nelsoni* spores were observed in the vascular system hemolymph sinuses and veins, in the mantle lobes and the gills, and being carried through stomach or mantle epithelia via diapedesis. Spores that occurred in the connective tissue were usually surrounded by aggregates of granular hemocytes. *H. nelsoni* spores were detected inside the lumens of digestive tubules, digestive ducts, and the intestine. *H. nelsoni* prespores, which did not retain stain in acid-fast reaction, were detected exclusively inside digestive cells.

It was as probable that spores would be found in oysters originating from natural set as in oysters originating from hatchery-raised seed ($\chi^2 = 0.68$ [not significant] [NS]). Oysters with spores were detected in most areas of Connecticut's shoreline. No sporulating specimens were detected in the north shore of Long Island, New York. The size of an oyster with spores did not differ significantly from the average size of the sample from which it was taken ($t = 0.08$ [NS]). The size of an oyster with spores also did not differ significantly from the average sizes of all oysters sampled for this study ($t = 0.97$ [NS]).

ISH results with *H. costale* and *H. nelsoni* DNA probes are summarized in Table 2. Five specimens had mixed infections, the rest were infected only with *H. nelsoni*. Two specimens with mixed infections had both types of spores present; three had only plasmodia. (An additional two specimens were diagnosed positive for both *H. costale* and *H. nelsoni* on the basis of the presence of spores [Table 1], with seven positive specimens altogether.) The two specimens with both spore types (Branford lots 179 and 316) that were subjected to ISH had prominent *H. costale* infections. Approximately 90% of the plasmodia hybridized with the *H. costale* probe and 10% hybridized with the *H. nelsoni* probe in these samples (Fig. 3). Two other specimens with mixed infections (Clinton and Norwalk 1131) had very light *H. costale* infections (Fig. 4). More than 99% of the plasmodia hybridized with the *H. nelsoni* probe and the very rare *H. costale* plasmodia would not have been detected without the probe. *H. costale* plasmodia in the

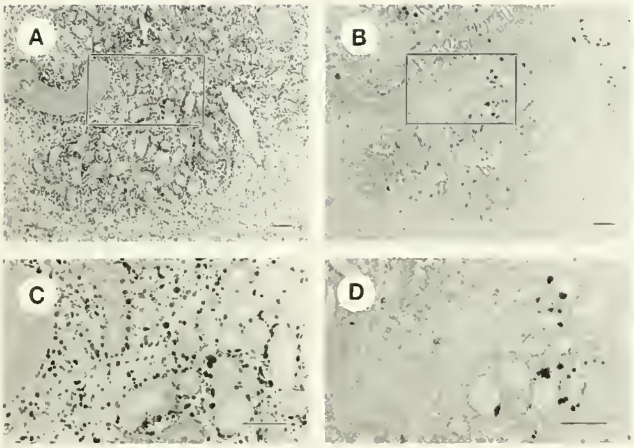

Figure 3. ISH of *H. costale*- and *H. nelsoni*-infected oyster from Long Island Sound. This is the same specimen as in Figure 2. (A) *H. costale* DNA probe hybridizing with *H. costale* plasmodia and prespores in the connective tissue surrounding digestive tubules. (B) *H. nelsoni* DNA probe hybridizing with *H. nelsoni* plasmodia and spores in digestive tubules. (C) Higher magnification of bracketed area in item (A). (D) Higher magnification of bracketed area in item (B). Scale bars 100 µm.

light infections were detected in the gills and the mantle, and in the heavy infections, were detected throughout the tissues.

ISH of an oyster with both *H. costale* and *H. nelsoni* spores is illustrated in Figure 3. *H. costale* probe hybridized to plasmodia and prespores scattered in the connective tissue surrounding the digestive diverticula (Fig. 3A and C), in the gills, and the mantle, whereas *H. nelsoni* probe hybridized to plasmodia and prespores mainly in the digestive tubules (Fig. 3B and D). This specimen represented a terminal infection of *H. nelsoni*, when migration of plasmodia to digestive tubules had already occurred. Both probes outlined mature spores but did not completely penetrate them. Serial sections of an oyster with mixed infection of *H. costale* and *H. nelsoni* plasmodia stained with hematoxylin-eosin and ISH with the DNA probes are illustrated in Figure 4A, B, and C.

DISCUSSION

The presence of *H. costale* in Long Island Sound has been suggested in several earlier reports (Andrews 1984; Andrews 1988; Katkansky & Warner 1970; Newman 1971); however, in the absence of sporulating stages, positive identification has been impossible. Failure to detect sporulating stages is easily explained on the basis of the results of the present report: spores were detected in only 0.08% of the oysters studied. We can assume that *H. costale* has been enzootic to the area, but its presence was finally verified, not because of increased prevalence, but because of increased sampling effort and the use of species-specific diagnostic tools. Furthermore, absence of spores in 1997 and in any of the samples collected from the north shore of Long Island, New York, is most likely due to small sample sizes (510 and 600 oysters, respectively), which would give <0.5% probability to encounter a sporulating specimen. High occurrence of positive specimens detected in Branford-Clinton area (Table 1) was due to intensive sampling in that area.

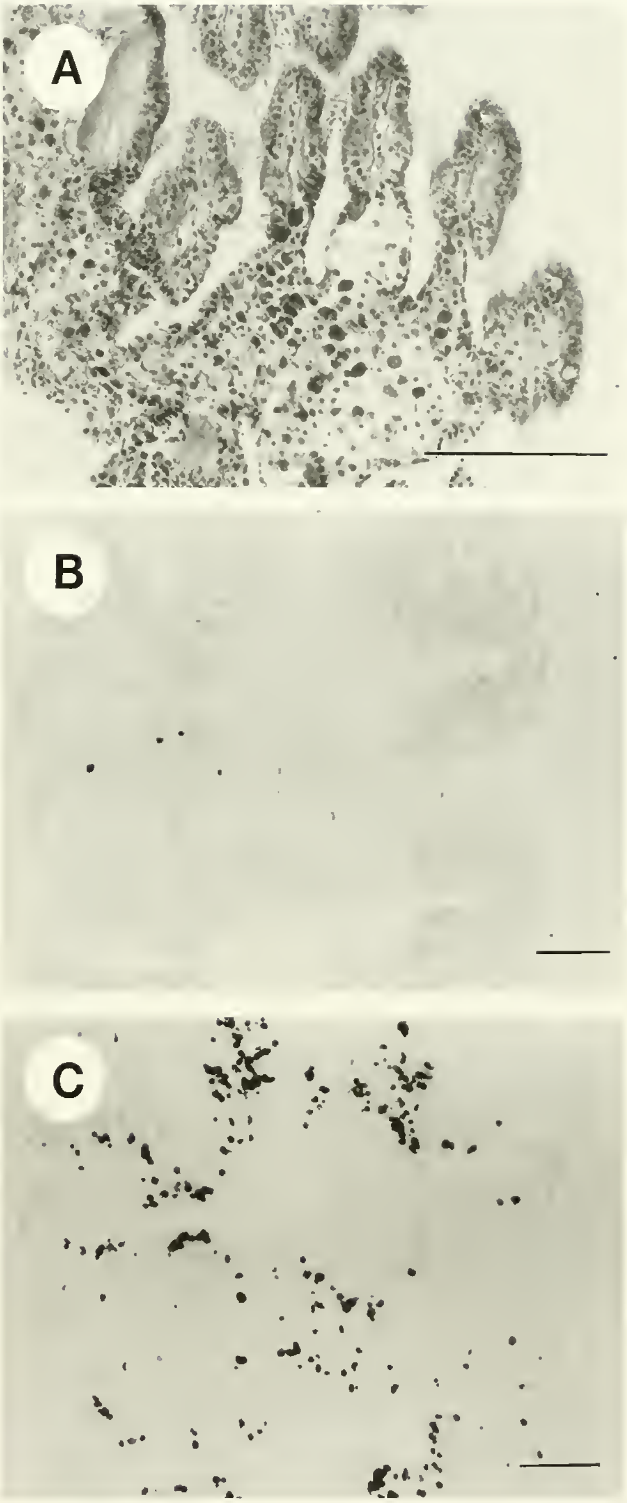

Figure 4. Serial sections of an oyster with mixed haplosporidian plasmodial infection. (A) Hematoxylin-eosin stain. (B) ISH with *H. costale* DNA probe detecting rare plasmodia in the gill. (C) ISH with *H. nelsoni* DNA probe of the same area shown in item (B). Scale bars 100 µm.

Detailed descriptions of sporulation and spore structures of *H. costale* or *H. nelsoni* are presented by Couch et al. (1966), Rosenfield et al. (1969), and Perkins (1969). Although morphological characteristics of *H. costale* spores or plasmodia in our material did not differ from those described in previous publications, *H. costale* in Long Island Sound appears to have a different pathogenesis than in the south. Gross signs as defined by Andrews (1988) (emaciation, failure of new shell growth in spring, high epizootic mortality mid-May–mid-June, and discoloration of gapers by spores) did not apply to our samples. In Virginia, infected oysters sporulate synchronously in May–July, presenting an obvious, easily diagnosed stage. All plasmodia develop into sporonts, and oysters die promptly after sporulation (Andrews 1984). *H. costale* is considered to be a well-adapted parasite that infects new oysters via spores that are released during mortality season (Andrews 1982). Spores are usually detected in moribund oysters and infection causes 20%–50% yearly mortalities (Andrews 1988). Cosporulation with *H. nelsoni* was reported previously by Couch (1967) in oysters collected from Chincoteague Bay, Virginia. The six cases with both spore types were dead and dying oysters collected in May and June during the characteristic *H. costale* sporulation time for oysters in Virginia (Couch 1967).

SSO disease in Long Island Sound differed from the above description in several ways. First, plasmodia and sporulation in the present material were found in October to December. During this time period, SSO disease in Virginia is subpatent and no plasmodia are detected before spring (Andrews 1988). However, in a recent paper describing *H. costale* probes also used in the present publication, Stokes and Burreson (2001) reported the presence of a positive ISH to *H. costale* plasmodia in an oyster sampled in October 1994 in Virginia. In the present paper, spores were detected in live specimens with no evidence of a synchronous mortality event. Spores were very rare, and infection always occurred as a coinfection with *H. nelsoni*. Because *H. costale* plasmodia were also detected in the samples, sporulation may occur infrequently. Rare sporulation such as presented in this report cannot sustain a widespread infection. Actual prevalence of *H. costale* in the area is not known based on the results of the present study, but the rare sporulation and the difficulty of finding positive specimens with ISH suggest a low prevalence.

Possible mortality associated with *H. costale* is impossible to estimate because of an *H. nelsoni* epizootic that occurred in Long Island Sound in 1997–1998 (Sunila et al. 1999). Oyster production in Connecticut decreased from more than 500,000 bushels in 1996 to 170,000 in 1999, reflecting high MSX-associated mortalities. According to Andrews (1984), *H. nelsoni* kills oysters much quicker than *H. costale*, and depresses manifestation of SSO disease during MSX epizootics.

H. costale is usually restricted to high-salinity bays with salinities >30‰. Its lower limit is 25‰ and salinities <20‰ appear to cause disease regression (Andrews 1979). It is possible that salinity in Long Island Sound's oyster beds is not high enough to sustain full epizootic *H. costale* activity. In Branford lots (Table 1), salinity varies between 26‰ and 27‰; in the Clinton Cedar Island Marina (in the mouth of Hammonassett River), salinity varies from 13‰ to 28‰. Oysters in the area are transplanted four times before they are marketed. This exposes them to even lower salinities, which may have provided a control for the disease.

Classically, the diagnosis of *H costale* relies on the presence of sporulating stages and the site of initial infection, which for *H. costale* is the epithelium of the digestive system and for *H. nelsoni* is the gill epithelium. In addition, history of the sampling area relating to past *H. costale* or *H. nelsoni* infections directs the diagnosis. In the present report, we were able to diagnose *H. costale* in a new geographic area with a deviating sporulation time by using DNA probes (Stokes & Burreson 1995; Stokes & Burreson 2001). Further research to study the infection cycle, prevalences, and possible association with mortalities is under way.

INFECTION INTENSITY, PREVALENCE, AND HISTOPATHOLOGY OF *PERKINSUS* SP. IN THE MANILA CLAM, *RUDITAPES PHILIPPINARUM*, IN ISAHAYA BAY, JAPAN

KWANG-SIK CHOI,[1]* KYUNG-IL PARK,[1] KI-WAN LEE,[1] AND KAZUMI MATSUOKA[2]
[1]*Faculty of Applied Marine Science, Cheju National University, 1 Ara 1-Dong, Jeju City Jeju-Do 690-756, Korea;* [2]*Laboratory of Coastal Environmental Sciences, Faculty of Fisheries, Nagasaki University, 1-14, Bunkyo-machi, Nagasaki 852-8521, Japan*

ABSTRACT Infection intensity, prevalence of infection, and pathologic features of *Perkinsus* parasitism among Manila clams inhabiting in Isahaya Bay, Japan, were investigated. Ray's fluid thioglycollate medium technique followed by Choi's 2 M NaOH digestion assay was applied to determine the infection intensity and prevalence. The infected tissues were also microscopically examined from histological preparations. The prevalence of infection was 57% in clams sampled in February 2001, and the mean infection intensity was 351,603 *Perkinsus* cells per clam or 225,701 *Perkinsus* cells/g of tissue. *Perkinsus* sp. was abundantly distributed in the gill and visceral mass, whereas it was rare in the adductor muscles and siphons. The total number of *Perkinsus* in the clams was linearly correlated with the number of *Perkinsus* cells in the gill tissues ($r^2 = 0.908$), suggesting that gill could be a target tissue for efficient diagnosis of *Perkinsus* infection. Heavily infected clams exhibited white nodules on the surface of the mantle as a consequence of inflammatory response to *Perkinsus* infection. Numerous trophozoites were observed in the connective tissue around the gonads and gill filaments, suggesting that heavy infection with *Perkinsus* may exert potential deleterious effects on growth and reproduction by interfering with the reproductive maturation and filtration activities of the clams.

KEY WORDS: *Perkinsus*, *Ruditapes philippinarum*, infection intensity, histopathology, Isahaya Bay, Japan

INTRODUCTION

The protozoan parasite *Perkinsus* sp. (Apicomplexa, Perkinsea) has been known to cause mass mortalities worldwide in commercially important shellfish, including oysters, scallops, clams, and abalones (Andrews & Hewatt 1957; Mackin 1962; Lester & Davis 1981; Navas et al. 1992; Blackbourn et al. 1998; Canestri-Trotti et al. 2000; Park & Choi 2001; Liang et al. 2001). In particular, *P. atlanticus* has been associated with mass mortalities of the venerid clams of the genus *Ruditapes* (i.e., *Tapes* or *Venerupis*) inhabiting the Mediterranean and Atlantic coasts (Da Ros & Canzonier 1985, Chagot et al. 1987, Sagrista et al. 1996). *Perkinsus* parasitism in the Manila clam ("short-necked clam"), *R. philippinarum*, was also recently confirmed in Japanese (Hamaguchi et al. 1998, Maeno et al. 1999) and Korean waters (Choi & Park 1997; Park & Choi 2001; Lee at al. 2001). *Perkinsus* sp. distributed in Korea is believed to be responsible for the mass mortality of Manila clams. This has occurred yearly, in late summer, since the early 1990s. Park and Choi (2001) postulated that the decline in Manila clam landings for the previous decade in Korea could be caused by *Perkinsus*-associated mortalities occurring in every late summer. As many other studies have reported, *Perkinsus* infection is associated with high salinity, temperature, and density of clam populations (Andrews & Hewatt 1957; Soniat 1996; Burreson & Ragone Calvo 1996; Cigarria et al. 1997).

Perkinsus-like microorganisms have been discovered in Manila clams distributed in Japan (Hamaguchi et al. 1998; Maeno et al. 1999) and China (Liang et al. 2001). Hamaguchi et al. (1998) reported on the occurrence of *Perkinsus* in the clams collected from Kumamoto and Hiroshima, in southern Japan. Comparison of the DNA sequence of *Perkinsus* with *P. atlanticus* and *P. olseni* indicated that the species of *Perkinsus* found in Kumamoto and Hiroshima, Japan, is taxonomically very close to *P. atlanticus* and *P. olseni* reported from Portugal and Australia (Hamaguchi et al. 1998). Manila clams are abundant in Isahaya Bay, southern Kyushu, Japan, where tidal flats are well developed and the clams are commercially cultured. Ishii et al. (2001) reported that the clam population in Ariake Sound has been declining significantly since 1987 due to overfishing, pollution, and predators. Because the presence of *Perkinsus* in clam populations inhabiting Ariake Sound was confirmed by Hamaguchi et al. (1998), detrimental effects of *Perkinsus* parasitism on clam growth, as well as on annual landings, cannot be ruled out in Isahaya Bay located on the west of Ariake Sound. However, infection intensity and prevalence of *Perkinsus* in the bay has not been reported previously.

Infection intensity and prevalence of *Perkinsus* parasitism on Manila clams was investigated from a clam population distributed in Isahaya Bay in the present study. This paper reports diagnosis, histopathologic features of the infected clams, infection intensity, and prevalence of *Perkinsus* parasitism in the clams collected in February 2001.

MATERIALS AND METHODS

A total of 191 clams were collected from Isahaya Bay, Kyushu, Japan, in February 2001 (Fig. 1). In the laboratory, shell length (SL), width (SW), thickness (ST), and tissue wet weight (TWT) of individual clams were recorded. Condition index (CI) was then calculated for evaluating fatness of the clams as

$$CI = [TWT/(ST \times SW \times SL)] \times 1{,}000$$

For evaluating *Perkinsus* infection, the clams were placed in two groups: one for histopathological examination and the other for measuring total body burden, which is the infection intensity of each clam as a total number of *Perkinsus* in a clam or number of *Perkinsus*/g tissue. For histopathology, a longitudinal section was made in the middle of the body, which included gills, digestive glands, gonads, mantle, and foot. A 5-μm thin section was cut for each clam after dehydration. The sections were then stained with Harris' hematoxylin and eosin Y. For measuring total body burden, the whole flesh of individual clams was immersed in fluid thioglycollate medium (FTM), fortified with nystatin and chloramphenicol to prevent bacterial activity (Ray 1966), and placed in

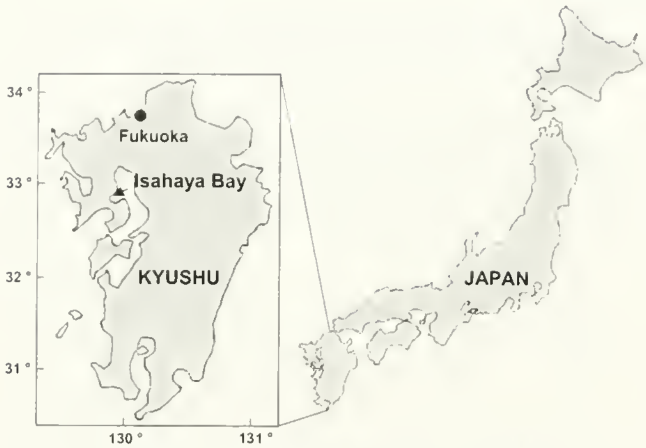

Figure 1. Location of the sampling site, Isahaya Bay, Kyushu, Japan.

a dark area for a week. After immersion, the tissues were digested in 2 M NaOH, and the number of *Perkinsus* cells was counted using a hemocytometer according to Choi et al. (1989). Total body burden was then standardized as the number of *Perkinsus*/g tissue. To determine the distribution pattern of *Perkinsus* per clam, the gills, mantle, adductor muscle, and body containing the visceral mass were excised separately from each clam and immersed independently in FTM. After 1 wk of immersion, the number of *Perkinsus* cells in the tissue was measured as described above (Choi et al. 1989). The infection intensity was standardized and expressed as the number of *Perkinsus* cells/g tissue.

RESULTS

Histopathological Observation of Perkinsus *sp.*

Numerous trophozoites were observed in the clams collected from Isahaya Bay. Eccentric vacuoles, nuclei, and nucleoli were observed from histological sections of the infected tissues (Fig. 2A). The diameter of the trophozoites, estimated microscopically, ranged from 7.73 to 15.80 μm, with a mean of 10.98 μm. Diameters of the nuclei varied from 4.20 to 6.59 μm, with a mean of 5.44 μm, whereas the diameters of the nucleoli varied from 1.90 to 2.67 μm, with a mean of 2.27 μm. Most trophozoites in the gills and mantle formed different sizes of clusters (Fig. 2A and B).

Perkinsus was predominantly found in gill filaments, mantles, and digestive tubules, although a few of the trophozoites were observed in the foot (Fig. 2B, C, and D). Heavy infection with *Perkinsus* in the gill lamellae resulted in swollen connective tissue with severe hemocyte infiltration (Fig. 2B). An inflammatory response to the parasite was also observed in heavily infected clams in the form of nodules on the mantle surface (Fig. 2C). Those nodules appeared as white spots on the mantle surface and could be observed even with the naked eye. Numerous *Perkinsus* trophozoites were also observed around the digestive glands, indicating that *Perkinsus* could inhibit the digestive activity of the clams in the visceral mass (Fig. 2D). Some clams exhibited mature eggs or sperm even in February because of the influence of the warm Kuroshio current in the bay. *Perkinsus* was also observed in the connective tissues of female as well as male gonads (Fig. 2E and F), indicating that *Perkinsus* infection in the Manila clam might disturb the reproductive processes. Sporocysts of a cercaria-like organism were also observed in the female gonad, although the prevalence was much lower than that of *Perkinsus* (Fig. 2H); only 2% of total clams investigated were infected.

Prevalence and Infection Intensity of Perkinsus *per Clam and in Different Types of Tissues*

The results of this *Perkinsus* infection survey conducted from a clam population in Isahaya Bay are summarized in Table 1. A total of 191 clams with a mean SL of 31.0 mm and a mean TWT of 1.566 g were analyzed in the study. Prevalence, the percentage of infection in the clams investigated, was 57.4%. Total body burden, in terms of the total number of *Perkinsus* cells in individual clams, varied from 0 to 2,609,375, with a mean of 351,603. Infection intensity, as number of *Perkinsus* cells/g tissue, varied from 0 to 1,817,196, with a mean of 225,701 (Table 1). No obvious correlation was observed between the infection intensity and size of the clams, as well as the CI.

Table 2 shows prevalence and infection intensity in various types of clam tissues. Among the four types of tissues examined, the gills showed the highest prevalence and infection intensity, with 85.71% and 1,019,817 cells/g gill tissue, respectively. Prevalence of infection in the visceral mass was as high as that observed in the gills, whereas the infection intensity as the number of *Perkinsus*/g tissue was much lower than the value observed in the gills. Infection intensity and prevalence was much lower in the adductor muscle and siphons compared to that in the gills and visceral mass. A positive correlation was observed between number of *Perkinsus* cells/g gill tissue and the total body burden (Fig. 3, $r^2 = 0.908$). The number of *Perkinsus* cells in the visceral mass was also highly correlated with the total body burden ($r^2 = 0.893$), suggesting that the gill and visceral mass are the main target tissues for *Perkinsus* infection in this species. Quantitative evaluation of *Perkinsus* infection among the various tissue types indicated that *Perkinsus* sp. is not evenly distributed in the clams; rather, it is concentrated in the gills and visceral mass.

DISCUSSION

Histopathological Features of Perkinsus

Although histology is not widely used in the diagnosis of *Perkinsus* infection, the technique provides valuable information on host-parasite cellular interactions (Hine & Thorne 2000; Diggles & Hine 2001; Lee et al. 2001). In the present study, pathogenicity of *Perkinsus* sp. was visually examined from histological preparations of the infected clams. Figure 2A shows typical *Perkinsus* trophozoites displaying a *Perkinsus*-specific "ring" structure (i.e., vacuole and nucleolus in a nucleus, Azevedo 1989; Azevedo et al. 1990; Auzoux-Bordenave et al. 1995; Perkins 1996; Park & Choi 2001). Trophozoite diameter measured in the present study was somewhat comparable to the size reported by Hamaguchi et al. (1998) and Maeno et al. (1999) in Japan. Trophozoite diameter measured in our study varied from 7.73 to 15.80 μm, with a mean of 10.98 μm. Hamaguchi et al. (1998) reported 5.3–32.5 μm, with a mean of 14.8 μm, as diameter of trophozoites in Manila clams, and Maeno et al. (1999) reported 5.7–11.4 μm. In contrast, trophozoites of *Perkinsus* sp. found in *R. philippinarum* on the northern coast of China varied from 2 to 10 μm (Liang et al. 2001). The size of trophozoites estimated in our study is also similar to the size of *P. olseni* [which is taxonomically very close to *Perkinsus* sp. found in Japan (Hamaguchi et al. 1998)], discovered in the Australian black-ribbed abalone, *Haliotis rubra* (Lester & Davis 1981).

Some heavily infected clams exhibited numerous clusters of trophozoites on their gill plicae and digestive tubules with severe hemocytic infiltration (Fig. 2B and D). Such a heavy infection in

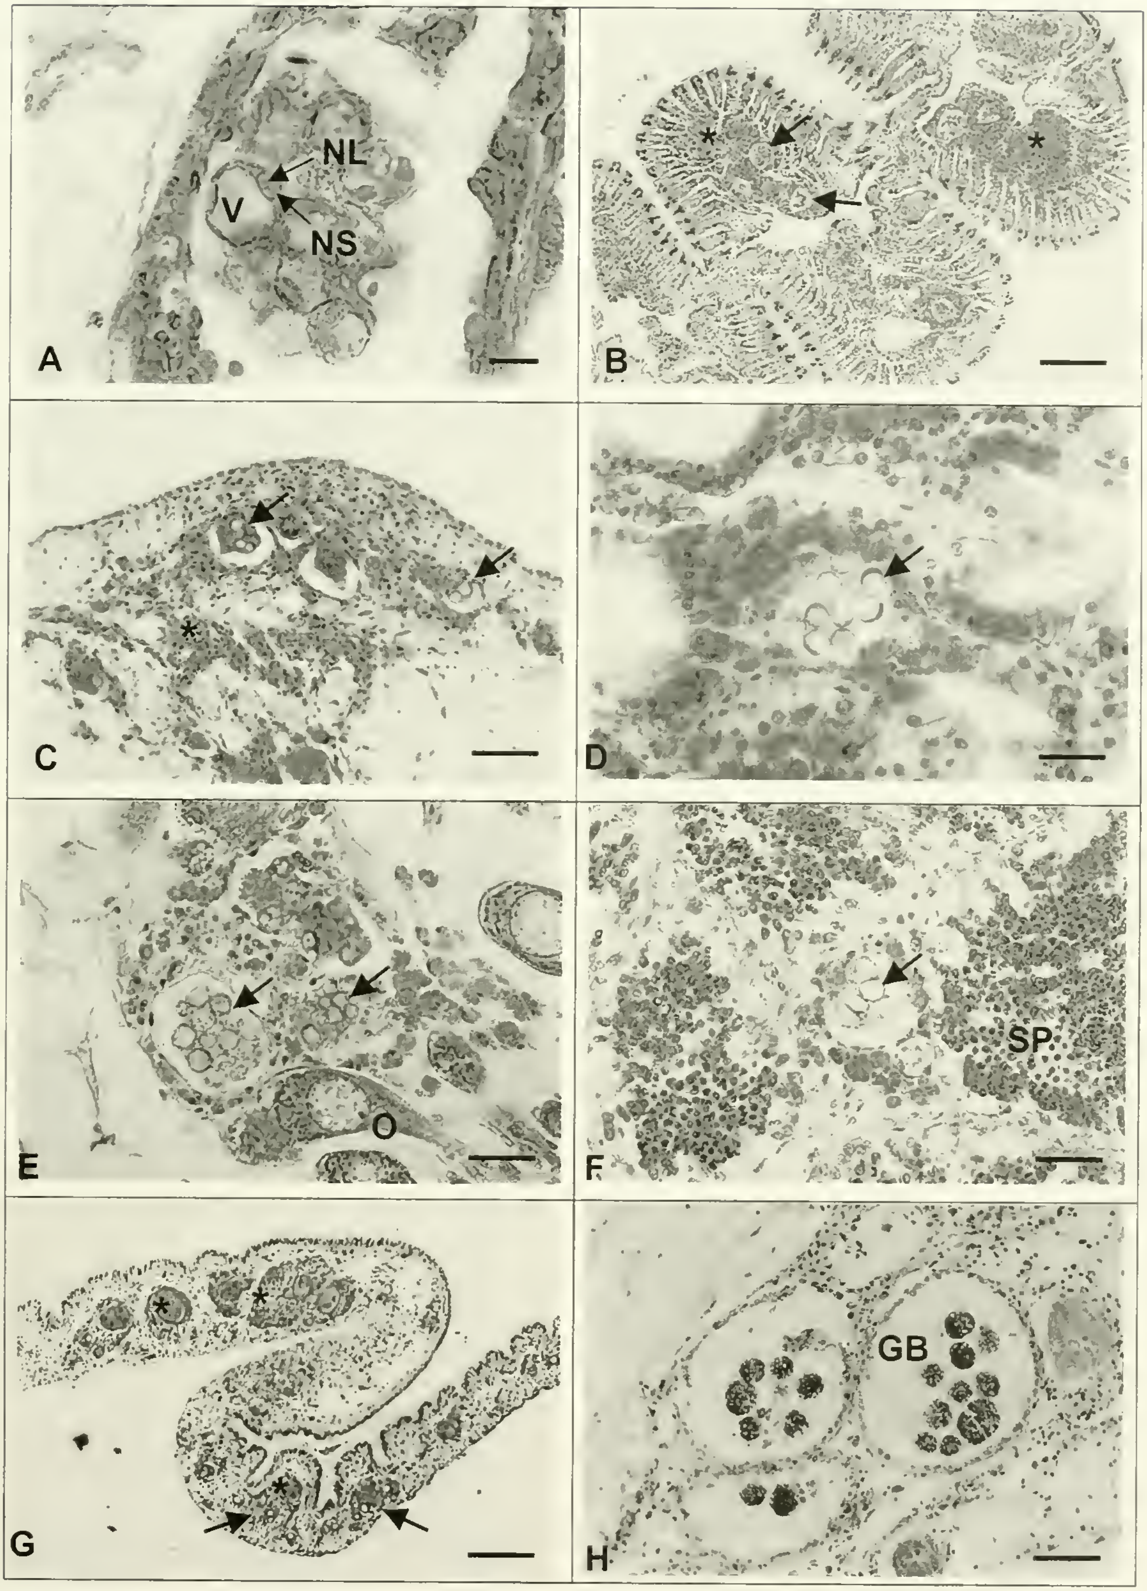

Figure 2. Histopathological features of *Perkinsus* infection. (A) Mature trophozoites containing vacuole (V). Nucleolus (NL) occurs in nucleus (NS). 1,000×, scale bar = 5 μm. (B) Severe inflammatory reaction (asterisk) occurs around trophozoites in gill tissues. 100×, scale bar = 100 μm. (C) Early stage of nodule formation. Infiltration of hemocytes (asterisks) around trophozoites (arrows) results in the swollen connective tissue of the foot. 200×, scale bar = 20 μm. (D) Trophozoites in connective tissues of digestive glands. 400×, scale bar = 40 μm. (E) Trophozoites in connective tissues of female gonad. Young oocytes (O) are seen around the capsulated trophozoites. 400×, scale bar = 500 μm. (F) Grouped trophozoites in connective tissues of male gonad. Concentrated hemocytes of the host enclose the trophozoites forming a capsule around spermatogonia (SP). 400×, scale bar = 20 μm. (G) Inflammation of host hemocytes (asterisk) in the mantle tissues. 100×, bar = 100 μm. (H) Sporocysts containing germ balls (GB). No inflammation observed. 200×, bar = 40 μm.

gill tissues may lower filtration efficiency and, in turn, cause retarded growth, although the effects of *Perkinsus* infection on filtration activity of the clams has not been experimentally proven. Infestation of *Perkinsus* in digestive tubules would cause digestive tubule atrophy and exert deleterious effects on the food digestion of the clams, as reported by Lee et al. (2001). Clams more heavily infected with *Perkinsus* exhibited white nodules on their mantle surfaces as well as gills, as was reported in other studies (Azevedo 1989; Navas et al. 1992; Montes et al. 1996; Almeida et al. 1999; Lee et al. 2001; Park & Choi 2001). A cross-section of the nodules revealed that they are the result of hemocytic encapsulations of trophozoites and massive hemocytic infiltration around the mantle tissues, evoking tissue inflammation (Fig. 2C). Several studies also have reported that *Perkinsus* secretes extracellular enzymes that perturb the host's immune system, which, in turn, allows the host animal to become more susceptible to other pathogens (Garreis et al. 1996; La Peyre et al. 1996; Faisal et al. 1999; Ordas et al. 2000).

Perkinsus was also observed among the connective tissues of female as well as male gonads (Fig. 2E and F), suggesting that *Perkinsus* infection also affects the reproduction of the clams in some way. Several studies have suggested that *Perkinsus* could (1) slow the gonad development process, or (2) reduce the reproductive output of the host animals by consuming net energy production needed for gamete production (White et al. 1988; Wilson et al. 1988; Choi et al. 1993; Choi et al. 1994). In *C. virginica*, no obvious correlation was observed between estimated fecundity and *P. marinus* infection (Choi et al. 1993). In contrast, the rate of egg protein synthesis was found to be slower in *C. virginica* heavily infected with *P. marinus*, whereas the rate was faster in oysters with relatively low infection (Choi et al. 1994). This suggests that the main effect of *Perkinsus* on host animal reproduction could be retardation of gonadal maturation rather than reduced gamete production. Reduced fecundity and impeded gonadal maturation were observed in Manila clams heavily infected with *Perkinsus* sp. in Korea (Park & Choi, in preparation).

Infection Intensity and Prevalence per Clam and in Various Types of Tissues

Numerous methods have been applied in the examination of *Perkinsus* parasitism since the first report on the occurrence of *P. marinus* in the American oyster, *Crassostrea virginica* (Mackin et al. 1950). *Perkinsus* infection has been diagnosed using histology (Perkins & Menzel 1966; Azevedo et al. 1990; Navas et al. 1992; Sagrista et al. 1995; Sagrista et al. 1996; Montes et al. 1996; Bower et al. 1998; Hine & Thorne 2000), FTM assay (Ray 1952; Ray 1966; Choi et al. 1989; Bushek et al. 1994; Rodriguez & Navas 1995; Fisher & Oliver 1996; Ford 1996; Almeida et al. 1999), immunological probes using *Perkinsus*-specific antibodies (Choi et al. 1991; Dungan & Roberson 1993; Maeno et al. 1999), and polymerase chain reaction (PCR) techniques (Marsh et al. 1995; Hamaguchi et al. 1998; Robledo et al. 1998; Figueras et al. 2000; Coss et al. 2001). Among these methods, FTM assay has been the most widely and frequently used in all types of *Perkinsus* diagnosis (Lester & Davis 1981; Azevedo 1989; Rodriguez & Navas 1995; Choi & Park 1997; Cigarria et al. 1997; Almeida et al. 1999; Liang et al. 2001), although FTM assay was initially designed for the detection of *P. marinus* (Ray 1953; Ray 1966). In the FTM assay, suspected tissues are immersed in 10 to 15 mL of FTM fortified with antibiotics for 1 or 2 wk. After immersion, hypnospores of *Perkinsus* developed in FTM and stained dark blue or brown with Lugol's iodine and were readily identifiable under a light microscope. The number of *Perkinsus* spores in FTM-assayed tissues can be accessed after digesting the tissues with 2 M NaOH, according to Choi et al. (1989). FTM assay combined with 2 M NaOH digestion has been successfully used in the quantification of *P. marinus* (Choi et al. 1989; Bushek et al. 1994; Fisher & Oliver 1996), as well as other *Perkinsus* species (Rodriguez & Navas 1995; Choi & Park 1997; Park 1999; Liang et al. 2001; Park & Choi 2001).

Infection intensity and prevalence of *Perkinsus* sp. in Manila clams in Isahaya Bay, Japan, is first reported in this study. Ray's FTM technique combined with Choi's NaOH digestion technique, which has been used in many other studies, was successfully applied in the quantification of *Perkinsus* in this study. Prevalence of infection and mean infection intensity of *Perkinsus* in the clams collected in February 2001 was 57% and 225,701 spores per gram tissue, respectively (Table 1). Hamaguchi et al. (1998) also reported the prevalence of *Perkinsus* in *R. philippinarum* collected from Kumamoto, east coast of Ariake Sound, and Hiroshima. The prevalence measured from Kumamoto was 87.5% in commercial clam beds and 56.3% in natural clam beds. The prevalence values reported by Hamaguchi et al. (1998) are similar to those estimated from Isahaya Bay. The prevalence observed in Hiroshima, 93.8% in commercial beds and 84.4% in natural habitats, was somewhat higher than the prevalence measured in Kumamoto and Isahaya Bay. No data on the infection intensity of *Perkinsus* in the Manila

clam are available so far in Japan with which to compare the infection intensity measured in this study. The infection intensity and prevalence observed in the present study is somewhat lower than the values reported from neighboring countries. Prevalence of *Perkinsus* infection in a survey of *R. philippinarum* from Komsoe Bay, on the west coast of Korea, where tidal flats are well developed and used as a clam culture ground, was almost 100%, with a mean infection intensity of 709,028 spore/g tissue (Park & Choi 2001). *Perkinsus* infection reported from populations of *R. philippinarum* in the northern Yellow Sea (38°50′26″:39°27′09″) was also comparable to the values reported in the present study. The prevalence varied from 20% to 100%, with mean infection intensity of 2 to 1,670,615 spores/g tissue in the northern Yellow Sea (Liang et al. 2001).

No obvious correlation was observed between the infection intensity and size of the clams, as well as the condition index, in this study, although several studies have reported that *Perkinsus* infection is often positively correlated with oyster or clam size. Mackin (1951) and Ray (1953) found that *C. virginica* juveniles less than 1 y old have lower levels of infection compared to market-sized oysters. *Perkinsus* sp. found in *R. philippinarum* in Korea, as well as in China, also showed similar size-dependent infection. Clams smaller than 13 mm in shell length normally exhibit no infection while the larger clams appeared to be susceptible to *Perkinsus* (Choi & Park 1997; Liang et al. 2001; Park & Choi 2001). Absence of any correlation between the clam size and *Perkinsus* infection intensity in this study could be explained by the low prevalence of infection in the clams. In this study, 43% of the clams examined showed zero infection, which, in turn, resulted in a poor correlation coefficient. Several studies have indicated that low *Perkinsus* infection prevalence matches well with low infection intensity in terms of number of *Perkinsus* cells/g tissue (Choi & Park 1997; Liang et al. 2001; Park & Choi 2001). However, it is unlikely that the observed low prevalence is related to the size of clams, because no juvenile clams (i.e., less than 15 mm SL) were included in the analysis. The clams used in this study were 22.3–39.9 mm in shell length, with a mean of 31.0 mm, and all of them are considered to be over 2 y old. Relatively low infection prevalence in Isahaya Bay could be attributed to the density of clams in their habitat. The clam density in the bay was observed to be lower than the clam density reported from other commercial clam beds, although the clam density in the sampling location was not estimated. High infection intensity and prevalence of *Perkinsus* is common among clam beds where the clams are intensively cultured, resulting in high density (Da Ros & Canzonier 1985; Choi & Park 1997; Liang et al. 2001; Park & Choi 2001). In a high-density bed of clams, *Perkinsus* disease can be transmitted quickly because any life stage of *Perkinsus* would be infectious (Ray & Mackin 1954; Andrews & Ray 1988; Auzoux-Bordenave et al. 1995; Perkins 1996).

Infection intensity of *Perkinsus* among different types of tissues in *R. philippinarum* was compared in this study using Ray's FTM following the 2 M NaOH digestion (Ray 1966; Choi et al. 1989). Infection intensity of mantle, gills, siphon, and body containing visceral mass was separately determined in this study for diagnostic purposes. As shown in Table 2, the prevalence of infection was found to be highest in the gills, followed by the visceral mass. *Perkinsus* density in the gills in terms of the number of *Perkinsus* cells/g tissue was also the highest among various types of clam tissues analyzed (Table 2). A strong positive correlation was also observed between the numbers of *Perkinsus* spores/g gill tissue and the total number of *Perkinsus*/g in whole clams (Fig 3, r^2 = 0.908). The number of *Perkinsus* spores in the visceral mass was also strongly correlated with the number of *Perkinsus* spores in whole tissues (Fig. 3, $r^2 = 0.893$). Park (1999) and Rodriguez and Navas (1995) also observed strong positive correlations between infection intensity in gill tissues and infection intensity of whole clams in Korea and Spain. The high density of *Perkinsus* in the gill and visceral mass indicates that a favorable condition for *Perkinsus* growth and reproduction is provided in these tissues, where more energy is believed to be available for *Perkinsus* (Choi et al. 1989). Our data suggest that gill assay is an excellent alternative for whole clam assay (i.e., body burden assay, Rodriguez & Navas 1995; Park 1999).

ACKNOWLEDGMENTS

We are grateful to the staff of the Shellfish Aquaculture and Research Laboratory of Cheju National University for their help with FTM and histopathology. We also thank Mr. Ronald Noseworthy for his proofreading and improvement of the manuscript. This study was supported from Cheju National University Grant and Grant-in-Aid for Scientific Research of Japan (No.11695080; Study on Environment and Biology in the East China Sea and Yellow Sea). We appreciate this support.

SEASONAL CHANGES IN THE HISTOLOGICAL AND BIOCHEMICAL PROFILE OF THE GONAD, DIGESTIVE GLAND, AND MUSCLE OF THE CALAFIA MOTHER-OF-PEARL OYSTER, *PINCTADA MAZATLANICA* (HANLEY, 1856) ASSOCIATED WITH GAMETOGENESIS

PEDRO SAUCEDO, ILIE RACOTTA, HUMBERTO VILLARREAL, AND MARIO MONTEFORTE

Centro de Investigaciones Biológicas del Noroeste, S.C., Mar Bermejo 195, Col. Playa Palo de Santa Rita, La Paz, Baja California Sur, México

ABSTRACT The relationship between the energy storage cycle and gametogenesis of the pearl oyster, *Pinctada mazatlanica* was studied over an annual cycle (January to December 1999). Histological analysis, combined with oocyte examination and measurements of carbohydrate, protein, total lipid, and triacylglycerides levels from gonadal tissue, digestive gland, and adductor muscle were performed. One-way ANOVA was used for assessing differences in the area of oocytes over time. Similarly, a two-way ANOVA was applied for differences in the biochemical composition of specimens over time and sex. The gametogenic cycle was affected by the presence of "La Niña" cold event during the first half of 1999. Gametogenesis commenced early in February and occurred synchronously throughout the annual cycle. There were two reproductive peaks, one in spring (March to May) and other in summer (July to September). A massive spawning was observed in September–October when water temperature was 29–29.5°C. Carbohydrates, either stored or obtained from ingested food, were used as an immediate fuel for the production of oocytes, which grew and increased their protein content during the first half of the year. Lipids and triacylglycerides also showed two important peaks in the female gonadal tissue and digestive gland, corresponding to the same peaks described histologically. Reserves stored in the muscle and digestive gland were actively used for gametogenesis. Muscle proteins were mobilized to the gonad during the first half of the year, while carbohydrates were used during the second half. The digestive gland acted as a short-term storage site of carbohydrates and lipids during gonad development. More studies on seasonal changes and energy storage and mobilization in pearl oysters are required, especially involving the participation of the mantle tissue.

KEY WORDS: Bahía de La Paz, gametogenesis, metabolism, pearl oysters, temperature, *Pinctada mazatlanica*

INTRODUCTION

Marine bivalves show cycles of energy storage and utilization that are closely related to gametogenic cycles (Gabbott 1975; Bayne 1976; Barber & Blake 1981). Most species are capable of storing nutrient reserves in their body tissues during periods of high food supply, which are subsequently mobilized during times of food shortage, decreased rates of feeding, and/or high energy demand (Ansell 1974; Gabbott 1975; Bayne 1976; Sastry 1979; Barber & Blake 1981, 1991; Epp et al. 1988). Gametogenesis represents a period of particularly high-energy demand, when both maintenance costs and the cost of gamete synthesis must be met by the food supply, stored reserves or a combination of both. The reproductive and biochemical cycles are thus closely coupled in most species of bivalves but vary in relation to environmental factors, between species, and between populations of the same species (Epp et al. 1988).

In addition, many marine bivalves inhabiting subtropical and temperate areas follow an annual reproductive cycle with precise periods of gonad maturation and spawning. Reproduction usually demands considerable consumption of energy and the weight loss during spawning can reach between 30 to 60% (Mathieu & Lubet 1993). In general, energy is stored prior to gametogenesis when food is abundant in the form of lipid, glycogen, and protein substrates, and subsequently is mobilized and utilized in the production of gametes when metabolic demand is high (Bayne 1976; Barber & Blake 1981, 1983, 1991).

Pearl oysters are marine bivalves having a considerable economic and commercial value because of their natural capacity to produce pearls of high quality (Monteforte 1990, 1996). In spite of this, the factors which affect reproductive success in these species are poorly studied and understood, although their basic reproductive biology has been well documented histologically (Tranter 1958a; Tranter 1958b; Wada 1959; Sevilla 1969; Chellam 1987; Rose et al. 1991; Hernández-Díaz 1993; Arizmendi-Castillo 1996; García-Domínguez et al. 1996; Saucedo & Monteforte 1997; Behzadi 1997).

Presently, the growing importance and value of pearl oysters has promoted the use of hatchery-produced stock, and as such, the need for knowledge relating to broodstock conditioning and larval rearing. However, in order to produce oocytes and spermatozoa of the best quality, which will develop into strong and viable larvae, it has been essential to understand the seasonal behavior of oysters from wild population. This information will be used further to determine the basic needs of broodstock in the laboratory. As an initial step toward a better understanding of reproductive success in the Calafia mother-of-pearl oyster *Pinctada mazatlanica* (Hanley), the relationship between the build-up and utilization of energy reserves and the annual cycle of gametogenesis and spawning has to be investigated. The objective of this work was to study the seasonal cycles of energy storage and depletion in the gonadal tissue, digestive gland, and adductor muscle of this species.

MATERIALS AND METHODS

Specimen Collection and Dissection

From January to December 1999, twenty oysters were collected monthly from the Submarine Experimental Farm of CIBNOR, located in Caleta El Merito, in Bahía de La Paz, México (24°16′N and 110°19′W). Only adult specimens ranging 140 (±8 mm SD)

Corresponding author. Pedro Saucedo. Centro de Investigaciones Biológicas del Noroeste, S.C., Mar Bermejo 195, Col. Playa Palo de Santa Rita, La Paz, Baja California Sur, México. E-mail: psaucedo@cibnor.mx

shell height were collected to assure the presence of both sexes in the sample (Saucedo & Monteforte 1997). Water temperature was recorded at the collecting site. Specimens were taken to the laboratory to be dissected. The gonadal tissue (which develops gradually within the visceral mass at the expense of the interconnective tissue matrix and the digestive gland, as gametogenesis proceeds) and adductor muscle were excised from each specimen. The former tissue component was preserved in Davidson's solution for 48 h and used for histological analyses. The muscle was preserved at –80°C for biochemical analyses.

Histological Analysis

Preserved samples of gonadal tissues were dehydrated, embedded in paraplast, sectioned at 5 μm along an anteroposterior plane, and stained with hematoxylin-eosin (Howard & Smith 1983). Gametogenic state was characterized as either early, mid, or late developing, ripe, partially spawned, and spent, based on a larger version of Tranter's original scheme for pearl oysters (Tranter, 1958a, b). In this larger version, early development corresponds to small acini showing only few layers of spermatogonia and spermatocytes (in the testis) or oogonia connected to the follicular wall (in the ovary). In mid development, acini tend to shrink and the lumen becomes restricted, while oocytes and/or spermatids and spermatozoa become increasingly common. Late development is characterized by mature or maturing spermatozoa and oocytes strongly packed within the follicular lumen, although immature stages are still present.

The advancement of the oogenesis process was also evaluated by counting the frequency of oocytes and measuring their size variation over time (Grant & Tyler 1983). As a previous step, oocytes were classified accordingly to their vitellogenic stage as previtellogenic, vitellogenic, and postvitellogenic, following the criterion of Gaulejac (1995) for the marine bivalve *Pinna nobilis*. Aside from Gaulejac's work, additional descriptions about the cytological characteristics of each type of oocyte may be found in Saucedo et al. (2001a).

The frequency was calculated by counting the total number of each type of oocyte appearing in three randomly selected areas of the ovary. The size of oocytes was also assessed measuring thirty oocytes of any type appearing in three random areas of the ovary. The diameter was not used for the analysis because this dimension usually provides data that vary considerably as a consequence of the plane on which thin sectioning is made with the microtome. Instead, the area is not affected that much by the sectioning process and thus provides more homogeneous and reliable data about the size of oocytes. Images were captured from the computer with a digital Cole-Snap camera (I-media Cybernetics) and processed with Sigma Scan Pro (vers. 5.0) designed for digital image analysis.

Biochemical Analysis

For the biochemical analyses, preserved samples of gonadal tissue and digestive gland were weighed and homogenized in 3 mL of cold saline solution (NaCl 35%) to obtain a crude extract. Similarly, muscle samples were weighed and homogenized in 5 mL of 10% trichloracetic acid (TCA) for carbohydrate analysis. Homogenized samples were then centrifuged at 3600 rpm at –5°C for 15 min, and the supernatant stored at –20°C for 24 h for further analyses.

The TCA supernatant was directly used for carbohydrate analysis in muscle. For other tissues, the saline crude extract was diluted with 20% TCA. After centrifugation, 0.1 mL of the supernatant was mixed with 1 mL of anthrone reagent (0.1% dissolved in 76% sulfuric acid), incubated for about 2 min at 90°C and immediately cooled to 4°C to stop further reaction (Van Handel 1965). Absorbance was read at 620 nm against a reagent blank and carbohydrate was quantified using dextrose solution as standard.

For protein determination, the saline crude extract was diluted 1:5 in 0.5 N NaOH for soluble protein determination (Bradford 1976), using commercial chromogen reagent (Sigma) and bovine serum albumin (Sigma) as standard solution. Absorbance was read at 595 nm. For muscle protein determination, 0.01 g of tissue was digested in 3 mL of 0.5 N NaOH for 24 h before following the above methodology.

Commercial kits from Merck were used to determine the composition of total lipids (Merck num. 3321) and triacylglycerides (GPO-PAP, Merck num. 1.1434.001). These methods were adapted to a microplate using 20 μL of supernatant and 200 μL of enzyme chromogen reagent (Racotta et al. 1998; Palacios et al. 2000). Absorbance was recorded on a microplate reader (Labsystems, Uniskan II) at 560 nm for total lipids and 495 nm for triacylglycerides.

Statistical Treatment

For studying the histological and biochemical variations related to the ongoing gametogenic cycle, one-way ANOVA was used to determine significant differences in the area of oocytes (factor T with 12 levels or months). A two-way ANOVA was applied for differences in the biochemical composition of gonadal tissue, digestive gland, and adductor muscle over time and sex of specimens (factor S with two levels). In addition, correlation analyses were performed to assess the grade of relation between some histological and biochemical parameters of the above tissue components. For all analyses, the significance level was set at $P < 0.05$ (Sokal & Rohlf 1981).

RESULTS

Variation of Temperature

Part of 1997 and 1998 were warm years because of the presence of "El Niño" phenomenon in waters of Bahía de La Paz. As a consequence, the second half of 1998 and first half of 1999 were "Niña" years characterized by abnormal cold-water temperatures (Lluch-Belda et al. 1999). The chronology and duration of the reproductive stages defined in this study over the annual cycle January to December 1999 are based in this abnormal cold event. Figure 1 presents the historical register of mean temperature variation recorded at Bahía de La Paz from 1990 to 1999. Values of water temperature in the present study showed a relatively high variation of ±1–2.5°C from the summer and winter average values registered during such period of time.

Histological Analysis

Reproductive Cycle

The annual gametogenic cycle is depicted in Figure 2. Inactive gonads (unable to be sexed) were found only in January and February. Gonadal development started early in February and proceeded continuous and synchronously throughout the annual cycle in both male and female gonads, showing two peaks of maximum

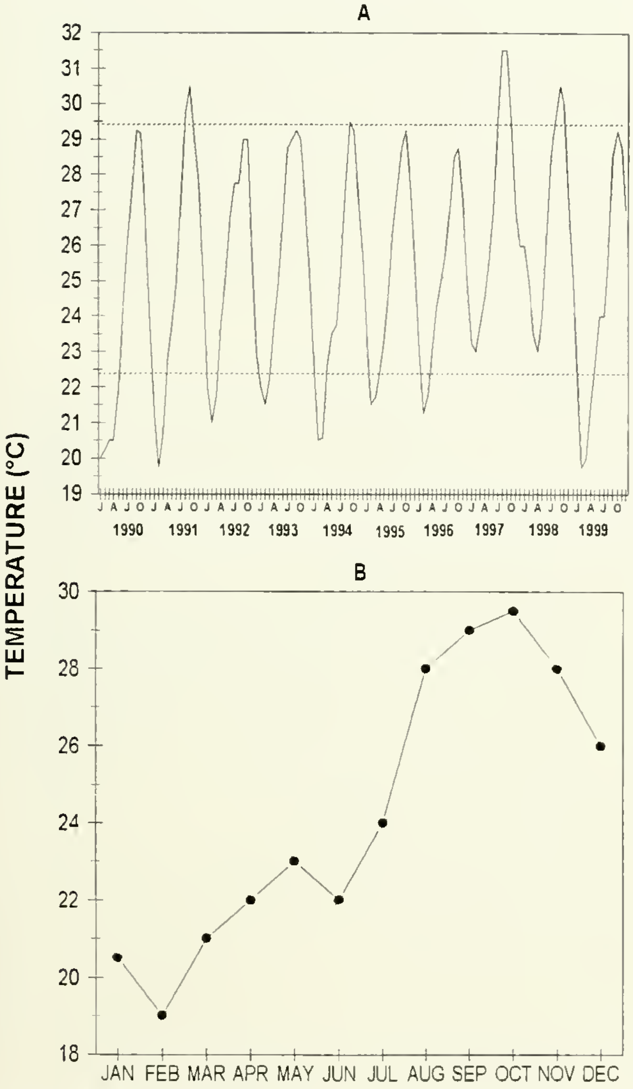

Figure 1. Mean range of temperature variation at different sites of Bahía de La Paz. A) Historical record from 1990 to 1999. Dotted lines at the top and bottom of the graph are the summer and winter average values, respectively; B) Values obtained from the present study during January to December 1999.

reproductive activity (defined in terms of the high incidence of specimens in late-development and ripe stages). The first peak was observed in spring (March to May), when water temperature was 21–23°C. However, no trace of spawning was detected during this season. The second peak was seen in summer (July to August), when water temperature rose to 25–26°C. In this case, a massive spawning occurred in the following month, when temperature reached its highest record (29–30°C). Organisms in spent stage were observed from October to November, although some other specimens were still spawning or starting a new gametogenic process.

Sex Ratio

The analysis for the whole gametogenic cycle revealed a higher frequency of males (49%) than of females (38%). Therefore, the female/male sex ratio was 0.78:1. The sample was also conformed by indeterminate specimens (7%), hermaphrodites (5%), and a small percentage of animals behaving as functional hermaphrodites (1%). Particularly, from January to May males completely outnumbered females and reached a mean percentage of 63% vs. 24% of females. From June to August this trend changed to 54% of males and 44% of females. Finally, from October on, the population of males decreased considerably (25%) while females strongly increased (51%).

Oocyte Examination

Figure 3 shows the variation of previtellogenic, vitellogenic, and postvitellogenic oocytes over time. All types of oocytes were observed throughout the annual cycle, although their frequencies of appearance were variable each month. Vitellogenic oocytes showed a relatively constant presence over time. An increase of previtellogenic oocytes was clear in November (31%) and December (58%) after the main spawning was achieved. In comparison, postvitellogenic oocytes showed higher incidences during March (51%), May (49%), and August (48%), corresponding to the same peaks of maximum reproductive activity detected histologically.

Temporal variations in the size (area) of oocytes are showed in Figure 4. Both decreases and increases in the volume of oocytes observed over the annual cycle are probably associated with changes in the temperature of water. Thus, small oocytes were observed in February (early development: 19°C), June (resorption process between both reproductive peaks: temperature dropped to 24°C), and October, November, and especially December (spawning and spent stage: 29.5, 28, and 26°C respectively). Large oocytes were observed in March, April, and May and August during the two reproductive peaks histologically detected. The

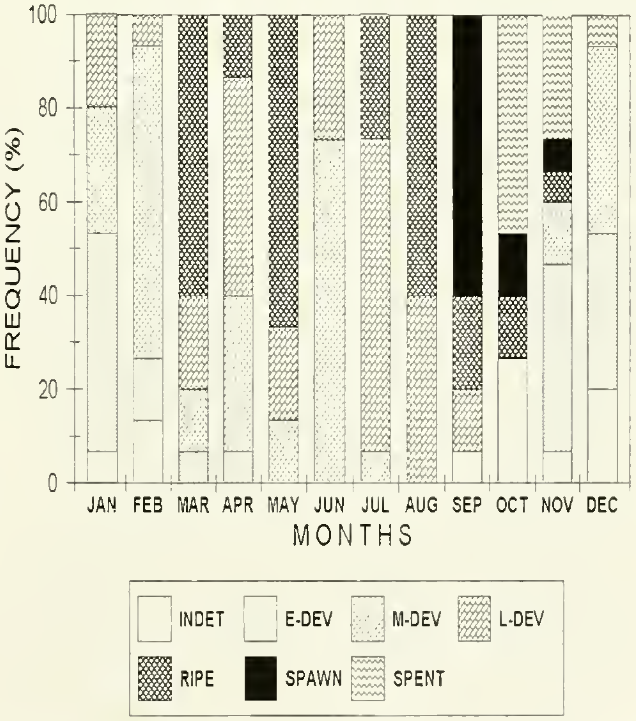

Figure 2. Sexual gametogenic stages in *Pinctada mazatlanica* over an annual cycle. Indet = Indeterminate stage; E-Dev = early-developmen stage; M-Dev = mid development; L-Dev = late-development; spaw spawning.

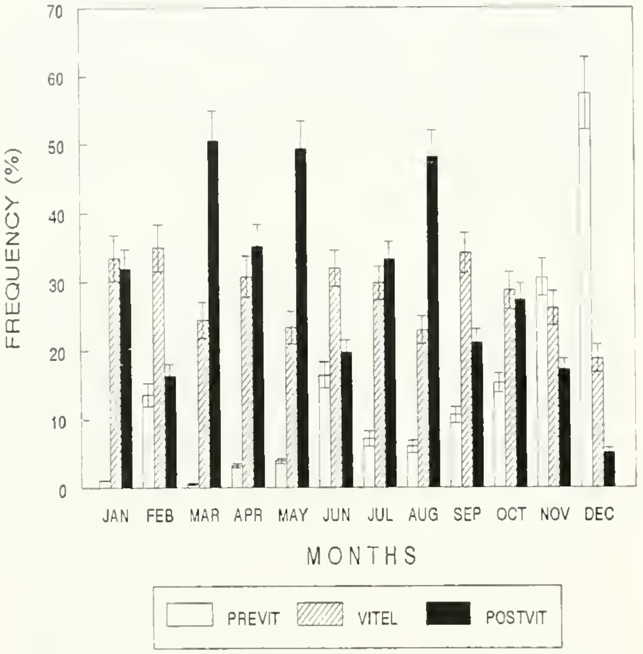

Figure 3. Temporal variations in the mean frequency of occurrence of different types of oocytes in *Pinctada mazatlanica* over an annual gametogenic cycle. Previt = previtellogenic oocytes; Vitel = vitellogenic oocytes; Postvit = postvitellogenic oocytes. Bars denote standard deviation.

ANOVA detected highly significant differences in the mean area of oocytes over time ($F = 102.97$; $P < 0.001$).

Biochemical Analysis

Gonadal Tissue

Preliminary tests made to measure the amount of carbohydrates in the gonadal tissue, digestive gland, and muscle indicated that over 80% was glycogen. Thus, glycogen is reported in this study as total carbohydrates (CHO).

When water temperature rose from 20 to 25°C, CHO were actively depleted during the first half of the year and decreased from 12 mg/g in January to 4 mg/g in July (Fig. 5A). Afterwards, CHO were not used for the production of gametes, yielding a slight increase in their concentration between 5 and 6 mg/g. The variation in the concentration of this component showed significant differences over time ($F = 35.83$; $P < 0.001$), but not according to the sex of specimens ($F = 0.414$; $P > 0.05$). The decrease in the levels of CHO in the gonadal tissue was not significantly correlated with the increase in the area of postvitellogenic oocytes ($r = 0.102$; $P > 0.05$).

Proteins (PRO) accumulated mainly in the female gonadal tissue during the first half of the reproductive cycle, resulting in a sharp rise in their concentration from 52 mg/g in January to 100 mg/g in May (Fig. 5B). After a drop in June to July, the concentration varied between 58 and 65 mg/g for both sexes during the second half of the year. There were not significant differences in the PRO content over time ($F = 0.954$; $P > 0.05$), but differences were significant in relation to the sex of specimens ($F = 8.16$; $P < 0.05$).

There were two peaks depicting the temporal variations in the concentration of total lipids (LIP; Fig. 5C) and triacylglycerides (TG; Fig. 5D) in the female gonadal tissue. The first peak was seen in April for LIP (20.4 mg/g) and in May for TG (13.5 mg/g), while the second peak was observed in August to September for both components (13.6 mg/g for LIP and 9.4 mg/g for TG). There were significant differences in the temporal variations of LIP ($F = 13.23$; $P < 0.001$) and TG ($F = 2.84$; $P < 0.05$) and also according to sex ($F = 14.24$; $P < 0.001$ for LIP; $F = 43.58$; $P < 0.001$ for TG). There was a positive and significant correlation between the variations of both elements over time ($r = 0.973$; $P < 0.001$). Similarly, variations in the concentration of LIP were significantly correlated to the increase in the area of postvitellogenic oocytes ($r = 0.64$; $P < 0.005$).

Digestive Gland

There was a continuous accumulation of CHO in this tissue from 23.4 mg/g in March to over 32 mg/g until November (Fig. 6A). After the spawning, the concentration of CHO decreased to 22 mg/g in December. There were significant differences in the concentration of this component over time ($F = 27.8$; $P < 0.001$). However, differences were not significant in relation to the sex of oysters ($F = 0.434$; $P > 0.05$).

PRO showed a gradual decrease from January (156 mg/g) to October (96 mg/g), especially in males (Fig. 6B). In females, this trend showed two minimum peaks in May and October. After the spawning in late September, a shift in the concentration of PRO was recorded again. The variations in the concentration of PRO denoted significant differences over time ($F = 24.86$; $P < 0.001$), while differences were not significant according to the sex of specimens ($F = 0.093$; $P > 0.05$).

LIP and TG in this tissue presented two peaks of concentration throughout time (Figs. 6C and D). The first peak occurred in April (25 mg/g for LIP and 15 mg/g for TG). The second peak was observed in August, with values of 17 mg/g (LIP) and 10 mg/g (TG). Unlike gonadal tissue, the concentration of both components during winter (spent stages) was the same or higher than that of the summer. There were significant differences in the variation of the LIP and TG content over time ($F = 56.28$; $P < 0.001$ for LIP; $F = 26.82$; $P < 0.001$ for TG), but differences were not significant

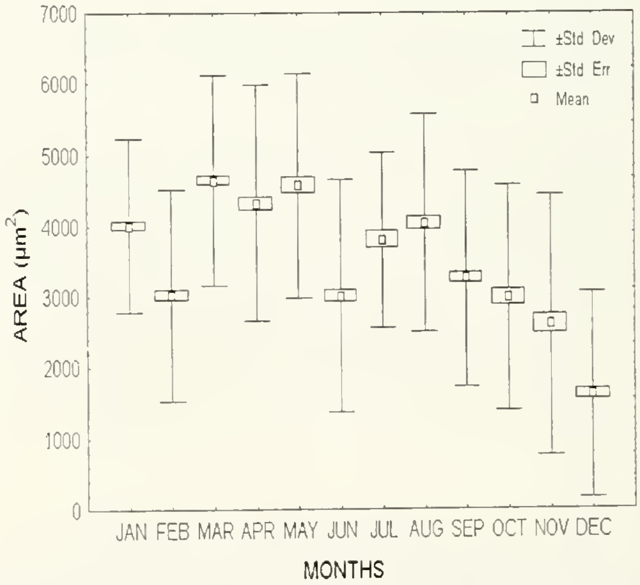

Figure 4. Box and Whisker for temporal variations in the mean area of oocytes in *Pinctada mazatlanica* over an annual gametogenic cycle.

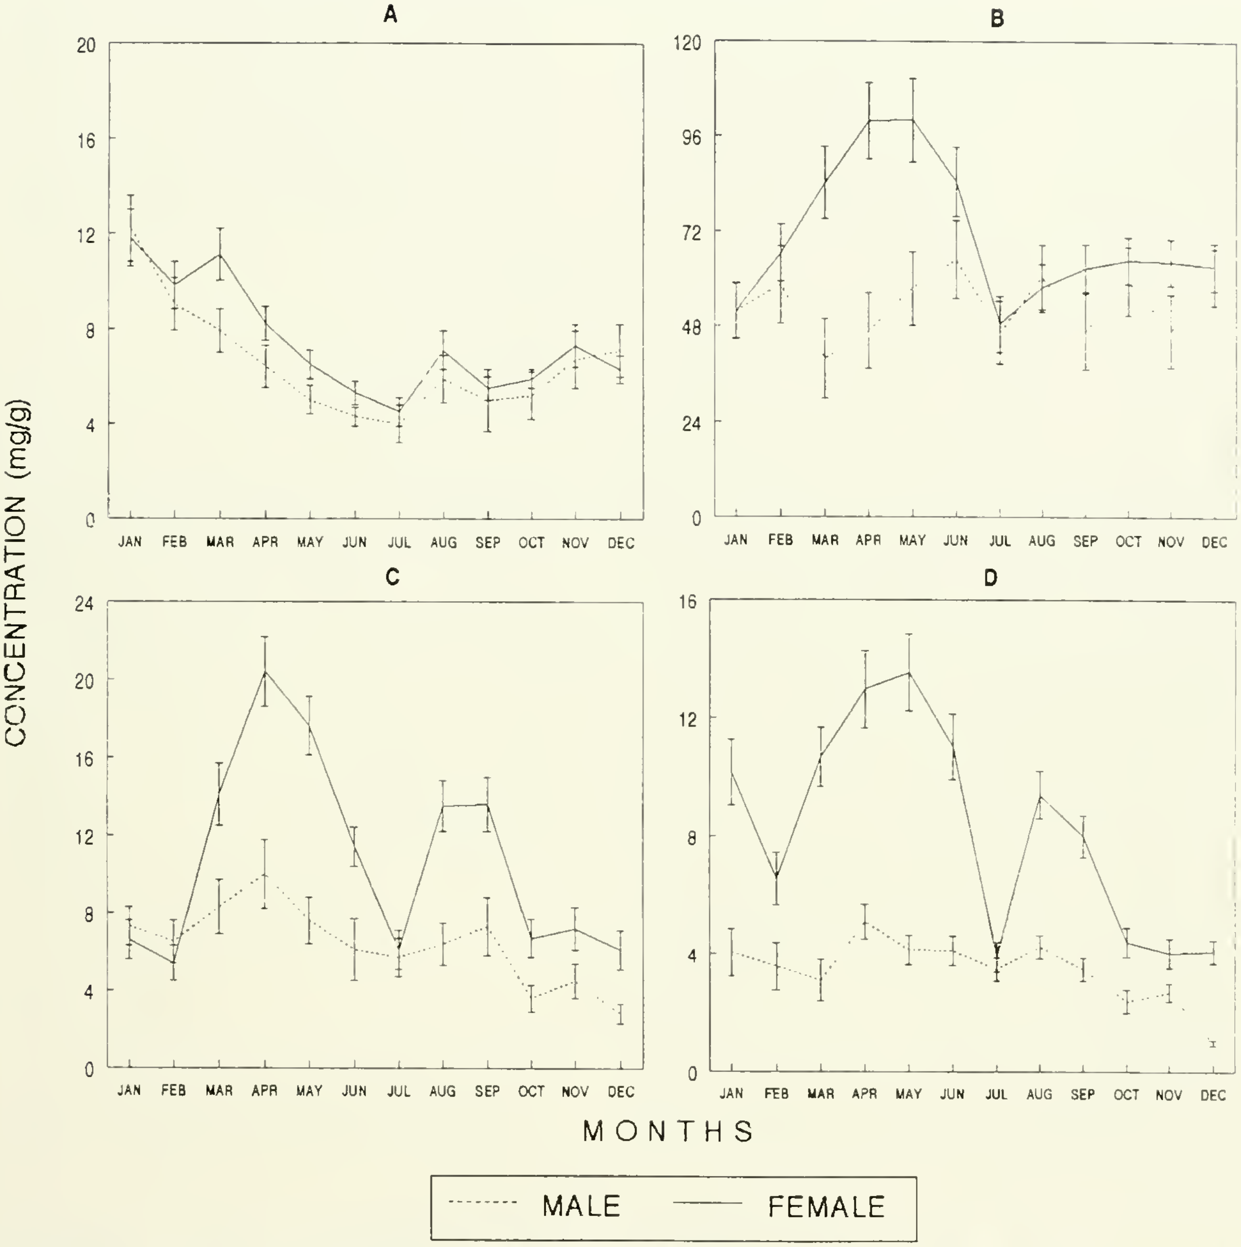

Figure 5. Temporal and sexual variations in the mean levels of total carbohydrates (A), proteins (B), total lipids (C), and triacylglycerides (D) in the gonadal tissue of *Pinctada mazatlanica* over an annual gametogenic cycle. Bars denote standard deviation.

between sexes ($F = 0.849$; $P > 0.05$ for LIP; $F = 0.267$; $P > 0.05$ for TG). The temporal variations of both components were significantly correlated ($r = 0.963$; $P < 0.001$).

Adductor Muscle

CHO in the muscle showed high concentrations during the first half of the gametogenic cycle, varying between 95 mg/g (January) and 115 mg/g (June) (Fig. 7A). Afterwards, a sharp drop to 50 mg/g in October was observed mainly during the mid and late-developing and ripe stages. After the spawning, a recovery in the content of CHO was noticed. The ANOVA found significant differences in the concentration of this component on time ($F = 47.95$; $P < 0.001$). Neither sex showed significant differences in their CHO content over time ($F = 1.39$; $P > 0.05$).

During the first reproductive peak, the level of PRO in the muscle decreased from 235 mg/g in February to 128 mg/g in May. After a short period of accumulation in June, such levels gradually rose and reached 227 mg/g in December (Fig. 7B). The variations in the concentration of PRO denoted highly significant differences over time ($F = 103.61$; $P < 0.001$), but differences were not significant between sexes ($F = 0.138$; $P > 0.05$). The decrease in the PRO content of the muscle was significantly correlated to the increase in the area of postvitellogenic oocytes ($r = 0.632$; $P < 0.05$).

DISCUSSION

Seasonal changes in energy storage and depletion in relati gametogenesis have been well documented during the las

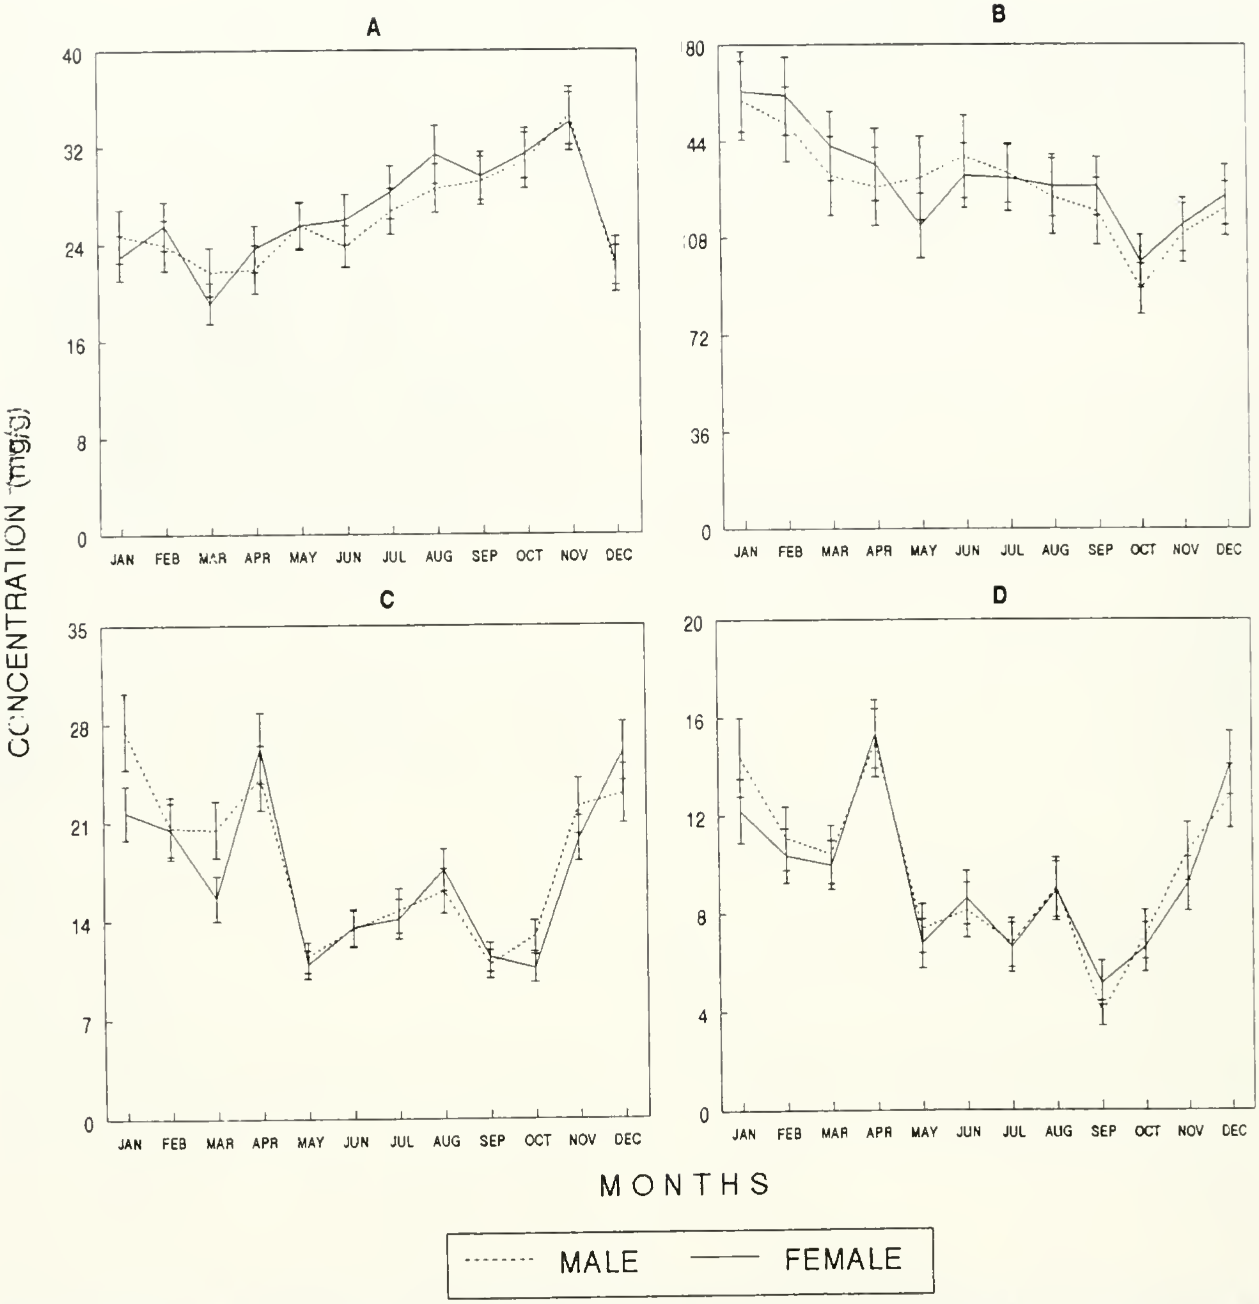

Figure 6. Temporal and sexual variations in the mean levels of total carbohydrates (A), proteins (B), total lipids (C), and triacylglycerides (D) in the digestive gland of *Pinctada mazatlanica* over an annual gametogenic cycle. Bars denote standard deviation.

decades for some commercial-edible species of marine bivalves, such as scallops, mussels, and oysters (Giese 1969; Sastry & Blake 1971; Ansell 1974; Comely 1974; Gabbott 1975, 1976, 1983, Bayne 1976; Taylor & Venn 1979; Zandee et al. 1980; Barber & Blake 1981, 1983, 1991; Robinson et al. 1981; Bayne et al. 1982; Epp et al. 1988; Couturier & Newkirk 1991; Martínez 1991; Pazos et al. 1997; Racotta et al. 1998). Nevertheless, most of the aspects concerning the storage capacity and mobilization of nutrients to satisfy metabolic needs related to gametogenesis seem to be species-specific (Barber & Blake 1981, 1991) and some important interspecific differences have been reported (Pazos et al. 1997). The present work couples for the first time both gametogenic and biochemical cycles for a species of pearl oyster.

Both histological and biochemical analyses showed the existence of two peaks of intense reproductive activity over the annual cycle; one in spring (March to May) when water temperature was rising from 21 to 23°C, and other in summer (August to October) when water temperature was about to reach a maximum value of 28–29°C. The first reproductive peak was clearly defined in terms of its high incidence of ripe specimens, high frequency of postvitellogenic oocytes, and high levels of protein, lipids, and triacylglycerides within the gonadal tissue. However, the histological analysis did not identify any spawning activity in the sample. This was confirmed by very low spatfall recorded in parallel field monitoring (CIBNOR-Pearl Oyster Research Program database). Such result was probably ascribed to the low and abnormal water tem-

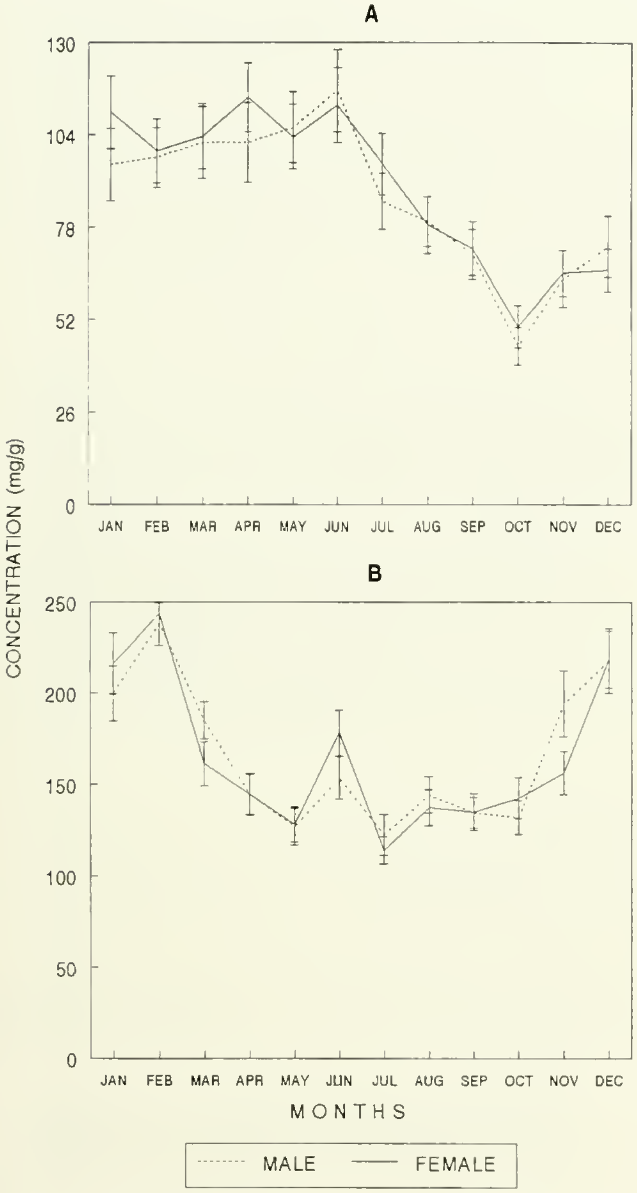

Figure 7. Temporal and sexual variations in the mean levels of total carbohydrates (A) and proteins (B) in the adductor muscle of *Pinctada mazatlanica* over an annual gametogenic cycle. Bars denote standard deviation.

perature registered during March to May (21–23°C) and also to the drop-out in the same parameter detected in June (22°C) as a consequence of the presence of "La Niña" phenomenon in waters of Bahía de La Paz during the first half of 1999, which caused gonads to undergo a partial lysis and resorption. Similar processes have been reported to occur in the scallops *Argopecten irradians concentricus* (Sastry 1966; Barber & Blake 1981, 1991; Epp et al. 1988) and *Placopecten magellanicus* (Robinson et al. 1981) under low temperatures conditions or during times of food shortage.

In this study, the three major tissues related to gametogenesis (gonad, digestive gland, and adductor muscle) were utilized differently over time, but showed a clear seasonal cycle of gonadal development, spawning, energy storage, and mobilization of nutrients. Gametogenesis started early in February, when food is commonly abundant from the phytoplankton (Signoret & Santoyo 1980; Lechuga-Devéze 1997), and wild specimens had stored enough energy reserves in the adductor muscle (mainly) and digestive gland (secondarily). When gametogenesis had already reached the early-development stage in March, the first previtellogenic and vitellogenic oocytes started to differentiate within acini. Because proteins in the muscle and digestive gland showed a downward trend from January to May, it seems evident that gonad growth took place at their expense during the first reproductive peak. Therefore, a substantial growth in the size of oocytes, an increase in the weight of gonadal tissue, and their levels of protein, lipids, and triacylglycerides was recorded. This was particularly evident in the female gonad, where the content of the last three elements doubled that of males, at least during the first reproductive peak, and partially during the second reproductive peak. On the contrary, as gametogenesis proceeded into the mid and late-developing and ripe stages (June to October), carbohydrates (glycogen) from the muscle were the only substrate mobilized and used for the build-up of gametes. Following the spawning in October–November, when gonadal tissue decreased in weight and their basic levels of lipids and triacylglycerides fell sharply, the condition of the digestive gland and muscle improved again.

Carbohydrates obtained from ingested food were used as an energy-rich fuel for the build-up of gametes, via their conversion into lipids and triacylglycerides reserves (lipogenesis). This process has been reported to occur in some bivalves to satisfy the metabolic demands derived from vitellogenesis (Gabbott 1975, 1976, 1983), especially because lipids and triacylglycerides are the basic energetic reserves for sustaining embryonic and larval development of most species of marine bivalves (Holland 1978; Fraser 1989). However, there was a lack of correlation between carbohydrates of the gonadal tissue and the total area of postvitellogenic oocytes. On the contrary, the correlation was significant between the area of oocytes and the content of lipids in this tissue. Several authors have discussed the relative contribution of food intake vs. energy reserves to satisfy the metabolic demands of growth and gonadal production in marine bivalves (Bayne 1976; Gabbott 1976; Barber & Blake 1981, 1983; Robinson et al. 1981; Epp et al. 1988; Racotta et al. 1998). However, because these processes are highly dependent on several exogenous and endogenous factors, no pattern has yet been established. For example, in *Pecten maximus* (Comely, 1974), *Chlamys opercularis* (Taylor & Venn, 1979), and *Mytilus edulis* (Gabbott, 1975), energy reserves are required for both the initiation of gametogenesis and subsequent gonadal growth, while in others such as *A. irradians concentricus*, food intake is necessary to sustain gonadal growth since reserves from the muscle, digestive gland, and mantle are inadequate.

Parallel to their utilization for gametogenesis, ingested nutrients were also incorporated into the adductor muscle and digestive gland for storage. The muscle stored high levels of protein both at the beginning and end of the annual cycle to sustain the start of gametogenesis. No other study with bivalves has reported protein values as high as those presented here for the adductor muscle of *P. mazatlanica*, neither for scallops whose adductor muscle is associated with locomotion. Because the decrease in protein content of the muscle was significantly related to the increase in the size of oocytes during vitellogenesis, the role of this organ as the most important site of energy storage is evident. In fact, a significant loss of weight in the muscle to less than half its maximum value was detected as both protein and carbohydrate reserves [illegible] rapidly consumed in benefit of gametogenesis. The contribution of the muscle has also been emphasized for other bivalves, such as *Chlamys* sp (Ansell 1974; Taylor & Venn 1979), *M. edulis* (Gabbott 1975; Bayne 1976), *A. irradians concentricus* (Barber & Blake 1981, 1991; Epp et al. 1988), *P. maximus* (Faveris & Lubet 1991), *A. purpuratus* (Martínez 1991), and *A. ventricosus* (Racotta et al. 1998).

Unlike the muscle, the digestive gland appears to have a secondary role in gonadal development of *P. mazatlanica*. This seems evident since protein was the only fuel transferred to the gonadal tissue during the first half of the year. On the contrary, carbohydrates were progressively stored from March to November, indicating that despite the advancement of gametogenesis, these nutrients are not used for the cycle in course and rather accumulated for further energy needs. This result is in agreement with the finding of Barber and Blake (1981, 1991) that the digestive gland acts as a short-term storage and transfer site of carbohydrates to meet the reproductive events in *M. edulis*. Regarding the storage function, Saucedo et al. (2001b) found specialized vesicular connective tissue (VCT) cells—filled mainly with carbohydrates—surrounding excretory conduits among the digestive gland and gonadal tissue. We believe that VCT cells from both tissues are probably communicated via the interconnective tissue matrix, which may be the vehicle for the transport of stored carbohydrates between the digestive gland and the gonadal tissue, and vice versa. Lipids and triacylglycerides reserves were stored and rapidly mobilized after each of the reproductive peaks detected. Therefore, *P. mazatlanica* may be considered a species that uses a strategy of storing large quantities of energy for starting and sustaining gametogenesis. However, our knowledge about the metabolic control of reproduction in pearl oysters is still limited. More studies on seasonal cycles of energy storage and mobilization are required, especially involving the participation of the mantle tissue, which has been proposed to be an important site of storage of glycogen and lipids in some bivalves. It would also be interesting to obtain data similar to that from this study for tropical species of *Pinctada*.

ACKNOWLEDGMENTS

This study was done as part of two institutional projects of CIBNOR on pearl oyster culture and pearl induction in Bahía de La Paz (Projects ABM-7 and ABM-39). Additional grants were provided by the Consejo Nacional de Ciencia y Tecnología (CONACYT-México, as a Ph.D. scholarship), the Consejo Nacional para la Biodiversidad (CONABIO), and the Fondo Mexicano para la Conservación de la Naturaleza (FMCN). The authors thank the following staff of CIBNOR: Diana Carreño and Carmen Rodríguez (for support during the biochemical and histological analyses, respectively) and to Horacio Bervera and Juan José Ramírez (for SCUBA diving assistance and collection of oysters). We also thank Dr. Paul Southgate (James Cook University, Australia) for his comments and suggestions during the revision of the paper and for editing the English-language text.

HYBRIDIZATION OF TETRAPLOID AND DIPLOID *CRASSOSTREA GIGAS* (THUNBERG) WITH DIPLOID *C. ARIAKENSIS* (FUJITA)

HUAYONG QUE[1] AND STANDISH K. ALLEN, JR.[2]*
[1]*Institute of Oceanology, Chinese Academy of Sciences, Qingdao, Shandong 266071, P.R. China;*

Port Norris, New Jersey 08349

ABSTRACT Three replicates of hybrid crosses of tetraploid and diploid *C. gigas* (Thunberg) with diploid *C. ariakensis* (Fujita) were produced with controls. Larval survival and growth were documented. Cytological events were also monitored in oocytes from hybrid crosses following insemination. Among the four types of hybrid crosses, diploid *C. gigas* (female) × diploid *C. ariakensis* (male) (GA) was the most successful. Survival of GA was about the same as that of controls in two of three replications, although its growth rate was 25–30% lower. Crosses of tetraploid *C. gigas* (female) and diploid *C. ariakensis* (male) (GGA) had poor yield at day 2 post-fertilization (0.05%), but grew nearly as well as controls subsequently. The other two types of hybrids (i.e., diploid *C. ariakensis* [female] and tetraploid *C. gigas* [male] [AGG], diploid *C. ariakensis* [female] and diploid *C. gigas* [male] [AG]) suffered very low yield at day 2 (0.01% and 0.003%) and grew very slowly. Spat were obtained from all replicates of GA crosses and one of three replicates of GGA, and proved to be hybrids by polymerase chain reaction/restriction fragment length polymorphism (PCR/RFLP) diagnosis. GGA hybrids were confirmed to be triploid by flow cytometry. No larvae survived to eyed stage in AGG or AG crosses. Cytological examination revealed that the vast majority (>99%) of oocytes from hybrid crosses had a prolonged meiotic prophase I or metaphase I at least through 180 min post-insemination.

KEY WORDS: *Crassostrea gigas, Crassostrea ariakensis,* diploid, hybrid, tetraploid, oyster, breeding, polyploidy

INTRODUCTION

There are numerous reports of attempted interspecific hybridization in the genus *Crassostrea* (Gaffney & Allen 1993). However, most should be viewed with caution because these reports were unaccompanied by genetic confirmation of putative hybrids. Even a modest amount of contamination may account for the majority or all of surviving progeny in hybrid crosses in which fertilization rate and viability are normally low or nil (Allen & Gaffney 1993). One case seems clear: Pacific oyster *C. gigas* (Thunberg) and Suminoe oyster *C. ariakensis* (Fujita—formerly *C. rivularis* Gould) can be crossed to produce viable hybrids (Allen & Gaffney 1993).

The production of hybrids is interesting because they may possess qualities that improve commercial traits. Hybrids also could be back-crossed to introgress certain traits into either of the parental species; for example, disease resistance. Introgression of disease resistance into *C. virginica* (the Eastern oyster) from *C. gigas* was the rationale for the extensive hybrid trials undertaken by Allen et al. (1993). Later, many more hybridization trials were attempted, using bridging crosses between races of *C. virginica,* using (only slightly) fertile *C. gigas* × *C. ariakensis* hybrids (GA), and using polyploidy (Lyu 1996). However, under no circumstances tested in the lab did *C. virginica* hybridize with *C. gigas* or *C. ariakensis.*

Although they failed as a bridging cross to *C. virginica,* GA hybrids are still of interest for several other reasons. First, no work has been done on the qualities of diploid GA hybrids as an aquaculture product, although this work might more appropriately be carried out where there is on-going commercial culture of these two Asian species. For the East coast, they are nonnative. Second, because diploid hybrids are possible, production of polyploid hybrids should also be possible. Polyploid hybrids are potentially useful for improvement of commercial traits (Longwell 1986). Virtually no work on polyploid hybrids of shellfish has been done. Third, and most apropos to research on the East Coast, is the issue of testing nonnative species as an alternative to the native Eastern oyster because of the decline in the fisheries there.

Trials of nonnatives were begun in Delaware Bay several years ago (Allen 1993) and have been conducted for *C. gigas* in the Chesapeake Bay (Calvo et al. 2000). Trials with *C. ariakensis* have been (Calvo et al. 2001) and continue to be conducted. *C. gigas* seems more suitable for higher salinity environments and *C. ariakensis* seems suitable for more estuarine conditions. In all field trials up to this point, triploids have been used to effect population control because of their sterility (Allen & Downing 1990, Gaffney & Allen 1992, Guo & Allen 1994a).

Triploid hybrids then are of interest because they are expected to be sterile, more so than diploids because of the added burden of gametogenesis in hybrids (Thorgaard & Allen 1986, Thorgaard & Allen 1992). Triploid hybrids may also have characteristics intermediate to the two parental species, for example, salinity preference. The genotypes that might be available for culture in an estuary as varied as the Chesapeake Bay, for example, could range from triploid *C. gigas* (GGG) through two types of triploid hybrids—either tetraploid *C. gigas* × diploid *C. ariakensis* (GGA) or diploid *C. gigas* × tetraploid *C. ariakensis* (GAA)—to triploid *C. ariakensis* (AAA), with phenotypes potentially encompassing the full range of estuarine and marine conditions.

To date, all hybrid crosses between *Crassostrea* species have been made between diploids. Diploids are also used in the production of triploid hybrids using ploidy induction techniques (Allen et al. 1989). For example, triploid hybrids were attempted between *C. virginica* and *C. gigas* by inhibiting polar body 2 with cytochalasin B treatment (Allen et al. 1993). However, this hybrid seems to be inviable in any form. Triploid hybrids were also attempted (S. K. Allen, Jr., unpublished data) between *C. gigas* and *C. ariakensis.* These, too, were unsuccessful for another rea fertilization in this cross is protracted, taking more than 3 h.

consequence, polar body 2 formation is asynchronous and treatments to inhibit polar body 2 are useless. The availability of tetraploid *C. gigas* (Guo & Allen 1994b), tetraploid *C. ariakensis*, or both, provides a new opportunity to produce triploid hybrids by crossing (Guo et al. 1996), rather than induction and to further investigate the fitness of them. As a first step, we examined the feasibility of hybridizing tetraploid *C. gigas* and diploid *C. ariakensis*. At the same time, we repeated crosses of diploid *C. gigas* with diploid *C. ariakensis* as controls and also examined early development of eggs cytogenetically.

MATERIALS AND METHODS

Oyster and Gametes

Sexually mature oysters used in this study were 2 years old and obtained from stocks held at the Cape Shore Laboratory, Haskin Shellfish Research Lab. Ploidy of tetraploid Pacific oysters was confirmed in all individuals by flow cytometry prior to spawning. Gametes were obtained by strip spawning. All surfaces and instruments contacting the oysters were cleaned with dilute bleach and rinsed with fresh water between handling and opening of different individuals. Sex was determined by gonad biopsy under a light microscope. Once the sex was determined, the animals from different sexes were removed to separate containers. Gametes from each oyster were dissected into individual beakers. Eggs were passed through a 60-μm Nytex screen to remove the large tissue debris and rinsed on a 25-μm screen, then suspended in filtered (2 μm) seawater at 23–25°C for at least 30 min to confirm that the eggs were not self-fertilized. Sperm were separated from debris by passing the suspension through a 15-μm screen.

Experimental Design

Abbreviations for gamete contributions of the two oyster species are as follows: G = diploid *C. gigas;* GG = tetraploid *C. gigas;* and A = diploid *C. ariakensis*, with female listed first. Eight types of crosses were conducted (Table 1) overall, although not all crosses were possible in all three replicates. For each replication, an individual female and male were used. After spawning, parents were frozen at −80°C for subsequent genetic confirmation of the progeny.

TABLE 1.

Experimental Design for Crosses Among 4n *C. gigas*, 2n *C. gigas*, and 2n *C. ariakensis*.

		♂		
	G	**GG**	**A**	
♀

A	AG	AGG	AA	

Individual females and males were used for each replication, and three replicates were made. Gamete contribution is represented by GG, G, or A, respectively, with female listed first.

Embryonic and Larval Development

Insemination was conducted at 23–25°C and for hybrids, high densities of sperm were used (Lyu & Allen 1999). Fertilization rate was assessed by directly examining at least 100 oocytes under the light microscope at 60–90 min post-insemination for controls and up to 180 min post-insemination for hybrid crosses. After determining fertilization rate, oocytes were transferred to culture vessels whether fertilization was observed or not. Fertilization was considered successful if the oocyte was at or beyond polar body 1 formation.

Yield at 48 h post-insemination was estimated by directly counting straight-hinge larvae with normal appearance. Yield was calculated as

(no. of straight-hinge × 100)/no. of eggs incubated

Temperature and salinity for larval cultures of crosses of GG, GA, GGA, G/GG, and GG/G, where *C. gigas* was the egg source, were 25°C, 22–23 ppt (Breese & Malouf 1975). For crosses of AA, AG, and AGG, where *C. ariakensis* was the egg source, temperature and salinity were 26°C and 20 ppt (Breese & Malouf, 1977). Seawater in the larval cultures was renewed every 2 days. In all hybrid cultures, densities of larvae were sufficiently low to prevent density-related growth effects; densities in parental culture were within those used in standard larval culture, beginning at 10/mL and winnowing out to 1–2 /mL. During water changes, numbers of remaining larvae were estimated and shell length was measured for 20 individuals for each cross. When larvae reached eyed stage, eyed larvae were collected and treated with a solution of 10^{-4} M epinephrine for 16 h (Coon et al. 1986). Following treatment, metamorphosed larvae were held in a downweller system until they reached a shell length of approximately 1 mm, when they were transferred to an upweller silo. We took great care to eliminate all sources of contamination throughout the culture process.

For cytological observations, eggs from each hybrid cross were sampled and fixed with Carnoy's solution (1:3 glacial acetic acid and absolute methanol) at 90, 120, 150, and 180 min post-insemination. Fixatives were changed twice following light centrifugation. Chromosomes were observed by acetic orcein stain (Guo et al. 1992).

Genetic Confirmation

We randomly sampled 28 spat from each replicate of GA crosses and all GGA spat. In progeny, the whole body was prepared for DNA extraction, whereas mantle tissue (2–8 mg) from corresponding parental species was prepared using a commercial kit (PureGene, Gentra, Minneapolis, MN). An additional gill tissue sample from GGA spat was taken and stored in DAPI/DMSO (Sigma, St. Louis, MO) solution at −80°C for flow cytometric analysis.

An approximately 550-bp region of the nuclear rDNA genome was amplified via polymerase chain reaction (PCR) using primer ITS-1. (The primer pair was designed by Dr. Patrick M. Gaffney, University of Delaware [Hedgecock et al. 1999]). Reaction volume of 25 μL contained 50 MM $MgCl_2$, 0.2 mM of each dNTP, 0.2 μM of each primer, 5 U/μL polymerase (Taq DNA polymerase, Sigma) and 1 μL DNA extraction. DNA amplifications were performed in a programmable thermal cycler (PTC-100, M.J. Research, Inc., Walthram, MA) using a 2-min initial denaturation at

94°C and then 34 cycles of 45-sec denaturation at 94°C, 1-min annealing at 52°C, 1-min extension at 72°C, and finally a 5-min extension at 72°C.

Restriction enzyme digestion of PCR products was made with restriction endonuclease Hinf I (Sigma). Digestion volume of 20 μL contained 1 × buffer (supplied by New England Biolab Inc., Beverly, MA), 5 units Hinf I, and 8 μL PCR product. Digestion mix was incubated at 37°C for 3–4 h, followed by 5 μL 10× loading dye to stop the digestion.

All PCR products and restriction digest fragments were electrophoresed in a 3% agarose (Sigma) gel in 1× TBE (0.089 M Tris-borate, pH 8.3, 0.002 M ethylenediamine tetraacetic acid [EDTA]) buffer. A molecular weight marker (pUC 18, digested with Hae III, Sigma) was loaded along with the product of interest. The gel was run at 60–90 V, stained with ethidium bromide (0.2 mg/mL) for 10–15 min, and visualized by transillumination.

Statistical Analyses

All data were analyzed with the computer program SYSTAT (Wilkinson 1990). Fertilization rates and yield data were arcsine transformed prior to statistical analysis (Sokal & Rohlf 1981). To compare the performance of hybrids to their controls, a two-way ANOVA was used. Paired *t*-tests were conducted to compare certain crosses to their reciprocals.

RESULTS

Fertilization Rate and 48-h Yield

Mean fertilization rates in the parental (nonhybrid) crosses were 94% (GG), 77% (AA), 88% (G/GG), and 85% (GG/G) (Table 2), with no statistically significant difference among them ($F = 3.118$, $P = 0.132$) by ANOVA. In hybrids, signs of fertilization did not appear until 180 min after insemination, precluding estimates of fertilization rate.

Yield at 48 h post-insemination varied significantly among crosses (Table 2) ($F = 3.964$, $P = 0.018$). Yield in GG was significantly greater than that in AA ($t = 4.162$, DF = 4, $P = 0.014$) but there was no difference between other parental crosses. Yields were similar in GGA and AGG ($t = 1.010$, DF = 4, $P = 0.369$), whereas GA had higher yields than AG ($t = 5.364$, DF = 4, $P = 0.006$). Yields of GA and AA crosses were about the same. GGA and AGG crosses produced many fewer larvae than controls. AG crosses suffered extremely low yield (0.003%).

TABLE 2.

Mean fertilization rates and yields ± SD (*n*) at 48-h in parental and hybrid crosses combined from three replicates.

Cross	Fertilization Rate (%)[a]	Yield (%)
GG	94 ± 4.9 (3)	21 ± 7.5 (3)
GA	ND	4 ± 1.2 (3)
GGA	ND	0.05 ± 0.01 (2)
AA	77 ± 13.9 (3)	3 ± 2.5 (3)
GG/G	85 (1)	4 (1)
G/GG	88 ± 5.0 (2)	18 ± 24.4 (2)
AGG	ND	0.01 ± 0.02 (3)
AG	ND	0.003 ± 0.006 (3)

ND = no data.

[a] Fertilization rate was observed at 60–90 min post-insemination for pure crosses; 180 min post-insemination for hybrid crosses.

Larval Survival and Growth

After 48 h post-insemination, survival of GA crosses was about equal to controls in two of three replicates (Fig. 1). Larvae of GGA crosses had high survival, although the number of eyed larvae was small (of 450 larvae on day two, 280 survived to eyed stage). For AGG and AG crosses, mortality was severe and steady for 13 days, with no survival to eyed stage. In GG crosses, mortality was generally density related, moderating at lower densities at about day 6–10. For AA crosses, survival was generally poor, making this cross a poor control. In general, survival ranked GG, GA, and AA, in descending order. Survival of G/GG was variable: better than GG in replicate 2 but worse than AA in replicate 3. Survival of

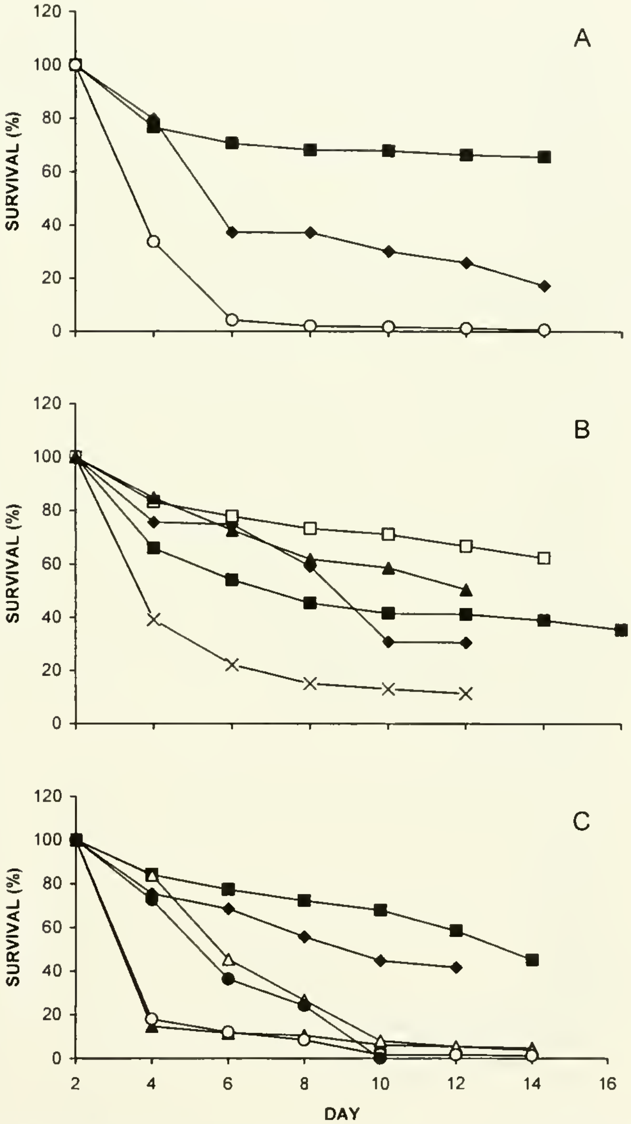

Figure 1. Mean survival of hybrid larvae and their respective controls from day 2 up to day 16 in crosses of diploid and tetraploid *C. gigas* with diploid *C. ariakensis*. (A) Six matings were made in replicate 1. No larvae survived to day 2 in AG, AGG, and GGA. (B) Eight matings were made in replicate 2. No larvae survived to day 2 in AG, AGG, and AA. (C) Seven matings were made in replicate 3. No larvae survived to day 2 in GGA. Counts were terminated when harvesting of eyed larvae was begun. GG (◆), GA (■), G/GG (▲), GG/G (×), GGA (□), AGG (△), AA (○), AG (●).

G/GG crosses was better than its reciprocal, GG/G. Larvae survived to setting in all replicates of GG and GA, 2 of 3 replicates of G/GG and 1 of 3 replicates of GGA. Spat were obtained from all of these.

Larvae of GG, G/GG, GG/G, and GGA crosses grew at similar rates. Crosses of GA grew slower than GG controls but faster than AA (Fig. 2). GA larvae were generally smaller than GG larvae. Both AG and AGG crosses grew very slowly (AG larvae died at day 10). AA crosses grew slowest of all controls. Mean size of eyed larvae was 350 μm for GG, 336 μm for GA, 360 μm for GGA, 361 μm for G/GG, and 361 μm for G/GG. ANOVA showed no significant difference in eyed larvae size among crosses ($F = 1.712$, $P = 0.199$). After 90 days post-setting, spat from GGA reached 12.0–17.5 mm in shell size compared with 2.87–8.0 mm in the corresponding GA cross ($t = 8.49$, DF = 6, $P < 0.001$).

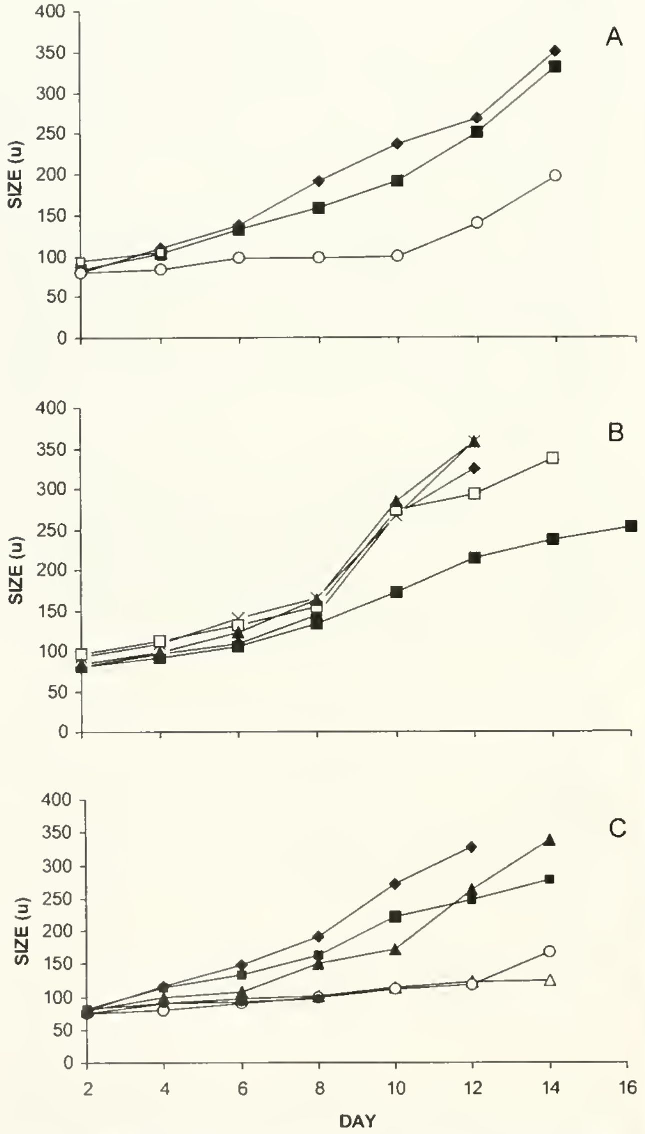

Figure 2. Mean size (μm) of hybrid and control larvae from day 2–16 in crosses of diploid and tetraploid *C. gigas* with diploid *C. ariakensis*. (A) Larvae from GG, GA, GGA, and AA in replicate 1; (B) larvae from GG, GA, GG/G, and G/GG in replicate 2; and (C) larvae from GG, GA, G/GG, AGG, AA, and AG in replicate 3. Measurement of surviving larvae was made until eyed larvae appeared. GG (◆), GA (■), G/GG (▲), GG/G (×), GGA (□), AGG (△), AA (○), AG (●).

Cytological Observation of Eggs from Hybrid Crosses

The vast majority of eggs from hybrid crosses were delayed at prophase I or metaphase I at least through 180 min post-insemination (Fig. 3A–E). In fact, of all eggs examined at 180 min post-insemination (≥150 observations from each of GA, AG, GGA, and AGG), only 2% of eggs from GGA had entered anaphase I (Fig. 3F). In GA, AG, and AGG, 10 bivalents were still observed at this time. Chromosome aggregation was much more complicated in eggs from GGA crosses. In general, eggs contained an average of 10 quadrivalents, although other types of synaptic chromosomes were also present, i.e., univalents, bivalents, and trivalents (Fig. 3D, E).

Genetic Confirmation

Agarose gel electrophoresis of the PCR products consistently revealed two bands, one at around 587 base pairs (bp) and the other at around 527 bp (Fig. 4, top). Restriction digest fragments resolved distinct bands in both parental species. Two bands were resolved, one at around 434 bp and the other around 138 bp in *C. gigas* females, both tetraploid and diploid. In contrast, two bands were resolved at around 267/257 bp and 174 bp in *C. ariakensis* males (Fig. 4, bottom). The hybrids (GA and GGA) expressed all four bands corresponding to their parental species. An additional band was detected at around 458 bp in hybrids. Identical band resolution was observed in replicates 1 and 2 of GA crosses, whereas an extra band was resolved at 587 bp consistently in both parental species and hybrids in replicate 3 (Fig. 4, bottom, last four lanes). All progeny samples (28 individuals from each replicate of GA and a total of 4 individuals from GGA) were hybrids. Three of four GGA hybrids were triploid as confirmed by flow cytometry; the other hybrid was diploid.

DISCUSSION

In hybrid crosses, fertilization was not apparent even as late as 180 min post-insemination. These same observations were reported previously (Miyazaki 1939, Imai & Sakai 1961), both

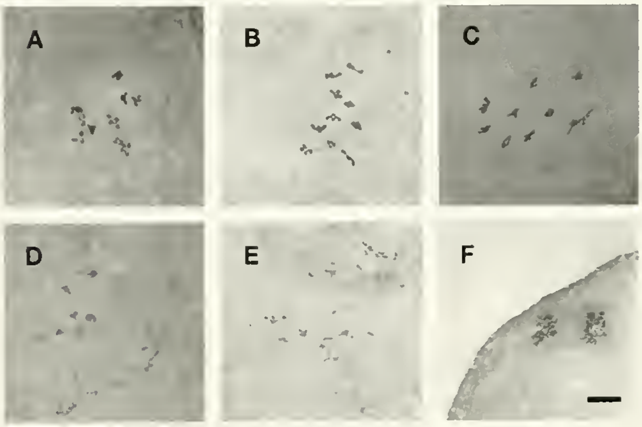

Figure 3. Chromosome observations in crosses of diploid and tetraploid *C. gigas* with diploid *C. ariakensis* at 180 min post-insemination. (A) Prophase I in oocytes from GA; (B) prophase I in oocytes from AG; (C) prophase I in oocytes from AGG; (D) and (E) prophase I in oocytes from GGA; and (F) anaphase I in oocytes from GGA. Scale bar on (D): 10 μm.

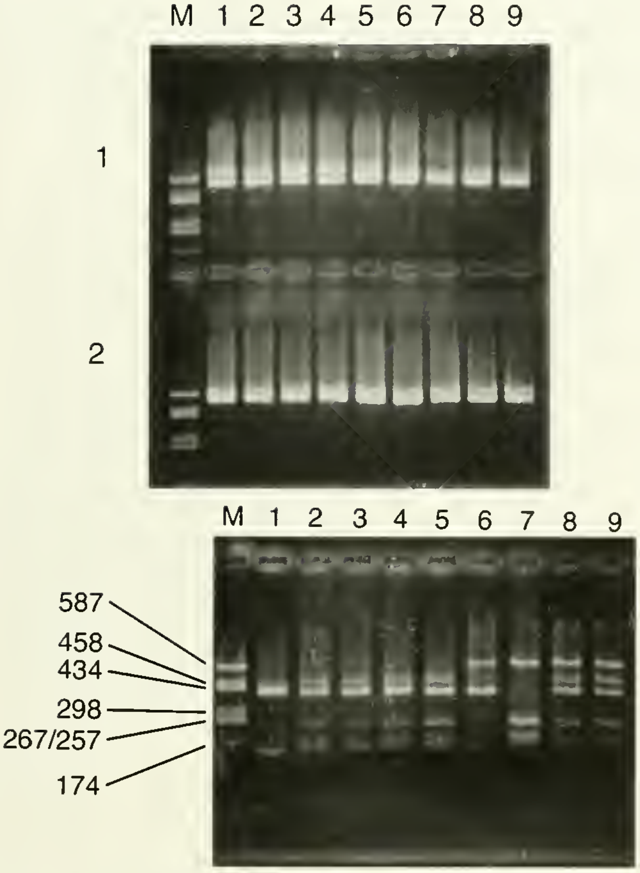

Figure 4. Top: Electrophoretic separation of undigested DNA products resulting from PCR amplification of genomic DNA, using primer of ITS-1. rDNA originated from parental species and their hybrid progeny. Row 1: lane 1 = diploid *C. gigas* (♀); lane 2 = diploid *C. ariakensis* (♂); lanes 3–4 = G × A progeny; lane 5 = diploid *C. gigas* (♀), lane 6 = diploid *C. ariakensis* (♂), lanes 7–9 = G × A progeny. Row 2: lane 1 = tetraploid *C. gigas* (♀), lanes 2–5 = GG × A progeny; lane 6 = diploid *C. gigas* (♀), lane 7 = diploid *C. ariakensis* (♂), lanes 8–9 = G × A progeny. Lane M = molecular weight marker. Bottom: Electrophoretic separation of PCR amplified rDNA products from GA and GGA crosses digested with restriction endonuclease Hinf I. M = molecular weight marker; lane 1 = tetraploid *C. gigas* (♀; lanes 2–5 = GG × A progeny, lane 6 = diploid *C. gigas* (♀), lane 7 = diploid *C. ariakensis* (♂), lanes 8–9 = G × A progeny. The molecular weights of bands resolved from the marker are, from largest (slowest migrating) to smallest: 587, 458, 434, 298, 267/257, 174, and 102 base pairs, respectively.

of whom found little or no fertilization between *C. gigas* and *C. ariakensis* in their studies of Japanese oysters. However, we observed 8%–9% fertilization rate in GA crosses in other experiments (data not shown). In a previous study, a mean fertilization rate of 12% was reported for GA crosses (Allen & Gaffney 1993). Zhou et al. (1982) revealed that fertilization rates in *C. gigas* (♀) × *C. ariakensis* (♂) were 0–52.6% and its reciprocal, 2.3%–18.8%. These data indicate that the fertilization rate in these hybrids varies widely. Success of hybridization should not be assessed solely on the fertilization rate. In contrast, fertilization between other species of *Crassostrea* occurred readily, and often showed relatively high rates, but larvae survived for only a short time before complete mortality (Menzel 1986; Allen et al. 1993).

Despite the apparent lack of fertilization (observed up to 180 min post-insemination), replicates of GA yielded viable spat, which reconfirms the compatibility of the gametes from *C. gigas* (♀) and *C. ariakensis* (♂). Buroker et al. (1979) reports a relatively high genetic similarity between these two species. Other studies also demonstrate the feasibility of hybridization between these two species (Allen & Gaffney 1993; Downing 1988; Downing 1991; Zhou et al. 1982), although only Allen & Gaffney (1993) confirmed hybrids genetically. In contrast to the success of GA, the reciprocal AG failed to produce any spat, although no morphological deformities were observed in the larvae. AG larvae were previously shown to be much less viable compared with the reciprocal although a few spat were obtained (Allen & Gaffney, 1993). The diploid control AA (three replicates) consistently survived poorly and grew slowly in this study. This may partly account for the failure to obtain any spat from the AG cross. According to published accounts (Breese & Malouf 1977; Langdon & Robinson 1996), the survival and growth of *C. ariakensis* are similar to *C. gigas* under appropriate culture conditions. It is not clear why larvae of *C. ariakensis* performed so poorly in this study, because we have routinely cultured *C. ariakensis* on other occasions.

Only one of three replicates of GGA yielded spat. The failure of the other two replicates might be attributable to low fecundity of tetraploid *C. gigas* used here (data not shown), although generally tetraploids have shown high fecundity (Guo et al. 1996; B. Eudeline, Taylor United, Inc. and S.K. Allen, Jr., unpublished data). In all three replicates, yield at day 2 was low. We suggest that the major barrier for GGA production on a pilot- or production-scale is low yield at day 2. Afterward, larvae of GGA crosses survived well (virtually no mortality). While it is clear that more GGA progeny could be obtained by using more parents, the real challenge is to find factors that lead to high levels of fertilization for the gametes that are available. We also suggest that there is a difference in growth rate between triploid (GGA) and diploid (GA) hybrids. First, GGA eyed larvae appeared 5–7 days earlier than GA and right after those of controls GG, G/GG, and GG/G. Second, the size of spat from GGA was greater than the size of GA at 90 days post-insemination, although the number of GGA spat was small.

All 28 progeny sampled from each of three replicates of GA were hybrids. With respect to GGA progeny, some eyed larvae attached to the culture containers, leading to loss of eyed larvae. Consequently, only four cultchless spat were obtained. However, the fact that three of the spat were triploid hybrids demonstrates that hybridization between tetraploid *C. gigas* (♀) and diploid *C. ariakensis* (♂) was successful. Triploid hybrids of *C. gigas* and *C. ariakensis* cannot be obtained in any other way. In particular, the use of cytochalasin B (or other polar body inhibitor) is precluded in GA crosses because of the prolonged period leading to syngamy and polar body formation. It is not possible to create triploids without some level of predictability and synchrony among developing eggs (Allen et al. 1989).

PCR restriction fragment length polymorphism (RFLP) diagnosis was an effective means to verify putative hybrid progeny. ITS-1 amplification/Hinf I digestion successfully distinguished among *C. gigas*, *C. ariakensis*, and hybrids, which show bands present from both parental species. Application of this method is based on availability of an appropriate primer: ITS-1 in this study Other methods have been used to confirm hybrid status (Allen & Gaffney 1993; Allen et al. 1993; Nakamura et al. 1990; Jiang et 1988). Karyotype analysis has been useful for hybrids among pearl oyster genus *Pinctada* (Jiang et al. 1988). For species within the genus *Crassostrea,* the great similarity in their karyotype renders this type of analysis useless in hybrid documentation until more discriminating markers are designed. Flow cytometry was equivocal in discriminating between hybrid and pure crosses using dissociated cells of pooled larvae (Allen et al. 1993).

Cytological examination of newly fertilized eggs from hybrid crosses revealed that either fertilization was severely delayed or early development of oocytes was extremely slow. The duration of meiotic maturation in hybrid crosses was at least triple that of controls. The delay of meiosis was probably not due to the quality of gametes because eggs in controls were normal and reached first cleavage at around 60 min post-insemination consistently (data not shown). Another hybridization attempt between *C. gigas* and *C. ariakensis* indicated there was no apparent difference in the time of development from eggs to the straight-hinge larvae (Zhou et al. 1982). Apparently, fertilization was also highly successful in the study by Zhou et al. leading us to suspect contamination. An alternative explanation is that Zhou et al. used a different population of *C. ariakensis.* The *C. ariakensis* used here are from a population derived from Ariake Bay in Japan. Those of Zhou et al. are likely from mainland China. In this study, despite the delay in fertilization, healthy larvae were obtained and cultured through metamorphosis in all replicates of GA and one replicate of GGA. Furthermore, hybrid spat were obtained. Success in obtaining larvae suggests that meiosis in GA and GGA crosses must have resumed at some time, despite being delayed for an uncommonly long time. A similar observation was made in *C. angulata* oocytes fertilized with sperm from *C. virginica,* where 47% of them exhibited metaphase I nearly 4 h after insemination. However, no parental crosses were made for comparison (Stiles 1973). Oocytes in hybrid crosses of *C. gigas* and *C. ariakensis* with *C. virginica* proceed through meiosis and early mitosis in fairly normal fashion (Scarpa & Allen 1992). The timing of meiotic and mitotic landmarks was the same for all crosses, parental and hybrid. However, hybrids of *C. gigas* and *C. ariakensis* with *C. virginica* were inviable (Allen et al. 1993) after a short larval period despite normal meiotic and early mitotic behavior. *C. gigas* × *C. ariakensis* crosses were not included in Scarpa and Allen's work.

Overall, this study reveals a new potential application for oyster breeding: triploid *C. gigas* × *C. ariakensis* hybrids. We were limited to relatively few tetraploid brood stock for this study, but since that time, tetraploids have become commercialized on the West coast of the United Staes. We were also limited to making the triploid hybrid in one direction; that is, using only *C. gigas* as the tetraploid, enabling experiments on GGA (4n♀) or AGG (4n♂). We were unable to explore GAA (4n♂ *C. ariakensis*) or AAG (4n♀ *C. ariakensis*). Presumably the former would behave like GA and GGA cultures, and the latter would behave like AG and AGG cultures. These experiments will have to wait for the tetraploid *C. ariakensis* that are currently under development. At present, GGA hybrids can be made only at a high cost of gametes from the parental species. Even with high fecundity, the losses are so severe that commercial production would be a problem. Studies on factors that promote higher fertilization rate, syngamy, development rates, or all of these would contribute to efforts to produce pilot-scale quantities of GGA for future testing.

ACKNOWLEDGMENTS

We thank Greg A. DeBrosse for care of brood stock, larval, and nursery cultures. We are especially grateful to Dr. Patrick M. Gaffney and Dr. Ziniu Yu for technical assistance in PCR/RFLP. This project was partly sponsored by the NOAA U.S.–China Marine and Fisheries Science and Technology Agreement in Living Marine Resources. MICROSCOPIC ANATOMY OF GONADAL TISSUE AND SPECIALIZED STORAGE CELLS ASSOCIATED WITH OOGENESIS AND SPERMATOGENESIS IN THE CALAFIA MOTHER-OF-PEARL OYSTER, *PINCTADA MAZATLANICA* (BIVALVIA: PTERIIDAE)

PEDRO SAUCEDO, CARMEN RODRÍGUEZ-JARAMILLO, AND MARIO MONTEFORTE
Centro de Investigaciones Biológicas del Noroeste, S.C. La Paz, Baja California Sur, México

ABSTRACT As part of a major experiment of the reproductive biology of wild *Pinctada mazatlanica*, this study was aimed to characterize the microscopic anatomy of the gonadal tissue and storage cellular elements involved in the seasonal advancement of oogenesis and spermatogenesis. Tissue samples were collected every fifteen days over an annual cycle and processed with histological and histochemical techniques. The hematoxylin-eosin (cytology description), Blue Alcian-PAS (PAS, for carbohydrates), and Black Sudan (BBS) and Oil Red (OR, for lipids) techniques were employed. Temporal variations of the sex ratio and sexuality of specimens were also analyzed. Gonadal tissue developed synchronously over time at the expense of a matrix of interconnective tissue and reserves stored in the adductor muscle and digestive gland. The interconnective tissue communicates the gonadal tissue with the digestive gland and also serves as substrate for the differentiation of vesicular connective tissue cells and auxiliary cells. In fact, gametes (particularly oocytes) were exogenously nourished by both kinds of cells as gametogenesis advanced. The vesicular connective tissue cells, very abundant among acini, adenomeres, and pearl sac, were observed surrounding excretory conduits in the first two tissues, and were identified as highly PAS++ and moderately BBS+ and OR+. The auxiliary cells were found attached to previtellogenic and vitellogenic oocytes. The endogenous synthesis of lipids during vitellogenesis was associated to the Balbiani body, a storage compartment of the oocyte ooplasm not previously described for any species of pearl oyster. The average female/male ratio is 0.35:1 when specimens were obtained from cultured conditions, but females outnumbered males when collected from the wild. Several cases of protoginic specimens and a few functional hermaphrodite oysters were seen.

KEY WORDS: pearl oysters, *Pinctada mazatlanica*, histology, oogenesis, spermatogenesis, storage cells

INTRODUCTION

When dealing with endangered or protected species, like the majority of members of the genus *Pinctada*, the success of aquaculture requires a proper knowledge of the biology and ecology of broodstock, and in particular, a clear understanding of their reproductive biology and physiology (Southgate & Beer 1997). In experiments focusing on gonadal conditioning, larval rearing, and hatchery spat production under controlled conditions, such knowledge is especially important for two reasons: (1) to assure the formation of spermatozoa and oocytes of the best quality, that will develop into viable and competitive larvae and, later, into settled spat; and (2) to maintain the continuity of the spat production process throughout the year, avoiding the geographic limitations that prevail in subtropical environments like Bahía de La Paz. At such localities, the main spawning season for most species of marine bivalves is restricted to a short period of one to two months of the annual cycle (Saucedo et al. 2001a; Saucedo et al. 2001b; Saucedo et al. 2001c).

Pearl oysters are marine bivalves having considerable economic and commercial value because of their natural capacity to produce pearls of high quality (Monteforte 1990, 1996). Despite this, the factors affecting reproductive success in these species are poorly studied and understood, although their basic reproductive biology has been well documented histologically (Tranter 1958a; Tranter 1958b; Tranter 1958c; Wada 1959; Sevilla 1969; Chellam 1987; Rose et al. 1991; Wada et al. 1995; García-Domínguez et al. 1996; Saucedo & Monteforte 1997; Behzadi et al. 1997; Saucedo et al. 2001a; Saucedo et al. 2001b; Saucedo et al. 2001c). These studies reveal that most aspects of the gametogenic cycle are common to all members of the genus *Pinctada*, with differences ascribed basically to the geographic location of each species. The gonad is absent as an anatomically discrete organ, and instead, gonadal tissue gradually develops as part of the visceral mass, intermingled with the digestive gland and interstitial connective tissue. Gametogenesis occurs continuously and synchronously throughout the annual cycle, but shows a variable number of spawning peaks. Adults behave as protandrous hermaphrodites, maturing as males and changing to females at a certain size/age. A female/male sex ratio of 1:1 is reached with increasing age.

In México, there have been some studies of the reproductive biology of the Calafia mother-of-pearl oyster, *Pinctada mazatlanica* (Hanley 1856) (Sevilla 1969; García-Domínguez et al. 1996; Saucedo & Monteforte 1997; Saucedo et al. 2001a; Saucedo et al. 2001b; Saucedo et al. 2001c). Little is known, however, about the step-by-step advancement of the gametogenic cycle and the role of accessory tissues and cells upon the seasonal build-up of gametes. This study describes the microscopic anatomy of gonadal tissue and specialized storage cellular elements involved in the annual cycle of oogenesis and spermatogenesis in *P. mazatlanica*. This experiment was conducted as part of a major study of the reproductive biology of the species.

MATERIALS AND METHODS

Twenty adult specimens averaging 139 (±9.7 mm *SD*) shell height were collected every fifteen days over a year (January to December 1999) from Caleta El Merito, Bahía de La Paz, Baja California Sur, México (24°16′N, 110°19′W). Cultured specimens coming from the Experimental Marine Farm of the Centro de Investigaciones Biológicas del Noroeste (CIBNOR) were collected from January to August. Wild specimens were collected from September through December because of the scarcity of cultured specimens remaining in the farm during the last third of the year.

After dissecting each specimen, a sample of the visceral mass (where gonadal tissue develops concomitantly with the digest

gland) was excised and preserved in Davidson's solution for 48 h. Samples were dehydrated in ascending ethanol series, embedded in Paraplast at 56°C, and sectioned with a rotatory microtome at 4–5 μm along the anteroposterior axis. To characterize the general morphology of tissues and the advancement of gametogenesis, thin sections were stained with the conventional hematoxylin-eosin technique (Howard & Smith 1983). To identify the presence of carbohydrates (CHO) and lipids (LIP) in storage tissular and cellular elements, additional sections were stained with blue Alcian-PAS (referred to as PAS for CHO) and black Sudan (BBS) and oil red (OR), both for LIP (Prophet et al. 1992). Finished slides were then examined with an Olympus BX-41 compound microscope. The resulting images were stored in the computer using a digital Cole-Snap camera (I-media Cybernetics) and processed with Sigma Scan Pro software (vers. 5.5).

To study the seasonal changes of oogenesis and spermatogenesis, a modified version of Tranter's original scheme (Tranter 1958a; Tranter 1958b; Tranter 1958c) for pearl oysters was used. Gametogenesis was characterized by eight stages: (a) inactive or resting); (b) sexual activation; (c) early development; (d) mid development; (e) late development; (f) ripeness; (g) partially spawned; and (h) spent. For oogenesis in particular, gametes were classified according to their vitellogenic stage as oogonias (corresponding in time to the sexual-activation stage), previtellogenic oocytes (for the early-developing stage), vitellogenic oocytes (mid-and late-developing stages during yolk formation), and postvitellogenic oocytes (ripe stage), adopting the criterion defined by de Gaulejac et al. (1995) for the bivalve *Pinna nobilis*. Apart from de Gaulejac's work, detailed descriptions of the cytological characteristics of each type of oocyte may be found in Saucedo et al. (2001a, b).

In addition, total area variation was recorded for thirty oocytes in each developmental stage measured at three randomly-selected areas of the ovary (Grant & Tyler 1983). The sex ratio and sexual condition of specimens were also recorded. One-way ANOVA was applied for differences in the mean area of oocytes over time.

RESULTS

Gonadal Tissue

Pearl oysters lack a true gonad organ. Instead, gonadal tissue develops gradually as part of the visceral mass by means of seasonal soma-germline interactions. Macroscopically, this tissue is formed by two symmetric lobules (a lobule corresponding to each valve) that grow asymmetrically toward the dorsal region of the visceral mass as gametogenesis proceeds, thus constituting an unpaired gland when specimens are ripe. When observed under the light microscope in a transversal, anteroposterior section (Fig. 1A), gonadal tissue appears delimited from the central region by the digestive gland, and from the pallial cavity (along the periphery) by a layer of neutral-acid mucopolysaccharides and collagen fibers. A thick matrix of interstitial connective tissue—appreciated in the form of a complex circulatory system running among acini—gives support, communication, and substrate for the differentiation of gonadal tissue and one kind of somatic nutritive-storage cells, named as vesicular connective tissue (VCT) cells. The size and grade of diffusion of the interconnective tissue matrix shows an inverse relation to the advancement of gametogenesis. The mucopolysaccharides layer is formed by eosinophilic highly PAS++ cells, with both fractions clearly contrasted, the neutral-inactive (with a pink-magenta color) from the acid-active (with an intense blue color) (Fig. 1A). This tissue is also BBS+ and OR+, although its low reaction to both colorants suggests the presence of relatively few lipids, which are present only in the form of esters of cholesterol.

The gonadal tissue is initially formed as a series of small and compact granular bags that latter enlarge and transform into a complex network of branched tubules as gametogenesis advances (Fig. 1A). These bags, representing the structural units of the gonadal tissue, are called acini or follicles, indistinct for the male testis or the female ovary. The sex cells, either oocytes or spermatozoa, develop within these units by permanent mitosis of oogonial or spermatogonial stem cells producing cloned-daughter cells by centripetal movements.

Digestive Gland

This tissue is formed by a large number of blind-end granular tubules that are connected to the stomach by branched conduits. When observed microscopically in transversal section (Fig. 1B), tubules are composed of structural units called adenomeres, each one having a typically round shape that conforms the blind-end of the tubule. Adenomeres are formed from an external layer of epithelial cells that have a round basophilic nucleus resting upon a thin, acidophilic basal membrane. A thin layer of interconnective tissue surrounds and supports the blind tubules. The digestive gland is involved in a double function; the first one, as tissue, is related to the digestion process of the oyster, while the second, as endocrine gland, is for storage and release of nutrients. Intracellular digestion takes place in the cells located in the basal membrane, via ciliated vesicles acting as carriers of the ingested food and their pinocytosis to enter the cell (processes observed only with an electron microscope). With light microscopy, the diameter of the blind tubules varies with regard to the light beam that can pass, indicating which digestive phase (assimilation or digestion) is being observed. The glandular function of the digestive gland is described in the section below.

Vesicular Connective Tissue (VCT) Cells

The glandular function of the digestive gland, which is closely related to that of gonadal tissue, is associated directly with the presence of a dense matrix of small, round or oval pleomorphic somatic VCT cells. As an integral part of the connective tissue network in which development and morphogenesis of the gonadal tissue takes place, these eosinophilic cells are widely distributed among adenomeres and acini (particularly in the former tissue) surrounding wide excretory conduits (Fig. 1C and D). These conduits are probably communicating with each other via the vascular interconnective tissue matrix, and may be the vehicle for transporting stored nutrients and energy reserves from the gonadal tissue to the digestive gland, or vice versa. When specimens reach the late-developing or ripe stage, this tissue network can grow and invade the intestinal loop (known as the pearl sac for pearl culture purposes), constituting an important storage site for nutrients. VCT cells are strongly PAS++ (Fig. 1C and D) and moderately BBS+ and OR+ (Fig. 1E), confirming a high proportion of carbohydrates (mainly glycogen), but also lipid droplets in a lower and variable percentage. Transverse sections through the gonad indicate that the proportion of VCT cells versus germ cells appears to be approximately the same in ovaries and testis.

Auxiliary Cells (AC)

These specialized intragonadal cells are observed only in female acini, always in intimate relation with developing oocytes, to

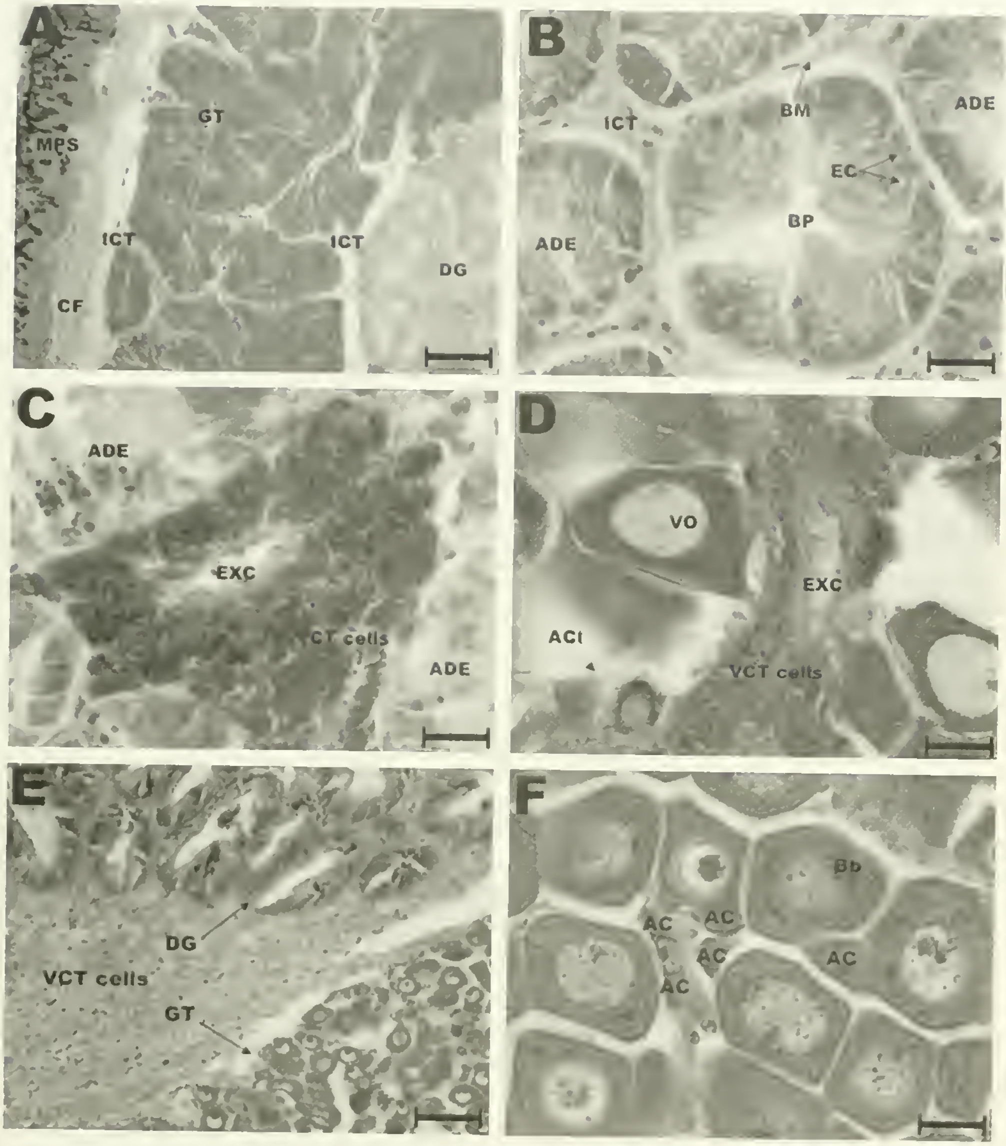

Figure 1. Color photomicrographs of accessory tissues and cells associated with oogenesis and spermatogenesis in *Pinctada mazatlanica*. A) Transversal section of the visceral mass at 10x, showing, from the periphery to center, the neutral (magenta) and acid (blue) highly PAS++ mucopolysaccharides layer (MPS), collagen fibers (CF), and interconnective tissue (ICT) supporting and communicating the male gonadal tissue (GT) with the digestive gland (DG); B) Microscopic anatomy of the DG at 40x, in which adenomeres (ADE) show several layers of eosinophilic cells (EC) resting upon a basal membrane (BM) and the blind part (BP) in the center; C) and D) Highly PAS++ vesicular connective tissue (VCT) cells at 40x, observed surrounding excretory conduits (EXC) among ADE and acini (ACI), respectively; E) Moderately BBS+ VCT cells at 10x, found in the boundaries between female GT and DG; F) Basophilic auxiliary cells (AC) at 40x, observed in different positions in relation to developing oocytes, and the Balbiani body (Bb). Scale bar = 50μm.

which they are attached by desmosome-like gap junctions (observed only with the electron microscope). AC range in size from 20–30 μm, and because of their basophilic character and strong affinity to hematoxylin, are easily distinguishable from oocytes (except those previtetellogenic that are also basophilic) by their dark purple color. AC exhibit an enormous plasticity to change their morphology according to the stage of gametogenesis and to their exact location with respect to growing oocytes. This plasticity is most likely due to the disposition and arrangement of the microtubule skeleton (cytoarchitecture) of these cells. Thus, AC may be observed basally (near the stalk region), laterally, or eccentrically (Fig. 1F). AC serve a nutritive function during oocyte development, especially during the construction of the lipid fraction of the yolk in the early-, mid-, and late-developing stages. In ripe specimens, these cells gradually disappear or, if still appearing, are detached from the oocytes.

Oogenesis

The step-by-step advancement of the annual oogenic cycle in *P. mazatlanica* is depicted in Figure 2. Here, the stages are described.

Inactive or Resting

There is no evidence of gonadal development and specimens are undifferentiated by sex. Acini are observed collapsed and empty, with some granulocytes and phagocytes remaining from th gamete resorption process. On the contrary, the vascular inter

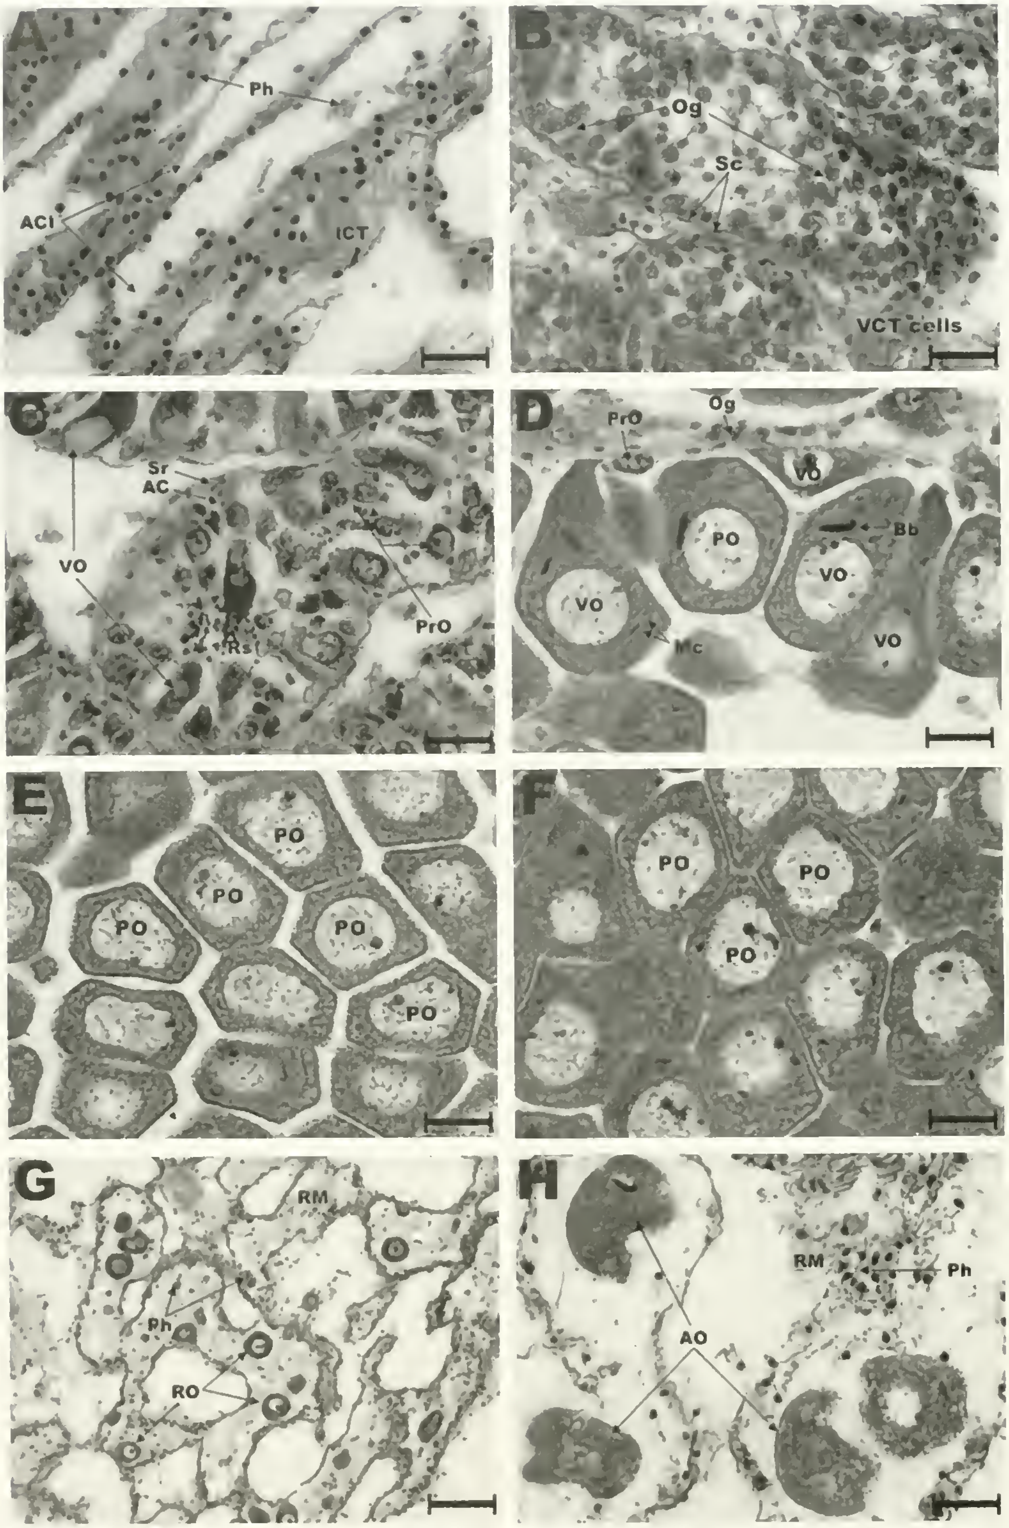

Figure 2. Photomicrographs of female gonadal tissue (40x), showing the sexual stages of oogenesis in *Pinctada mazatlanica.* A) Inactive stage, with empty and collapsed ACI containing some phagocytes (Ph) and abundant ICT; B) Activation stage, in which only stem cells (Sc) and oogonia (Og) are attached to ACI walls, and, among them, large amounts of VCT; C) Early development, dominated by previtellogenic oocytes (PrO) still attached to the acinus wall by the stalk region (Sr) and accompanied by AC and a few vitellogenic oocytes (VO); D) Mid-developing stage, with only a few Og and PrO present, while more VO and postvitellogenic oocytes (PO) start dominating the ACI. The Bb and the mitochondrial clusters (Mc) are common during this stage; E) Late development, showing free PO filling the ACI lumen, but still leaving a wide interoocyte space; F) Ripe stage, with large, free PO and the interoocyte space reduced to its minimum; G) Partial spawning, presenting many scattered residual oocytes (RO), resorptive material (RM), and a few Ph; H) Spent stage, showing empty ACI with atresic oocytes (AO), RM, and more signs of Ph. Scale bar = 50 μm.

nective tissue grows and appears distended and greatly diffused among acini (Fig. 2A).

Sexual Activation

Acini look small, round or oval, and easily distinguished from other acini. They are supported by interconnective tissue and nourished by VCT cells. Each acinus is lined up exclusively with small (3–4 μm diameter) spherical stem cells and larger oogonias (5–6 μm), either attached in clusters to the acinus wall or progressively expanding toward the lumen (Fig. 2B). Apart from these cells no other developmental stage has yet appeared.

Early Development

Acini begin to grow and enlarge, but their individuality is still clear. Oogonias rapidly proliferate by mitosis and give rise, by centripetal movements, to the first previtellogenic oocytes (Fig. 2C). These oocytes are easily distinguished from other types of oocytes by the dark blue-purple color of their ooplasma. They enlarge to a diameter of 14–23 μm in diameter, lack yolk, and are still connected to the acinus wall by the stalk region, in which some AC are commonly observed. At the end of this stage, a few vitellogenic oocytes appear in the acinus, but the interoocyte space is still wide.

Mid Development

Acini continue to grow, adopting a more complex anastomosed shape. The proportion of interconnective tissue and VCT cells decreases, but AC are still observed. All developmental stages are present within acini, but vitellogenic oocytes—characterized by the growth of the yolk ooplasm and increase in diameter to 30 to 55 μm—are the dominant stage (Fig. 2D). This oocyte is still connected to the acini wall, presents a peduncle or pear shape, and shows a large nucleus and one or two dense, blue-stained nucleoli. Two different basophilic structures are observed in the ooplasm for the first time: the Balbiani body (seen as a black spot of variable size and shape) and many smaller, irregularly scattered black spots that probably correspond to mitochondrial clusters (Figs. 1F and 2D).

Late Development

Acini continue to grow and stratify and interconnective tissue and VCT cells to decrease. AC tend to disappear or, if still occurring, they appear separated from oocytes. The interoocyte space reduces as previtellogenic oocytes diminish and vitellogenic and postvitellogenic oocytes progressively develop (Fig. 2E). Postvitellogenic oocytes are seen free in the lumen, have a polyhedral or polygonal shape, and increase in diameter to 60–70 μm. A dense amorphous mass (probably chromatin) is observed in the nucleoplasm. The nucleolus is dense, compact, and usually in a marginal position. The Balbiani body and mitochondrial clusters may still be present.

Ripeness

This stage marks the end of vitellogenesis. Acini are strongly anastomosed and packed almost entirely with mature, free postvitellogenic oocytes that attain a maximum diameter of 70–75 μm (Fig. 2F). VCT cells in gonadal tissue almost disappear and interoocyte space is reduced to the minimum. The nucleus now occupies a large area in the middle of the oocyte. Many oocytes begin to enter the germinal vesicle stage, in which a gap between the nuclear envelope and the ooplasm appears, indicating a readiness for spawning.

Partially Spawned

After the germinal vesicle breakdown, oocytes are released outside the acini, which look distended and partially empty (Fig. 2G). Some types of phagocytes and granulocytes appear in the space between the free residual oocytes, which now look rounded or pear-shaped. Large amounts of resorptive material are noticeable. The nucleolus and chromatin disaggregate, but if still present, they may be associated with a new developmental process. This may be a strategy to recycle nutrients (proteins and lipids of the yolk) destined for the new oocyte.

Spent

Acini are collapsed and empty, with clear signs of phagocytic activity, oocyte degeneration, and much resorptive material. Depending on the duration of this phase, residual oocytes, especially those of small diameter whose nucleus is not polylobed, undergo atresia (Fig. 2H). This process represents deterioration and disintegration of most of the major cellular constituents and thereby the breakdown of the oocyte.

Spermatogenesis

The step-by-step advancement of the annual spermatogenic cycle in *P. mazatlanica* is depicted in Figure 3. The stages are described as follows:

Sexual Activation

Acini initially are small, round or oval, and supported by vascular interconnective tissue and VCT cells. The germinal epithelium is formed exclusively by a single layer of small (3–4 μm diameter) spherical stem cells that are strongly attached to the acinus wall and by some spermatogonias starting to differentiate. Development into spermatocytes, spermatides, or spermatozoa has not yet appeared (Fig. 3A).

Early Development

Acini grow and look enlarged and slightly branched, but their individuality is still recognizable. Spermatogonias rapidly proliferate in a centripetal direction, giving rise to several layers of small (2–2.5 μm diameter) primary and secondary spermatocytes expanding toward the lumen, which are the dominant stage present (Fig. 3B). A few isolated pockets of spermatids and spermatozoa can also be observed. The proportion of interconnective tissue and VCT cells decreases.

Mid Development

Acini begin to show stratification, causing a reduction of the interconnective tissue and storage cells. Starting from the outer layers to the center, all developmental stages are present: spermatogonia, abundant spermatocytes, spermatids, and ripe spermatozoa (showing their acidophilic tails as pink lines radiating from the center of the lumen) (Fig. 3C). Cell diameter decreases to approximately 1–0.5 μm.

Late Development

Acini continue their growth and stratification, appearing highly anastomosed. As a consequence, the matrix, previously occupied by interconnective tissue and VCT cells, has almost disappeared. Spermatogonia and spermatocytes have been reduced in thickness to a few layers of cells located at the periphery. Acini are pac[illegible]

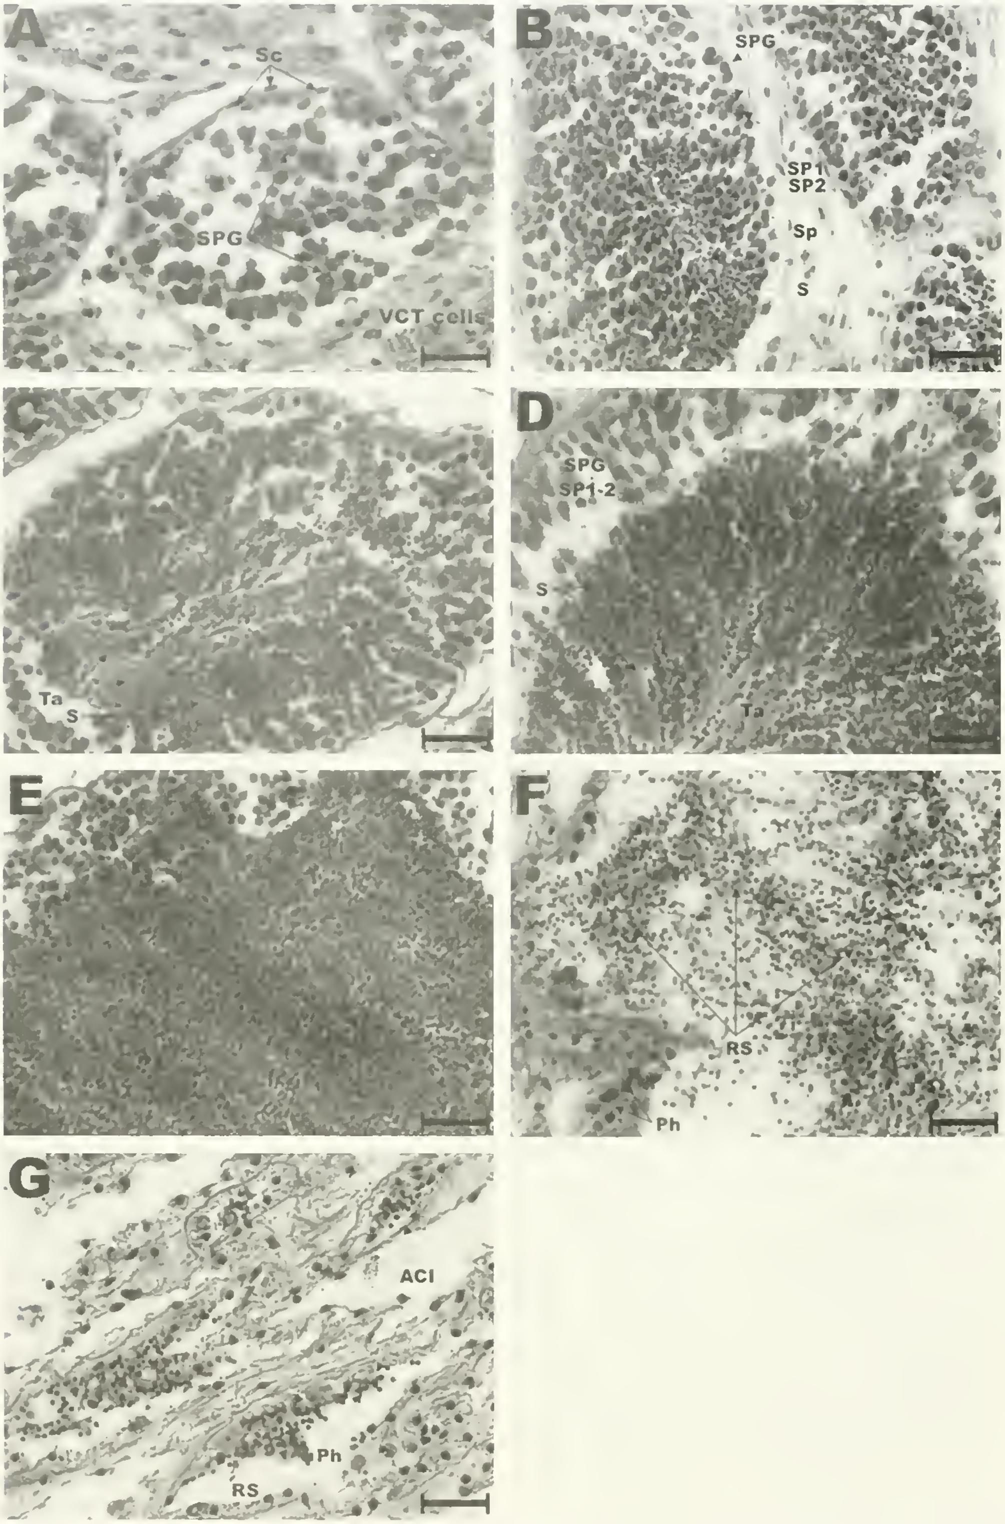

Figure 3. Photomicrographs of male gonadal tissue (40x), showing the sexual stages of spermatogenesis in *Pinctada mazatlanica*. A) Activation stage, showing ACI filled only with stem cells (Sc) and spermatogonias (SPG) proliferating toward the lumen. Abundant ICT with VCT cells can be observed; B) Early development, with many SPG and primary and secondary spermatocytes (SP1 and SP2) rapidly differentiating into the first pockets of spermatides (Sp) and spermatozoa (S); C) Mid development, characterized by the presence of all type of cellular stages, but more mature S showing their acidophilic tails (T) radiating from the center; D) Late-developing stage, in which SPG decrease in number and instead S sharply increase their frequency; E) Ripe stage, evidencing a dense volume of ripe S packing the acini; F) Partial spawning, showing distended but empty acini, residual spermatozoa (RS) and some Ph starting to appear; G) Spent stage, with collapsed ACI and evident signs of RS undergoing cytolysis. Scale bar = 50 µm.

with a dense, dark-blue band of ripe spermatozoa several cells deep (Fig. 3D).

Ripeness

Acini look like a complex network of branched tubules that make distinguishing the boundaries between them difficult. The dominant stage is now the spermatozoa, which strongly pack the acini. Stem cells and spermatogonia are latent and restricted to a thin layer at the periphery of the acini (Fig. 3E). Only a small amount of interstitial connective tissue is evident at this stage.

Partially Spawned

After spermatozoa are expelled into the surrounding environment, acini walls look broken but still distended (Fig. 3F). Many residual spermatozoa are observed scattered, with the first signals of phagocytic activity. Much residual material is also noticeable. A gap between acinus walls and the mass of residual spermatozoa appears. In some cases, redevelopment or sex reversal processes occur.

Spent

Because spawning is never complete, the spent stage may be skipped when new gonadal replenishment occurs off the main reproductive cycle. However, when gamete resorption starts, acini look collapsed and empty, with no evidence of active spermatogenesis taking place. This phase is characterized by the rapid proliferation of different kinds of phagocytes, granulocytes, and amoebocytes surrounding and destroying residual spermatozoa (Fig. 3G). The matrix of interconnective tissue starts to grow and develop again.

Bisexuality (Hermaphroditism)

This condition was observed in 8.3% of the sample (40 of 480 specimens). Bisexuality was classified as either consecutive sexuality or functional hermaphroditism.

Consecutive Sexuality

The individual functions as one sex when young and later changes to the opposite sex. As for bisexuality, two manifestations of this condition were observed: (1) Protandrous hermaphroditism: when sex reversal occurs, this is the normal condition reported for many bivalves and pearl oysters. In this situation both germinal lineages overlap in the same acinus, but the male gonadal tissue, which developed initially, undergoes regression and lysis. Only a few residual spermatozoa accompany oocyte development (Fig. 4A). This condition, which corresponds to the relation between stage 7 of spermatogenesis and stages 1, 2, or 3 of oogenesis, was observed in 5.8% of the sample (28 of 480 specimens). (2) Protoginic hermaphroditism: observed in only 1.7% of the total sample (8 of 480 specimens). Again, both germinal lineages overlap in the same acinus, but now the male gonadal tissue proliferates as female gametes gradually disappear. Therefore, only atresic oocytes are found in the acini together with developing male gametes (Fig. 4B). This condition corresponds to the relation of stage 7 of oogenesis and stages 1, 2, or 3 of spermatogenesis.

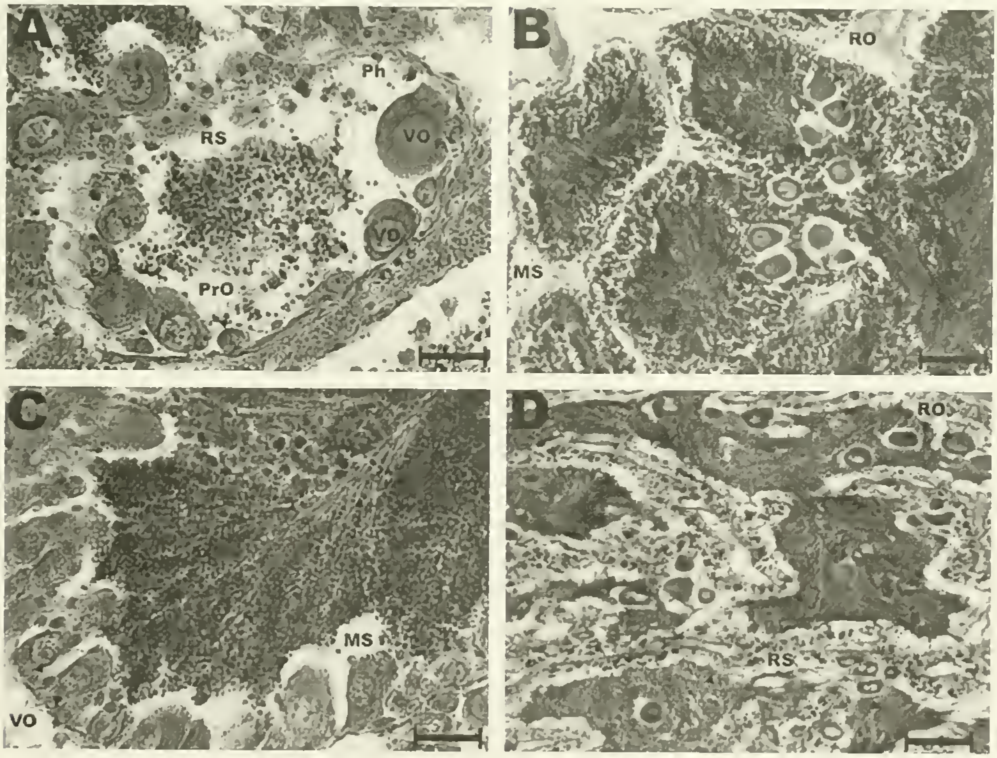

Figure 4. Photomicrographs of hermaphrodite specimens of *Pinctada mazatlanica stained with hematoxylin-eosin.* A) Protandrous hermaphrodite, with active Ph surrounding and destroying RS, while PrO and VO present active development; B) Protoginic hermaphrodite, showing a few RO undergoing regression among mature spermatozoa (MS) filling the ACI; C) Functional hermaphrodite, presenting MS with tails and growing oocytes (PrO and VO) in equal proportion and apparent functionality; D) Functional hermaphrodite, in which both male and female lineages spawned at the same time, and only RS and RO can be seen within ACI. Scale bar = 50 μm.

Functional Hermaphroditism

This condition was detected in 0.8% of the sample (4 oysters). Both sexes are present concomitantly within the same acinus in apparently equal proportion and display no sign of gonadal regression in either gamete (Fig. 4C). Both lineages may be observed spawning and undergoing regression at the same time (Fig. 4D).

Temporal Variation of Gametogenesis, Oocyte Area, and Sex Ratio

Temporal variations of the main developmental stages of gametogenesis, oocyte area, and sex ratio of *Pinctada mazatlanica* are shown in Table 1. Gonadal development started early in February and proceeded synchronously throughout the annual cycle, showing two reproductive peaks, one in March to May (in which no trace of spawning activity was detected) and other in July to August (concluding with a massive spawning in September and October). Small oocytes were observed in February, June, and October to December. Large oocytes were observed in March, May, and August, corresponding to the two reproductive peaks detected histologically. There were significant differences in the mean area of oocytes over time ($F = 102.97$; $P < 0.001$). During most of the annual cycle (January to August), when cultured specimens were collected, males outnumbered females and led to an average female/male ratio of 0.6:1. From September until December, when wild animals were collected, females doubled in number relative to males, yielding an average female/male ratio of 2:1.

DISCUSSION

In this study of *P. mazatlanica*, oogenesis and spermatogenesis were analyzed using a scheme of eight stages that adequately describe developmental variations in the microscopic anatomy of the gonadal tissues and storage cells. A 15-day sampling interval was selected as the best procedure for obtaining detailed documentation of the step-by-step advancement of gametogenesis. The timing of sampling also avoided the major problem of missing partial spawns or sex reversal phenomena, and allowed us to observe many unreported phenomena of the reproductive process of *P. mazatlanica*. We introduced, for the first time, the activation stage to classify acini in which no other developmental stage rather than oogonias or spermatogonias can be distinguished. This stage — not previously described for any marine bivalve—clearly marks the moment of sexual differentiation of germ cells and the very incipient commencement of gametogenesis. Both events occurred early in February to March, when phytoplankton is usually abundant in Bahía de La Paz (Lechuga-Devéze 1997) and wild oysters had stored sufficient energy reserves in the adductor muscle and digestive gland for starting gametogenesis (Saucedo et al. 2001b).

TABLE 1.

Temporal variations in the main developmental stages, mean oocyte area (± standard deviation), and sexual condition of *Pinctada mazatlanica* during an annual gametogenic cycle.

* Oocyte area was evaluated on a monthly basis only.

ORI = origin of specimens; DEV. STAGE = developmental stage; TIM = timing correspondence (Activ = activation stage; E-Dev = early development; M-Dev = mid development; L-Dev = late development; M = male; F = female; I = inactive or resting; B = bisexual or hermaphrodite; F/M SR = female/male sex ratio).

The developing stage was divided into three subcategories (early, mid, and late) as a strategy to identify, especially in previtellogenic, vitellogenic, and postvitellogenic oocytes, the presence of specific cellular structures whose expression is short lived. The Balbiani body and the mitochondrial clusters observed in the oocyte ooplasm are examples of these structures. The Balbiani body was initially described by Sastry (1968) in *Aequipecten irradians concentricus*, and thereafter, it has been rarely cited (Guraya 1979; Dohem 1983; as cited in de Gaulejac et al. 1995 for the bivalve *Pin. nobilis*). This structure, not previously described for any species of pearl oyster, was mostly seen in vitellogenic oocytes and seldom in postvitellogenic oocytes of *P. mazatlanica*. According to Pipe (1987a, 1987b) and de Gaulejac et al. (1995), this body is probably filled with lipid droplets arising from the degeneration and transformation of mitochondria and other membranous organelles, such as the Golgi complex. However, the mechanisms for the endogenous supply of lipids and other materials needed by the growing oocyte are poorly understood, although pinocytosis was proposed (Pipe 1987a; Pipe 1987b; de Gaulejac et al. 1995). The mitochondrial clusters (whose presence cannot be confirmed using light microscopy, but suggested because of their strong basophilic character), appeared initially near the stalk region and later scattered in the vicinity of the nucleus during the previtellogenic and vitellogenic stages of oogenesis. Certainly, their expression is ascribed to the intense respiratory rate of early and mid-developing oocytes and the active synthesis of energy related to the formation of the yolk molecule.

Several bisexual specimens were detected during the annual cycle. Although sex reversal in pearl oysters is basically protandrous (Gervis & Sims 1992), many protoginic and functional hermaphrodite specimens were found in this study, especially from September through December, when wild oysters were collected. This alteration in the sexual behavior of specimens was previously considered by Coe (1945) an accidental or abnormal mode of embryonic development, resulting from the failure of the hereditary sex-differentiating mechanism to function normally. However, environmental influence is presently recognized as one of the most important factors controlling sexual differentiation of germ cells in the direction of maleness or femaleness. We believe that females appear more frequently in the wild population, while males predominate under culture conditions. Thus, oyster's age (as a biotic factor) and the density in which individuals are kept within the culture baskets (abiotic factor) may be important factors regulating sex reversal from female to male in *P. mazatlanica*. Taylor (1999) reported a similar expression of sexuality in cultured *P. margaritifera*.

In subtropical areas, such as in Bahía de La Paz, the range of temperature variation over an annual cycle is 11–12°C (Pearl Oyster Project database). Therefore, the energy to fuel gametogenesis, parallel to that arising from food intake, have to come from specialized somatic cells involved in the storage of nutrients (Lubet 1959). According to Mathieu and Lubet (1993), there are three types of cellular elements commonly recognized as participating in these processes in bivalves: specific storage cells (adipogranular cells and VCT cells), intragonadal cells (follicular cells, Sertoli cells, and AC), and muscular cells. We identified the presence of two of them in *P. mazatlanica*: VCT cells (constituting an integral part of the interconnective tissue matrix, observed in the gonadal tissue, digestive gland, and pearl sac) and AC (within acini, always attached to developing oocytes). The muscular cells were not considered in this study, since their active role upon gametogenesis has been clearly demonstrated for several bivalves (Ansell 1974; Gabbott 1975; Bayne 1976; Taylor & Venn 1979; Barber & Blake 1981, 1991; Epp et al. 1988; Faveris & Lubet 1991; Martínez 1991; Racotta et al. 1998), including the pearl oyster, *P. mazatlanica* (Saucedo et al. 2001b). Follicular and Sertoli cells were not observed with light microscopy. Storage cells are expressed differently between families. For example, Mytilidae possess both types, VCT and ADG cells (Lubet 1959; Bayne et al. 1982; Pipe 1987a; Pipe 1987b; Peek & Gabbott 1989a; Peek & Gabbott 1989b), Glycymeridae only one type corresponding to ADG cells (Mathieu & Lubet 1993), and Ostreidae only VCT cells (Swift et al. 1988), but with an intermediate structure between ADG and VCT cells as described for Mytilidae. In contrast, Pectinidae, Veneridae, Cardidae, and Pinnidae possess none of them (Yongqiang & Xiang 1988; Dorange & Le Pennec 1989; Dorange et al. 1989; Rodríguez-Jaramillo et al. 2001) since they rely mostly on energy stored in the adductor muscle for the synthesis of gametes.

Storage cells also show important differences in their biochemical composition and ways of releasing nutrients. In this study, VCT cells were strongly PAS++ and moderately BBS+ and OR+, demonstrating that although specialized in the storage of carbohydrates (glycogen), they also contain lipids. In *M. edulis*, nutrients are released by a progressive autophagic mechanism that involves the sequestration of small membrane-bound vacuoles from the large, stored glycogen vesicle, which causes a reduction in cellular volume (Bayne et al. 1982; Mathieu & Lubet 1993). As proposed by Pipe (1987a, 1987b), these vacuoles fuse with the cell membrane and release their glycogen content by eccrine secretion. VCT cells were commonly observed surrounding excretory conduits in the gonadal tissue and digestive gland, indicating that both tissues must be communicating by the interconnective tissue matrix, which probably serves as the vehicle to transport the stored carbohydrates from the gonadal tissue to the digestive gland, or vice versa. Although it is difficult to determine the timing when carbohydrate reserves flow from one tissue to another, we believe that carbohydrates obtained from ingested food are initially used as an energy-rich fuel for the immediate build-up of gametes, and later incorporated into the digestive gland for storage. This proposal is in agreement with results of Saucedo et al. (2001b), who observed progressive accumulation of carbohydrates in this tissue, despite the advancement of gametogenesis in the same species (at least during the developing and ripe stages and later during the spawning occurring in October to November). This trend indicates that carbohydrates from the digestive gland are not transferred to the gonadal tissue for usage during the reproductive cycle in course, but instead stored and used to cover further energy demands. This argument also coincides with the finding of Barber and Blake (1981, 1991) that the digestive gland acts as a short-term storage and transfer site of nutrients to meet the reproductive events in *M. edulis*.

In this study, another cellular storage component associated with the growing oocyte was the auxiliary cells. Although their presence has been associated mainly with the nutrition of previtellogenic and vitellogenic oocytes, an alternate function related to the resorption of residual oocytes was hypothesized by de Gaulejac et al. (1995). The first function was attributed to the intimate relation of these cells with oocytes by means of desmosome-like junctions and to their rich content of glycogen granules and lipid droplets. In contrast, the presence of an active Golgi complex and large autophagic vacuoles suggests these cells may also have the ability to phagocytize, and as such, auxiliary cells might be implicated in the growth of oocytes by recycling nutrients originating by phagocytosis.

With the results previously reported in Saucedo et al. (200

2001c) and those presented in this study, we believe that successful trials for the continuous production of *P. mazatlanica* spat can be conducted if nutrients with the correct biochemical composition, energy profile, and quantity are supplied to broodstock during their gonadal conditioning. This is especially important to allow the vital energy storage process, either extracellular (in VCT cells and auxiliary cells) and intracellular (in the Balbiani body) to be accomplished. More studies on seasonal cycles of expression, mobilization, and depletion of VCT cells and AC are needed to confirm these findings, especially for the role of mantle tissue, which is an important site of storage of glycogen and lipids associated with gametogenesis in bivalves. Ultrastructure studies of gametogenesis are also required.

ACKNOWLEDGMENTS

This study was done as part of two institutional projects of CIBNOR on Pearl Oyster Culture and Pearl Induction in Bahía de La Paz (Projects PAC-7 and PAC-39). Additional grants were provided by the Consejo Nacional de Ciencia y Tecnología (CONACYT-México, as a Ph.D. scholarship), the Consejo Nacional para la Biodiversidad (CONABIO), and the Fondo Mexicano para la conservación de la naturaleza (FMCN). The authors are grateful to the following staff of CIBNOR: Horacio Bervera León and Juan José Ramírez Rosas for SCUBA diving assistance and collection of oysters, Teresa Arteche for histological processing of samples, and Mr. Ira Fogel for editing the English-language text.

GROWTH AND GAMETOGENIC CYCLE OF THE BLOOD ARK, *ANADARA OVALIS* (BRUGUIÉRE, 1789) IN COASTAL GEORGIA

ALAN J. POWER AND RANDAL L. WALKER
Marine Extension Service, Shellfish Research & Aquaculture Laboratory, University of Georgia, 20 Ocean Science Circle, Savannah, Georgia 31411-1011

ABSTRACT We collected two cohorts (1994, 1995) of blood arks, *Anadara ovalis* (Bruguiére 1789) from sets that had occurred on surf clam cages in Wassaw Sound, Georgia. Subsequent to transferal into pearl nets, the arks were suspended from the main dock at the Skidaway Institute of Oceanography on the Skidaway River, Georgia, between January 1995 and April 1997. To determine the reproductive cycle and growth rate, we collected arks monthly, measured each individual for shell length, and took a gonadal sample for histological analysis. Arks from the 1994 cohort grew from a mean shell length of 17.8 mm to 39.9 mm in 15 months, a rate of 1.47 mm per month. Arks from the 1995 cohort grew from a mean shell length of 9.9 mm to 42.6 mm in 16 months, a rate of 2.04 mm per month. Growth was most rapid during the spring and summer months. Of the 747 arks sectioned for histological examination, males dominated the population (66%) and 7.2% were sexually indeterminate. A minor spawning event occurred in the winter months of the first year for each cohort (0+ years) followed by a major spawning commencing in April and continuing through the summer months. In Georgia, it appears that blood arks recruit in summer-early fall, and that juveniles grow rapidly to reach sexual maturity at an early size (10–12 mm) and age (~8 months).

KEY WORDS: *Anadara ovalis*, arks, gametogenesis, growth, sex ratio, spawning

INTRODUCTION

A member of the ark shell family (Arcidae), the blood ark, *Anadara ovalis* (Bruguière 1789) is reported to inhabit estuarine waters from Cape Cod, Massachusetts, to the West Indies and Brazil, at depths ranging from the low-tide line to >3 m (Abbott 1974; Anderson et al. 1984; Rehder 1981; Walker & Gates 2001). This bivalve is found over a variety of substrate types, but is most commonly found in sandy deposits (Alexander 1993). The blood ark inhabits Chesapeake Bay waters in area where salinity is above 15 ppt (Chanley & Andrews 1971). Blood arks are equivalved, and somewhat oval in shape, ranging in size (shell length) from 28 to 76 mm (Rehder 1981). Shell height is slightly less than the shell length, with a reported length/height ratio of 1.16 (Alexander 1993); shell depth reaches approximately 70% of height (McGraw et al. 1996). The blood ark is a short-lived species, which has up to 80% mortality in the third year of life, and a maximum life span of five years (McGraw et al. 1996; Walker 1998).

Several ark shell species form the basis of economically significant molluscan fisheries and extensive culture operations throughout the world (Baqueiro et al. 1982; Broom 1985; Baqueiro 1989; Manzi & Castagna 1989; Nie 1990; Umezawa 1992). The 1997 worldwide harvest of arks (*Scapharca*, *Arca*, and *Anadara* spp.) was 97,296 metric tons, landed in Cuba, Fiji, Indonesia, Korea, Japan, Mexico, Philippines, and Venezuela (FAO 1999). In the United States, ark resources have been largely ignored by the fishing industry until recently. Some interest was expressed in South Carolina in the 1980s, however, there were problems identifying viable markets (Anderson et al. 1984; Anderson and Eversole 1985). Since then a small fishery, primarily for the blood ark, *Anadara ovalis* (Bruguiére 1789), and the ponderous ark, *Noetia ponderosa* (Say 1822), has developed in Virginia. Meats are sold primarily as an ethnic food in Chicago, New York, Los Angeles, and Washington D.C. or exported to Mexico (McGraw & Castagna 1994; McGraw et al. 1996; McGraw et al. 1998).

The demand for arks has recently outpaced the numbers that can be supplied by the Virginia fishery. Since blood arks have been reported to grow up to twice as rapidly as ponderous arks in the first 2 years after settlement in Virginia waters, it has become the principal aquacultural species of interest (McGraw et al. 1996). Growth rates of Georgia stocks have been reported to almost double those observed in these more northern waters, reaching a marketable size in a 1-year period (Walker 1998). Consequently, the great potential of *Anadara ovalis* as a new commercial resource in Georgia has been recognized, and an aquacultural fishery is currently being investigated (Power & Walker 2001). Unfortunately, little life-history information other than from Virginia (McGraw & Castagna 1994; McGraw et al. 1996; McGraw et al. 1998) exists for this species in the United States. This study describes the growth and gametogenic cycle of the blood ark from the coastal waters of Georgia.

MATERIALS AND METHODS

We collected blood ark cohorts in January 1995 (1994 cohort) and December 1995 (1995 cohort) at the mouth of House Creek, Little Tybee Island, Wassaw Sound, Georgia. The clams had attached themselves to surfclam (*Spisula solidissima similis*, Say 1822) grow-out cages (6 mm vinyl coated, 1 × 1 × 0.6 m) that were partially buried (0.3 m) at the spring-low-water mark on a sand flat. Cages had been deployed in September of both years and when we stocked with surfclam seed in October, we noted that ark wild spat had settled and attached with byssal threads to the wire mesh sides of the cages. In the laboratory on Skidaway Island, we measured for shell length (longest possible measurement, i.e., anterior-posterior) using Vernier calipers. Arks from the 1994 and 1995 cohorts had a mean shell length of 17.8 ± 1.52 (SE) mm (range: 11.9–28.3 mm) and 9.9 ± 0.19 mm (range: 4.3–17.7 mm), respectively. Each cohort was placed in a separate 3 mm mesh pearl net, and suspended from a floating dock on the Skidaway River. The 1994 recruitment was a small set (approximately 20–30 arks per cage), while the 1995 recruitment was a massive set with over 500 arks collected per cage.

Between January 1995 and April 1996 we randomly collected arks (N ≈ 10, 1994 cohort) from the pearl nets. We repeated this procedure for the 1995 cohort collecting arks (N ≈ 30) monthly between December 1995 and April 1997. We measured these for shell length, and dissected a mid-lateral gonadal sample (ca. 1 cm^2) from each animal. Smaller specimens with meats <1 cm^2 were preserved and sectioned whole. We also noted the coloration of gonads during the dissections. Gonadal tissue was fixed in Davidson's solution, refrigerated for 48 h, washed with 50% ethanol, and preserved in 70% ethanol until processing. We processed tissues according to procedures outlined in Howard and Smith (1983). The examination of prepared gonadal slides was conducted with a Zeiss Standard 20 microscope (20X). Each section was sexed, and assigned to a developmental stage as described by Walker and Heffernan (1994) and Spruck et al. (1994). A staging criteria of 0 to 5 was employed for Early Active (EA = 3), Late Active (LA = 4), Ripe (R = 5), Partially Spawned (PS = 2), Spent (SP = 1), and Inactive (IA = 0). The determination of monthly gonadal index (G.I.) values was obtained by averaging the number of specimens ascribed to each category score. We tested sex ratios against a 1:1 ratio with Chi-square statistics (Elliott 1977).

Surface water temperature and salinity data were taken daily from the dock of the Marine Extension Service, adjacent to the grow-out site at 0800 h (Monday–Friday) from January 1995 to April 1997.

RESULTS

Monthly mean water temperature and salinity data for the Skidaway River are given in Figure 1. Water temperatures were coolest during the months of January and February 1995, 1996, and 1997 ranging from a mean low of 9.34°C to a high of 13.32°C. Water temperatures reached their peak during the months of July and August 1995, and 1996 ranging from 28.61°C to 30.46°C. Mean salinity values were less cyclical but typically reached their lowest in the spring months each year (14.63 ppt in March 1995). The highest salinity recorded over the study period was 28.00 ppt in December 1996.

Both cohorts exhibited similar growth trends (Fig. 2), increasing in size rapidly during the spring-summer months with growth rates diminishing in the fall of the first culture year (i.e., 1+ aged individuals). Arks from the 1994 cohort grew from a mean shell length of 17.8 mm to 39.9 mm in 15 months, a rate of 1.47 mm per month. Arks from the 1995 cohort grew from a mean shell length of 9.9 mm to 42.6 mm in 16 months, a rate of 2.04 mm per month.

Of the 747 arks examined, 54 (7.2%) were sexually indeterminate, 493 (66%) were male, and 200 (26.7%) were females. The Chi-square test revealed that the overall male/female ratio of 2.44 was significantly different from parity (χ^2 = 123.9; $P < 0.001$). Males dominated in both cohorts (1994: 1.00:0.36; and 1995: 1.00: 0.42) and in every monthly sample. Histological examination and visual observations of the gonads revealed that all orange-red colored gonads were late active or ripe females, while those showing white coloration were typically ripe males.

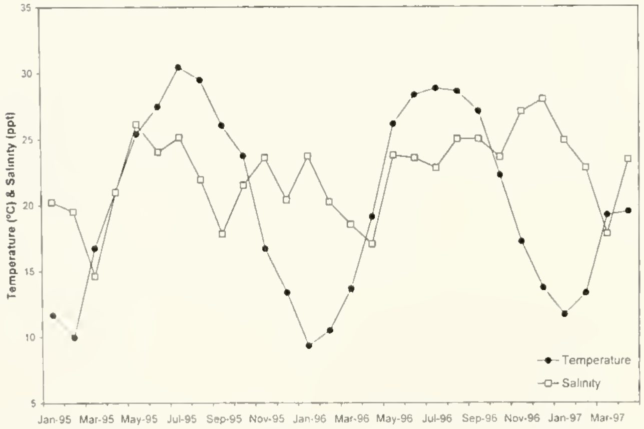

Figure 1. The mean monthly water temperature and salinity of the Skidaway River, Georgia from January 1995 to April 1997.

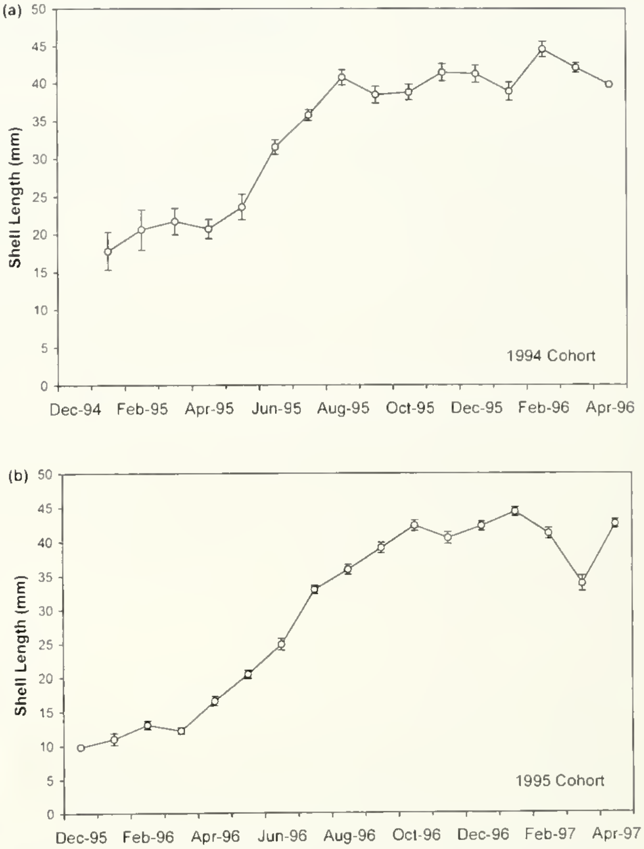

Figure 2. (a) The mean monthly shell length (mm ± standard error) of the 1994 cohort of blood arks, *Anadara ovalis*, grown in pearl nets suspended in the Skidaway River, Georgia from January 1995 to April 1996. (b) The mean monthly shell length (mm ± standard error) of the 1995 cohort of blood arks, *Anadara ovalis*, grown in pearl nets suspended in the Skidaway River, Georgia from December 1995 to April 1997.

Blood arks reached sexual maturity at an early age, exhibiting ripe specimens in the winter months of the first year in both cohorts with major spawning commencing after April–May and continuing to September–December (Figs. 3–5). A comparison of the gonadal stages for the two cohorts shows a striking difference for the cohorts in December 1995 (1994 cohort age 1+ years, 1995 cohort age 0+ years) indicating that the 0+ year arks develop gametes more easily during the winter months of their first year. For the 1994 cohort, 22% were ripe, 22% were partially spawned and 56% were spent in January 1995. In February and March, arks were either spent or in the early active stage. By April, late active (37.5%), ripe stages (25%) and spent stages (25%) were present. The gonadal index increased between March (1.9) and April (3.1)-May (3.2) as more animals became reproductively active, with ripe individuals dominating in May (60%) and June (42.9%). The gonadal index decreased to 1.4 by June, reflecting the occurrence of partially spawned individuals. Partial spawning dominated from

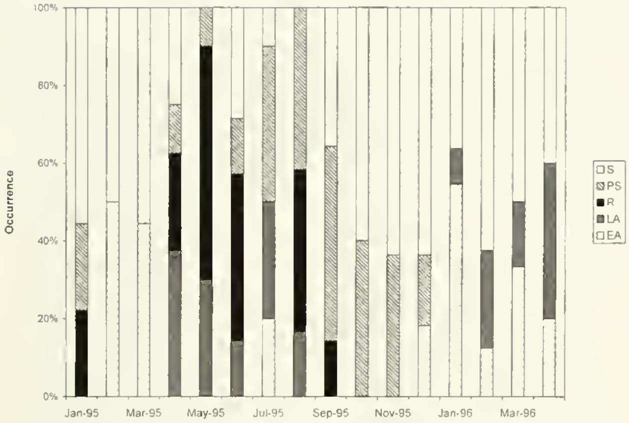

Figure 3. The relative frequency (percentage) of each gonadal developmental phase (EA = early active, LA = late active, R = ripe, PS = partially spawned, and S = spent) for the 1994 *Anadara ovalis* cohort from January 1995 to April 1996.

July (40%) through September (50%), with spent individuals occurring most frequently through the latter part of the year. This resulted in low gonadal index values until the initiation of gametogenesis again in January (G.I. = 1.5 in December to 2.36 in January).

For the 1995 cohort, 22% of arks were ripe in December 1995, with 28% in the early active and 50% in the late active stage (G.I. = 3.93). Most arks were in the early active stage (50%) with 41.7% exhibiting the spent stage by January (G.I. = 2.25), indicating a minor spawning event having taken place. Ripe individuals occurred again in March (9.4%) with most (76.7%) being ripe in April (G.I. = 4.53). Ripe individuals were present through August, but partially spawned and spent individuals dominated until December 1996. As in previous years, early active and late active individuals began occurring in December 1996 with ripe individuals again dominating by April (69.2%) (G.I. = 4.82).

For the 1995 set, 225 arks in December 1995 were histologically processed to determine the size at sexual maturity for the blood ark. Of the 225 arks examined, 26 (11.6%) were sexually indeterminate, 156 (69.6%) were males and 43 (19.2%) were females. The sex ratio was 1.00:0.28 (M:F), which significantly differed from parity ($\chi^2 = 64.17$; $P < 0.001$). Males averaged 9.9 ± 0.26 mm and ranged from 4.3 mm to 16.2 mm in shell length. Females average 11.5 ± 0.37 mm and ranged from 7.4 mm to 17.7 mm in shell length. Indeterminate animals averaged 6.5 ± 0.29 mm and ranged from 4.5 mm to 8.9 mm. Of the 199 arks that had started gametogenesis, most were in the late active stage for males (54.5%, 10.2 ± 0.27 mm, range: 6.3–16.2 mm) and the ripe stage for females (44.2%, 11.8 ± 0.50 mm, range: 8.2–16.6 mm). At this time, males also had 30.1% in the early active stage (7.3 ± 0.25 mm, range: 4.3 mm–13.4 mm), while females had 20.9% (9.6 ± 0.68, range: 7.4–14.2 mm).

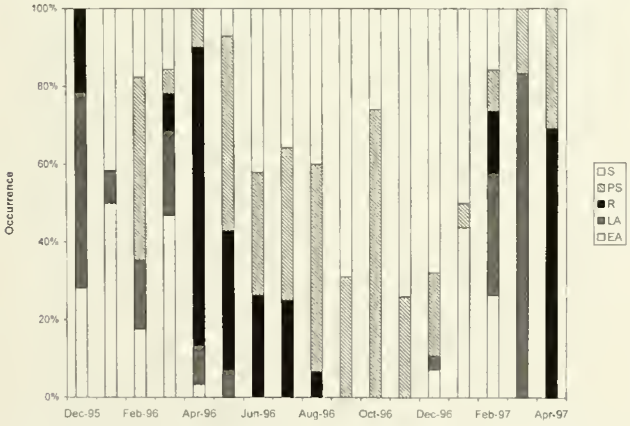

Figure 4. The relative frequency (percentage) of each gonadal developmental phase (EA = early active, LA = late active, R = ripe, PS = partially spawned, and S = spent) for the 1995 *Anadara ovalis* cohort from December 1995 to April 1997.

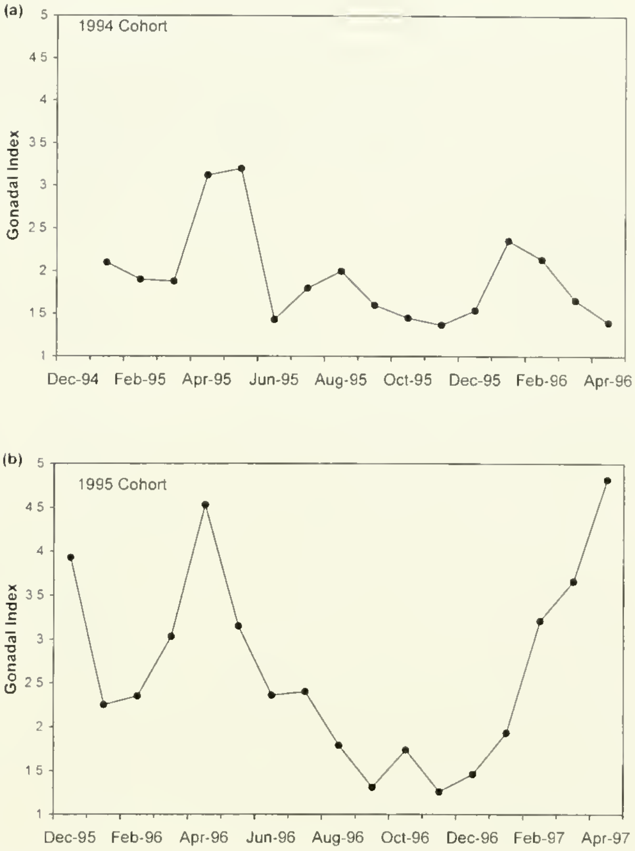

Figure 5. (a) The monthly gonadal index values of the 1994 cohort of blood arks, *Anadara ovalis*, from the coastal waters of Georgia between January 1995 and April 1996. Monthly gonadal index (G.I.) values were determined by averaging the number of specimens ascribed to each category score (EA = 3, LA = 4, R = 5, PS = 2, SP = 1). (b) The monthly gonadal index values of the 1995 cohort of blood arks, *Anadara ovalis*, from the coastal waters of Georgia between December 1995 and April 1997. Monthly gonadal index (G.I.) values were determined by averaging the number of specimens ascribed to each category score (EA = 3, LA = 4, R = 5, PS = 2, SP = 1).

DISCUSSION

In Georgia, bloods arks recruit during the summer and early fall; the spat grow rapidly and reach sexual maturity by the end of the year. A minor spawning event occurs at this point, followed by the major spawning period in the subsequent summer months. As observed with one-year-old arks from the 1995 cohort, the minor winter spawning event is not repeated in the subsequent year.

Rapid growth rates recorded for arks (<2-years-old) in

present study (1.47 and 2.04 mm/mo) were comparable to earlier reported growth rates for natural populations in Virginian waters, and cultured arks in the coastal waters of Georgia. In Georgia, arks that were similarly grown in pearl nets for 36 months exhibited rapid growth in the first year (<10 mm size class: 2.58 mm/mo; 10–20 mm: 2.01 mm/mo) with decreased annual growth for years two (0.83 and 0.89 mm/mo) and three (0.19 and 0.18 mm/mo) (Walker 1998). In Virginia, blood arks grew from an initial size of 14 mm to 30 mm in 11 months, a lower rate of 1.45 mm/mo (McGraw & Castagna 1994). Arks were noted in the present study to grow faster in the spring and summer months, therefore the slower growth rates in Virginia may result from colder water temperatures.

Sexual maturity was attained at an approximate mean size of 10 mm in shell length for males and 12 mm for females (age 7 to 8 months) however; gametogenesis was noted to occur at minimum sizes of 4 mm and 7 mm, for males and females, respectively. Animals from the 1995 cohort were known to be at least three months old when gathered in December, since the cages were deployed in September. At this time, 20% of the 225 collected were ripe and 44% were in the late active stage. Because major spawning for blood arks starts in April–May, the maximum age of the new recruits on the cages is about 8 months. We believe that blood arks had already recruited to the sand flat prior to the placement of the field grow-out cages. Once the cages were in place, we postulate that the arks migrated up the sides and attached themselves with byssal threads. Blood ark juveniles are commonly found attached to the upper ends of *Dioptera* tubes in the estuary (Walker, personal observations). An upward migration of juvenile arks has also been observed with transverse arks, *Anadara transversa* within the laboratory. Transverse arks contained within a northern quahog, *Mercenaria mercenaria*, seed shipment were observed to migrate to the top of the quahog seed mass and even up the sides of the holding tray to the surface/water interface (Walker & Power, in press). Members of the Arcidae are reported to initiate gametogenesis and reach sexual maturity at a small size (Table 1). The blood arks mature at a similar age to *Anadara granosa* (Linnaeus 1758; Narasimham 1968) and *Senilia senilis* (Lamarck 1758; Yoloye 1974), but typically at a smaller size than most of the family (Table 1).

Temperature is one of the main exogenous factors controlling reproduction in marine invertebrates (Giese 1959; Sastry 1975). In Virginia, blood arks are reported to spawn in the summer months when water temperatures reach above 17°C (Chanley & Andrews

Noetia ponderosa	181	1.00:1.26		McGraw et al., 1998

1971; McGraw et al. 1998). In Georgia blood arks spawned earlier, from late spring through summer, presumably due to the coastal waters warming earlier in the year than in Virginia. By April–May 1995 and 1996, water temperatures were already above 20°C in the Skidaway River. In general, spawning periods and gametogenesis in marine bivalves start earlier and last longer in southern geographical areas than in northern ones (Eversole 1989; Thompson et al. 1996).

In this study, males dominated the population of blood arks with an overall sex ratio of 2.38:1.00 (M:F). This is in agreement with the observed sex ratio (1.98:1.00 M:F) reported by McGraw et al. (1998) for a Virginia population of 1-year-old blood arks (Table 1). An equal sex ratio has been observed in *Andara granosa* (Pathansali 1966; Broom 1983) and *Anadara subcrenata* (Lischke 1869; Ting et al. 1972); however, males dominated *Senilia senilis* populations (Yoloye 1974). For *Anadara scapha* (Linnaeus 1758), males were reported to dominate in the smaller size-classes while females were more frequent in the larger-size classes (Baron 1992). This may indicate a sex change but may also be a consequence of the differential energy requirements of males vs. females. No hermaphroditic *Anadara ovalis* were observed in the present study. Hermaphroditism is rare in the Family Arcidae (Table 2); *Anadara scapha* and *Senilia senilis* have been classified as a protandric hermaphrodite (Baron 1992; Yoloye 1974). The present study examined newly recruited blood arks, while in Virginia 1-year-old individuals were examined. Males typically dominate protandric bivalve species in the first year; whereas older age classes are generally equal. Blood arks can reach a maximum of 5 years and therefore these older age classes need to be examined to determine if this species is protandric.

TEMPORAL FLUCTUATIONS (1989–1999) IN THE POPULATIONS OF *HALIOTIS FULGENS* AND *H. CORRUGATA* (GASTROPODA: HALIOTIDAE), AT ISLAS SAN BENITO (BAJA CALIFORNIA, MEXICO)

J. A. RODRÍGUEZ-VALENCIA* AND F. CABALLERO-ALEGRÍA
Instituto Nacional de la Pesca, CRIP-Ensenada, Carretera Tijuana-Ensenada Km 107, Parque Industrial Fondeport, El Sauzal, Baja California, Mexico

ABSTRACT In our study area, green abalone (*Haliotis fulgens*) was more abundant than pink abalone (*H. corrugata*) until the end of the 1980s, but nowadays, both species have similar density levels and are close to values were recruitment failures may occur. In comparison to pink abalone, green abalone showed higher abundance of legal-sized stock and condition factors. Abundance of the legal-sized stock of both species has significantly decreased, but the density extracted by fishing remained the same. Overfishing of legal sizes and recruits, or poaching, may have not significantly contributed to the observed patterns. Only the proportion of recruits of pink abalone decreased significantly along the time and its fluctuation patterns support the idea that non-severe "El Niño" events may have a positive effect on recruitment. The lack of significant changes in recruitment of green abalone suggests that this effect may be species-specific. On the other hand, our results indicate that "El Niño" events lead to poor physiological condition. Mean condition factors of both species decreased significantly along the time, and are significantly related with the mean annual surface temperatures. The proportion of sexually mature organisms of both sexes, in both species, also decreased significantly along the time and could be a by-product of impoverished condition. Additionally, the sex ratio of green abalone varied significantly along the time, in favor to males.

KEY WORDS: abalone surveys, long-term dynamics, Baja California, *Haliotis fulgens*, *H. corrugata*

INTRODUCTION

The quantification of abalone and the assessment of its temporal fluctuations are often difficult tasks. Aggregated spatial distributions difficult the obtainment of precise abundance estimates at large spatial scales (McShane 1995), and even at small spatial scales estimates may have with high variance and low precision (McShane 1994).

The first attempts to quantify abalone in Baja California were done between 1968 and 1970, covering wide spatial scales along the coast (Guzmán-del-Próo 1992). Mean density estimates derived from these attempts had very low precision, due to habitat heterogeneity (Guzmán-del-Próo 1992). After 1988, abalone surveys were restricted to each fishing area, in order to calculate local yearly catch quotes, and regulate the fishery. We present the results of abundance surveys made between 1989 and 1999, for green abalone (*Haliotis fulgens*, Philippi 1854) and pink abalone (*H. corrugata*, Gray 1828), at Islas San Benito. These three islands are located at the current main abalone fishing area of Mexico.

This work brings information about one of the few long-term monitoring efforts applied to natural abalone banks in North America. Additionally to density values, we bring data that are rarely collected during surveys: namely, sizes, condition factors, sex ratios, and gonadal maturity of both species. We tried to assess the contribution of commercial extractions, overfishing of legal sizes, recruitment overfishing, and local climate forcing to the observed fluctuations.

MATERIALS AND METHODS

Study Area

Islas San Benito are located at the Pacific coast of Baja California, 40 km northwest from Cedros Island (Fig. 1a). They are away from continental runoff and pollution, and strong seasonal upwelling favor the growth of *Macrocystis pyrifera*, *Eisenia arborea*, and *Egregia menziessi* (González-Avilés & Shepherd 1996). The extension of the abalone fishing area is 6,862,155 m^2 (Arano-Castañon & Uribe-Osorio 1998). The fishermen cooperative "S.C.P.P. Pescadores Nacionales de Abulón" is the unique concessionaire of the abalone and lobster fishery in the area.

Survey Methodology

Surveys were conducted in the whole fishing area of the islands, when the fishery is closed (October to January), between 1988 and 1999. The coastline of the three islands has always been divided into 35 sections (≈500 m width) placed in the same location during all the surveys, using floats as markers. The offshore extension of each section has been fixed at the 30 m isobath; therefore, the length of each section varied between 88 m and 1473 m, perpendicular to the shore (Arano-Castañon & Uribe-Osorio 1998) (Fig. 1a).

Abalone divers from the fishermen cooperative collected all visible abalone inside each section, but the sampling procedure varied along the time (Fig. 1b):

1989 to 1995. Six to 12 sampling stations were randomly distributed inside each section, depending on the number of divers. A 4 m^2-quadrat was used as a sampling unit from:

1996 to 1999. Each section was divided into three bathymetric strata: 0–10 m, 10–20 m, and 20–30 m. Three, five, and two sampling stations were randomly located inside each bathymetric strata, respectively. A 10 m^2-quadrat was used as sampling unit.

Density Estimations

Only sampling stations located on rocky bottom were used fo density estimations. The mean density was calculated conside

all sizes. Estimations of the mean density of the legal-sized stock were done considering only sizes larger than the minimum legal size of capture (green abalone: 150 mm of shell length; pink abalone: 140 mm of shell length). Ninety-five percent confidence limits and standard errors of the total mean density, as well as 95% confidence limits of the mean density of the legal-sized stocks are shown. Significant temporal differences in the mean values were tested with ANOVA, in both species. We estimated the statistical power for the total mean density comparisons, at the given level of replication, and $\alpha = 0.05$ (Zar 1999).

Recruitment Estimations

Our survey methodology is inadequate to estimate recruitment accurately, but serious recruitment failures due to recruitment overfishing or environmental changes should be reflected in our data (Shepherd et al. 1998). From the 1989 to 1998 for size-frequency data, we calculated the percentage of recruits of both species, using the size criteria of Shepherd et al. (1998). Overall, significant differences between percentages (inside each species) were tested with Chi-squared analyses (Zar 1999). Paired comparisons are shown, to estimate statistical power (Zar 1999).

Assessing the Effect of the Fishery

The density extracted by fishing, between 1989 to 1996, was estimated for each species. The following data were used: local captures provided by the fishermen cooperative, legal-sized stock densities, local area of suitable habitat for both species (Rodriguez-Valencia et al. 1998), and mean weight of muscle (as described later). Significant temporal changes were tested by Chi-squared analyses.

Biametric Data

Biometric data of all captured abalone are available for the 1989 to 1998 surveys.

Sizes and Weights

Shell lengths of all captured abalone were measured to the nearest millimeter and muscles were weighed to the nearest gram. Each 5-mm size category contained at least three individuals. Since measuring and weighing is time-consuming, abalone were maintained in shadowed places and were covered with wet algae to prevent desiccation. Significant temporal differences in mean shell sizes were tested with ANOVA. Significant ascendant or descendant trends were tested by the significance of the slope (Beta) of simple linear regressions using the time as independent variable. Modal and maximum sizes of each species, at each survey, were compared using Chi-square tests.

Condition Factor

The condition factor of each sacrificed abalone was obtained dividing the muscle weight by the shell length, and the mean condition of each species at each survey was estimated. Significant temporal changes between mean condition factors were tested with ANOVA.

Sex Ratio and Gonadal Maturity

Sexes and gonadal maturity were determined to randomly selected abalone at each survey. Significant temporal changes in both variables were tested using Chi-square analyses.

RESULTS

Patterns of the Total Mean Density

Green abalone was 2.5 times more abundant than pink abalone at the end of the 1980s, but at the beginning of the 1990s its density decreased, while that of pink abalone increased. After 1995, both reached their lowest density levels and followed comparable abundance trends (Fig. 2a). Temporal fluctuations are significant (Table 1). Modifications in sampling methods were more precise after 1995, because the confidence limits and standard errors of the means decreased (Fig. 2a and Table 2).

Patterns of the Mean Density of Legal-Sized Stocks and Density Extracted by Fishing

The proportion of harvestable sizes of green abalone has been twice as high as that of pink abalone (Table 3), and its density of legal-sized stock is significantly higher ($F_{(1,3499)} = 189.3^{**}$). The mean density of the legal-sized stock of both species has significantly varied and decreased along the time (green abalone: $F_{(6,\ 1744)} = 34.0^{**}$; pink abalone: $F_{(6,1744)} = 8.0^{**}$) (Fig 2b). On average, the fishery extracted 24% and 14% of the legal-sized stocks of green and pink abalone, respectively, corresponding to 15% and 7% of their total mean densities. The extraction by fishing has remained constant, since the densities extracted by fishing of both species remained constant along the time (green abalone: $\chi^2_{(4)} = 0.02$; pink abalone: $\chi^2_{(3)} = 0.004$), although that of green abalone seems to have increased (Fig 2c).

Recruitment Estimations

Recruits of pink abalone have been more abundant than green (Fig. 2d). Overall comparisons between the percentages of recruits of green abalone indicated non-significant changes ($\chi^2_{(6)} = 1.8$), but those of pink abalone varied significantly ($\chi^2_{(6)} = 19.5^{**}$), with increasing percentages until 1995 and decreasing percentages after. Paired comparisons indicated non-significant changes for green abalone, and significant changes for pink abalone (Table 4). The average power of the paired comparisons was 0.81 and 0.83, for green and pink abalone, respectively.

TABLE 2.

Standard errors of the total mean density estimations (Abalone*m^{-2}).

Survey	*Haliotis fulgens*	*Haliotis corrugata*
1989	0.061	0.030
1991	0.045	0.039
1993	0.046	0.042
1995	0.028	0.027
1996	0.026	0.017
1997	0.028	0.017
1998	0.025	0.018
1999	0.027	0.021

Patterns of Sizes and Condition

Mean sizes of both species showed significant temporal variations (Table 3) without trend (green abalone: $F_{(1,6)} = 1.2$; pink abalone: $F_{(1,6)} = 3.5$). Modal and maximum sizes showed non-significant temporal variations (Table 3).

The mean condition of green abalone was significantly higher than that of pink abalone during the studied period (1.6 vs. 1.1; $F_{(1,1177)} = 196.7^{**}$). No significant differences were detected between sexes, inside each species. Significant temporal changes in the mean condition of both species were detected (green abalone: $F_{(6,1032)} = 10.1^{**}$; pink abalone: $F_{(6,844)} = 3.0^{**}$), and both species showed significant decreasing trends (Fig. 3a). The mean condition of both species was significantly related with the mean annual surface temperature (Fig. 3b), which increased 2.1°C between 1989 to 1998, in the study area.

Patterns of Sex Ratio and Gonadal Maturity

The sex ratio of green abalone showed significant temporal changes in favor of males, while that of pink abalone remained close to 1:1, without significant changes (Table 5). The proportion of mature organisms of both sexes, inside each species, decreased significantly along the time (Table 4). In 1995, a conspicuous peak of mature organisms of both sexes was detected, in both species. Relationships between the proportion of mature organisms of green abalone and its mean condition factors and mean annual surface temperature were suggestive, but non-significant (Fig. 3 c–d). On the other hand, these relationships were significant for pink abalone (Fig. 3 c–d).

DISCUSSION

The Surveys

We have tried to follow the survey approach proposed by Hilborn and Walters (1992), Van der Meer (1997), and Gorfine et al. (1998), distributing sampling points in the whole capture area and applying low sampling effort at each point. The method used to estimate abalone abundance seems to be appropriate. However, main disadvantages are: (a) The small portion of potential habitat sampled (0.01%–0.02% between 1989 to 1995; 0.05%–0.07% be-

tween 1996 to 1998); and (b) The lack of use of specific methods to properly quantify juveniles (e.g., anesthetics (Prince & Ford 1985); sub-aquatic amplifiers (Shepherd & Turner 1985); suction method (McShane & Smith 1988). Differences in efficiency among divers were surely low, since only on-duty abalone divers participated, and they are highly efficient locating abalone (Prince & Guzmán-del-Próo 1993). Additionally, the use of quadrants and diving transects prevents over estimations and competition among divers (Findlay & Willerton 1996, McShane 1996). Shepherd et al. (1998) stated that Mexico is the only country making serious efforts to quantify the abundance of its abalone banks: nevertheless, surveys are frequently criticized by local cooperatives and academics.

Interpretation of Abalone Dynamics

Both species reflect the decline of the Mexican abalone fishery, observed since 1984 (Guzmán-del-Próo 1992; Shepherd et al. 1998), and their abundance patterns are similar to those reported for Isla Natividad (Shepherd et al. 1998). Their most recent density levels are close to values where recruitment failures may occur (Shepherd & Partington 1995) and a clear tendency to recover is still absent.

Vega et al. (1997) and Shepherd et al. (1998) proposed causing factors for the decline. Here we discuss the local role of some of these as follows: (a) overfishing of legal sizes and/or recruits; (b) negative effect of "El Nino" events over recruitment (independently of their intensity); and possible increases of recruitment during non-severe "El Niño" events; (c) physiological weakening during "El Niño" events.

Overfishing of Legal Sizes and/or Recruits

Overfishing can happen by fishermen cooperatives not respecting authorized fishing quotes, poaching, cooperatives fishing at erroneously calculated quotes, or the mixture of all of them. The first two choices have not occurred at Islas San Benito, since the local cooperative has been exemplarily adhered to the regulations and authorized quotes. Additionally, the location of the islands, and strict surveillance programs applied to owners and strangers resulting in rare poaching. The absence of significant temporal changes in the recruits of green abalone support our suppositions, and although that of pink abalone changed significantly, there is no reason to believe that only this species has been affected by poaching or recruitment overfishing. Changes in the percentage of recruits of pink abalone may be related to climatic changes, (see later). It seems that fishing quotes were erroneously estimated, since densities extracted by fishing remained constant, while the abundance of the legal-sized stock decreased significantly in both species.

Catches of green abalone have been higher than that of pink abalone, at Islas San Benito (Fig. 4). Pink abalone was the dominant species in the local catches between 1957 to 1984 and green abalone became dominant until 1985 (S. A. Guzmán-del-Próo, pers. comm.). Nowadays, green abalone is preferably fished for having a higher proportion of harvestable sizes and being more

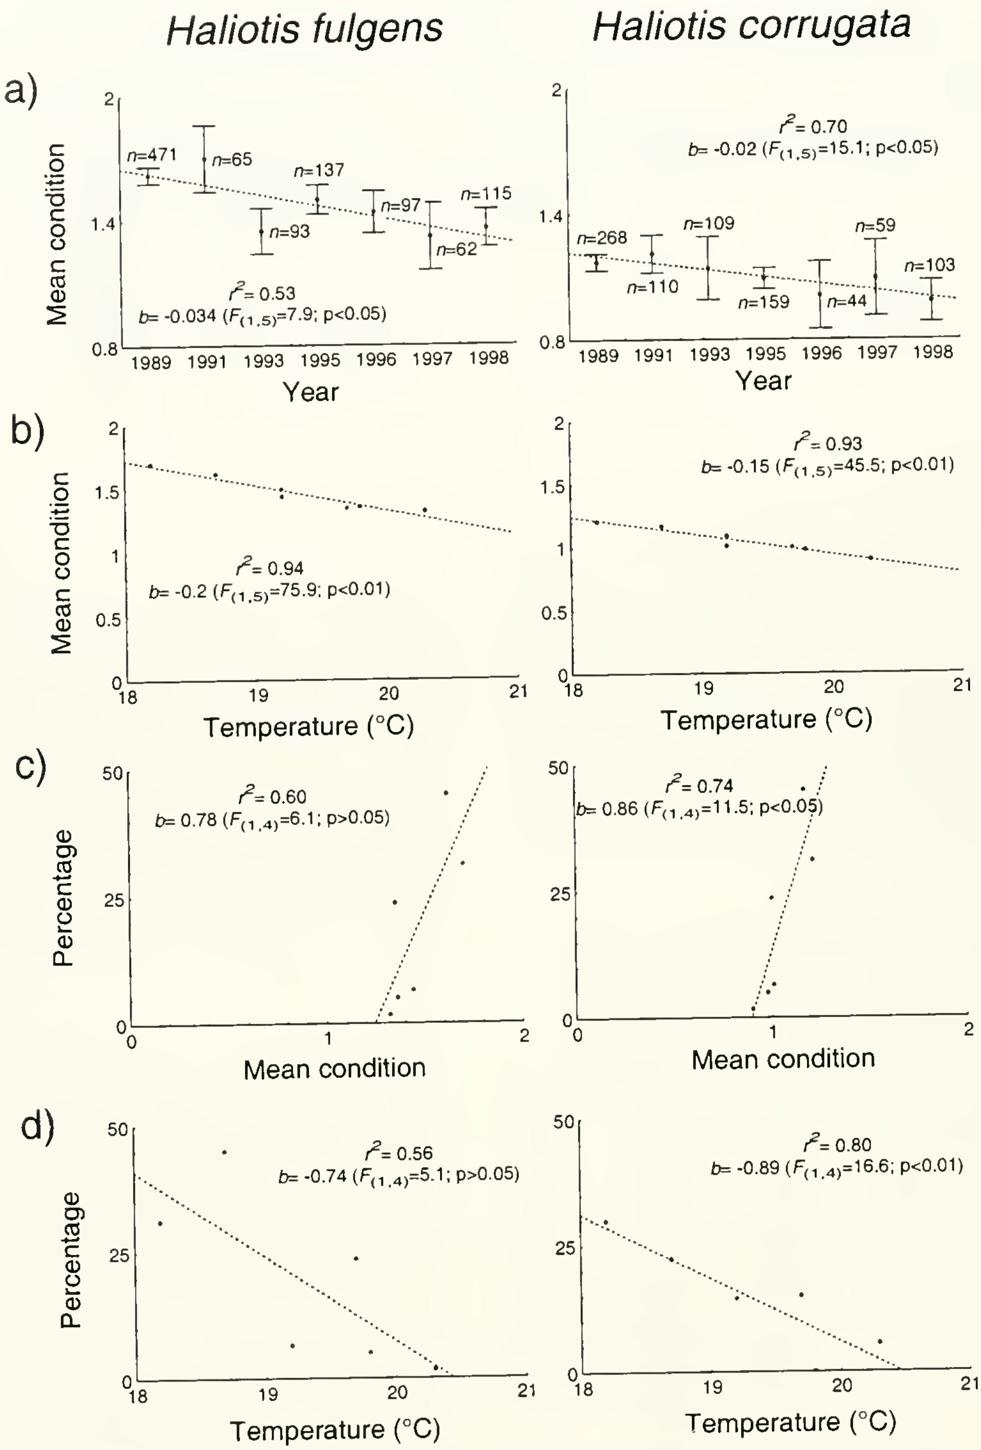

Figure. 3. (a) Temporal patterns of the mean condition factors. (*n*) represents the number of analyzed organisms; (b) Relationship between mean condition factors and mean annual surface temperatures; (c) Relationship between the percentage of sexual mature organisms and mean condition factors; (d) Relationship between the percentage of sexual mature organisms and mean annual surface temperatures.

revenue yielding by having larger sizes and shells that are more valuable. Fishing has been surely more important for the decline of green abalone than for that of pink abalone.

It would be desirable to have estimations of mortality by fishing, but this is out of our reach. We can only speculate that they would be lower than those at Isla Natividad (Shepherd et al. 1998), since captures of both species have been much higher at Isla Natividad (Fig. 4), but Isla Natividad and Islas San Benito have similar density levels. Additionally, quotes at Isla Natividad have been fixed considering an extraction of 30% of the legal-sized stocks (Shepherd et al. 1998) and this percentage at Islas San Benito has been lower.

** $P < 0.01$.

Negative Effect of "El Niño" Events over Recruitment (Independently of their Intensity); and Possible Increases of Recruitment During Non-severe "El Niño" Events

According to Vega et al. (1997), increased water temperatures during "El Niño" events reduce the extensions of kelp beds and negatively affect the recruitment, because larvae are taken away from the banks by the currents. The frequent occurrence of "El Niño" events during the last decade (Fig. 5) should have continuously affected the recruitment, but our results of green abalone do not support this. The recruitment patterns of pink abalone support the hypothesis about a possible positive effect of non-severe "El Niño" events (Shepherd et al. 1998). Increasing recruitment was detected until 1995, because between 1981 and 1988 larvae settled under the influence of non-strong "El Niño" events (Fig. 5), but the 1981 to 1986 "El Niño" was one of the strongest ever observed (Arntz & Fahrbach 1996). Decreasing percentages were detected after 1996, because after 1989 larvae settled under the influence of frequent strong "El Niño" events (Fig. 5). It seems that the "El Niño" events determine a positive or negative effect over recruitment, but differences between species suggest that this could be species-specific. Data series longer than a decade are still necessary in order to have evidence that is more reliable.

Physiological Weakening During "El Niño" Events

Vega et al. (1997) and Shepherd et al. (1998) suggested that the reduction of food during warm periods could have lead to poor physiological condition and greater susceptibility to predation. The association between decreased physiological condition in both species and increased water temperatures support this. Local fishermen affirm that the local extensions of kelp beds declined due to the incidence of warm events, but we have no data to prove this. Kelp beds are also exploited by the local chemical industry, but records about the crop are rare.

The relationship between impoverished physiological condition and reduced proportions of sexually mature organisms was significant for only one species and suggestive for the other. Again, longer time series are needed. The remarkable peak in maturity detected in 1995 could have been produced by delayed spawning and/or shift in the reproductive season. Changes in the sex ratio of green abalone could be a by-product of changes in physiological condition, but it is hard to find a clear explanation. Guzmán-del-Próo (1992) also reported inter annual variations and deviations from the normal 1:1, in favor of females, in both species at other locations. This indicates that the sex ratio in abalone is also a dynamic parameter (Table 6).

Finally, as Shepherd et al. (1998) proposed, climatic variability, represented in our case by the surface water temperature, contributed to the decline of the populations by their weakened physiological condition. These effects have been underestimated, and although the environmental effect of sea temperature anomalies is considered in using the modified version of the Schaefer surplus production model (Shepherd et al. 1998), it seems that this caution has not been enough. Fluctuations in physiological condition should be taken into account when deciding the fishing quotes,

since they are fixed considering only abundance estimations and negotiation (Ponce-Diaz et al. 1998; Shepherd et al. 1998).

ACKNOWLEDGMENTS

We dedicate this work to the memory of our colleagues F. Salgado, G. Pérez, and A. Lelevier. We thank all members and directors of the cooperative "S.C.P.P. Pescadores Nacionales de Abulón" for their help and resources offered during the surveys, especially to D. G. Romero-Árce. We appreciate the support of F. Uribe, J. Cordova, J. L. Rivera, J. Castro, R. Sánchez, L. Vélez, M. Navarrete, J. Talavera, and O. Pedrín-Osúna during the surveys. We thank S. A. Shepherd, S. A. Guzmán-del-Próo, G. Davis, M. Strasser, and K. Reise for their valuable suggestions.

ABSTRACT The development of cells in the ganglia during various ages of the abalone, *Haliotis asinina*, was studied. There were three types of neurosecretory cells (NS$_{1-3}$), four types of neurons (NR$_{1-4}$) and three types of neuroglia (NG$_{1-3}$). In the cerebral ganglia, NS$_1$ and NR$_1$ (giant neurons) first appeared in 1-month-old abalone while NS$_2$ and NS$_3$ first appeared in 3-month-old and 4-month-old abalone, respectively. These cells increased in number in 5- and 10-month-old abalone, reaching a maximum number at 12 months, and thereafter remained constant. In the pleuropedal ganglia, NS$_1$ and NR$_1$ first appeared in 1-month-old abalone, while NS$_2$ and NS$_3$ first appeared in 2-month-old and 4-month-old abalone, respectively. They increased in number in 4- and 7-month-old abalone, reaching a maximum at 11 months, and thereafter remained constant. In the visceral ganglia, NS$_1$ and NR$_1$ first appeared in 2-month-old abalone while NS$_2$ and NS$_3$ appeared later in 3-month-old and 5-month-old abalone, respectively. They increased in number at 4 months, reaching a maximum number at 11 months, and thereafter remained constant. NR$_2$, NR$_3$, NR$_4$ and NG were present in all ganglia early in development from one month onwards, and their numbers increased rapidly with age.

KEY WORDS: development, nerve ganglia, abalone, *Haliotis asinina*

INTRODUCTION

During neurogenesis of gastropods, the central ganglia of gastropods arise by proliferation and later delamination and/or invagination of the ectoderm. Cell division continues in the peripheral proliferative zones throughout embryogenesis, and post-mitotic cells then migrate inwardly to join the central ganglia which are formed nearby (Jacob 1984). Gangliogenesis in gastropods progresses from anterior to posterior with the cerebral ganglia developing first, followed by the pedal ganglia and then the more posterior ganglia of the abdominal loop (Kerkut & Walker 1975). The pattern of neurogenesis in the gastropod central nervous system resembles the proliferation of cells in the neural tube and the migration of the neural crest and ectodermal placode cells in the vertebrate nervous system but differs from the pattern described for other invertebrates (Jacob 1984).

Although the nervous systems of more derived species of gastropods as well as the development of neurons and individual transmitter systems have been studied (Lever et al. 1965; Coggeshall 1967; Kerkut & Walker 1975; Van Minnen and Sokolove 1984; Roubos et al. 1988; Carroll & Kempf 1994; Kruatrachue et al. 1994; Kempf et al. 1997; Marois & Carew 1997), the nervous development of prosobranchs has not been investigated in detail. Most studies of ganglia development in gastropods were conducted on opisthobranchs and pulmonates. In pulmonates, variation in morphology and lobulization of the ganglia is related to age and development (Kerkut & Walker 1975). Roubos et al. (1988) studied the development of neuroendocrine centers of *Lymnaea stagnalis* (Linnaeus) and found that the dorsal bodies and light green cells were already present in snails of 1 mm in shell length and that the caudo-dorsal cells first appeared in snails of 3 mm in shell length. The dorsal bodies and caudo-dorsal cells increased in number and size with increasing shell length. In *Achatina fulica* (Bowdich), the size of the ganglia and the number of nerve cells in the ganglia increased with increasing age. The prominent nerve cells in the ganglia were large cells and giant cells. The large cells were already present in all ganglia of the newly hatched snails, while the giant cells first appeared in 1-month-old snails. The neurosecretory cells in the cerebral ganglia of *A. fulica* first appeared in 2-month-old snails and increased in number and size with increasing age, reaching a maximum number in 8-month-old snails and thereafter remained constant in 9- to 12-month-old snails (Kruatrachue et al. 1994).

In general, the number of nerve cells in the ganglia of gastropods increases with age (Kerkut & Walker 1975; Lever et al. 1965; Coggeshall 1967). Coggeshall (1967) studied the opisthobranch snail, *Aplysia californica* (Cooper), and found that, during its maturation, the number of nerve cells in the ganglia increased by 40% and that the greatest number of large neurosecretory cells occurred in full grown animals. In the stylommatophoran snail, *Limax maximus* (Linnaeus), the morphology of the dorsal body cells also changed during maturation (Van Minnen & Sokolove 1984). The neurosecretory cells were small and released little secretory product in the immature and early male-phase animals. In contrast, these cells became larger and released large amounts of secretory product in the later female-phase animals (Van Minnen & Sokolove 1984). To the best of our knowledge, there is little information on the development of ganglia in prosobranch snails. Hence, the aim of the present investigation was to study the development of nerve ganglia of *Haliotis asinina* (Linnaeus), a common abalone species found along the coastal waters of Thailand.

MATERIALS AND METHODS

Ten adult *H. asinina* (average shell length 66.58 mm) (five males and five females) were obtained from the Marine Biological Station, Chulalongkorn University, Chonburi Province, Thailand. They were relaxed with 5% MgCl$_2$ for 3–4 hours prior to dissection. Dissections of the nervous system were done under an Olympus stereoscopic binocular microscope with a fiber optic dissecting light and drawings were made with the aid of a camera lucida.

To study the histological development of the nervous system of *H. asinina*, adult abalone and those from 1 to 12 months old were obtained. Ten animals from each age class were examined. They were relaxed and the cerebral, pleuropedal and visceral ganglia were dissected out and fixed in Bouin's fluid in 0.14 M NaCl f

24 hours, and washed with 70% ethyl alcohol. Then, they were dehydrated through a graded series of ethanol, cleared in dioxane, infiltrated and embedded in paraffin. Serial frontal sections of 5 μm thickness were cut and alternating sections were stained with hematoxylin and eosin, chrome-hematoxylin-phloxine (Gomori 1941) and paraldehyde-fuchsin (Gomori 1950). Sections were examined under an Olympus Vanox light microscope. Measurements (width, length and thickness) of the ganglia were taken from the median frontal sections (10 sections per ganglion; 10 animals for each age group). Neurons and neruosecretory cells in all ganglia were identified based on their histological characteristics (cell size and shape, nuclear size and shape) and staining affinities (Upatham et al. 1998; Kruatrachue et al. 1999; Thongkukiatkul et al. 2000). In addition, the numbers of cells in each ganglion of each age group were counted. For each animal, the cell count was done on the median frontal sections (10 sections per ganglion). The cell type and number were scored as follows:

Neurosecretory Cell (per section)		Neuron (per section)	
(−)	= 0 cell	(−)	= 0 cell
(+)	= 1–5 cells	(+)	= 1–10 cells
(++)	= 6–10 cells	(++)	= 11–20 cells
(+++)	= 11–15 cells	(+++)	= 21–30 cells
(++++)	= >15 cells	(++++)	= >30 cells

RESULTS

Figure 1 shows a diagramatic drawing of the gross anatomy of adult *H. asinina*. The nervous system consists of a pair of cerebral ganglia, a pleuropedal ganglion and a visceral ganglion.

Figure 2 shows the frontal sections of the cerebral (Fig. 2A), pleuropedal (Fig. 2B) and visceral ganglia (Fig. 2C) in adult *H. asinina*. There are 10 types of nerve cells in all ganglia of *H. asinina* (Figs. 2D, 3A), i.e., three types of neurosecretory cells (NS_{1-3}), four types of neurons (NR_{1-4}) and three types of neuroglia (NG_{1-3}) (Upatham et al. 1998; Kruatrachue et al. 1999; Thongkukiatkul et al. 2000). The NS cells were identified using special stains, i.e. chrome-hematoxylin- phloxine (Gomori 1941) and paraldehyde-fuchsin (Gomori, 1950).

The shape, size, and type of cells and their number in ganglia during various ages of developing abalone are summarized in Tables 1, 2 and 3.

Cerebral Ganglia

In 1-month-old abalone, the cerebral ganglion appeared as an elongated bean shape whose size was approximately 121 × 471 × 100 μm (Fig. 3B). Most of the ventral, dorsal and lateral parts of the ganglia had a thick cortex that contained 3-4 cell layers, while the medial part contained only 0–1 cell layers (Table 1). NS_1 cells first appeared in 1-month-old abalone; there were 1–2 cells per section. These cells were concentrated in the dorsal horn of the ganglion (Table 1). Most types of neurons (NR_{1-4}) were present, but NR_2 were the most numerous. NR_3 and NR_4 were moderate in number, while the NR_1 or the giant neurons were rarely found but when present were usually located in the dorsal horn similar to NS cells (Table 1). All types of NG were present but in a small number.

At 2–4 months, the ganglia appeared bean shape similar to those in 1-month-old abalone. The number of cell layers increased with age. The number of NS cells increased to about 2–5 cells per section (Table 1). Most of these were NS_1, while NS_2 were observed in 3-month-old and NS_3 in 4-month-old abalone. Most NS cells were concentrated in the dorso-lateral and dorso-medial, ventral and ventro-medial parts of the ganglia (Table 1). NR cells were similar in type and number to those in 1-month-old abalone. NG cells increased in number from one month onwards.

At 5 months, the size of the ganglion increased to 203 × 632 × 200 μm (Table 1). From 5 months onwards, the ganglion assumed a sickle shape (Fig. 3C). The number of cell layers in the cortex increased, especially in the ventral and dorsal parts. The number of NS cells increased to about 10 cells per section, and although all types of NS were scattered in all parts of the ganglia, most were still concentrated in the dorsal and ventral horns (Table 1). The number of NR increased with age, and the NR_1 count was approximately 11–20 cells per section (Table 1). They were present in the dorsal and ventral areas. At this age, the number of NG slightly increased.

From 6 to 10 months, the ganglia appeared sickle shaped but were larger and more elongated than those of 5-month-old abalone. The cortex in all areas thickened and the quantities and distribution of NS and NR cells were similar to those of 5-month-old abalone (Table 1).

At 11 months, the cerebral ganglia increased in size to about 377 × 810 × 300 μm (Fig. 3D). Other appearances were similar to those of 5- to 10-month-old abalone. However, the numbers of NS and NR_1 cells increased (Table 1). NG also increased with increasing age. When abalone were 12 months old, their ganglia (377 × 901 × 325 μm in size) were fully developed and appeared similar in all aspects to those of the adult abalone (Fig. 2A).

Pleuropedal Ganglia

In 1-month-old abalone, the pleuropedal ganglion appeared butterfly-shaped and about 189 × 418 × 150 μm in size (Fig. 4A). In the ventral and lateral parts of the ganglia, the cortex was thick and contained 2–5 cell layers (Table 2). The remaining parts of cortex were relatively thin. There were only about 1–2 NS cells per section. These cells were confined to the dorsal-sulcus of the ganglion; most of them being NS_1 (Table 2). There were all types of NR, but a few NR_1 and NR_4 were present in the dorso-medial part (Table 2). All types of NG cells were found in the ganglion at this age.

At 2–3 months, the size of the ganglia increased from 273 × 497 × 155 to 289 × 522 × 170 μm, but the shape was not altered (Fig. 4B). The number of cell layers in the cortex, NS and NR cells appeared to increase, and most cells were found in all parts of the cortex. However, NR cells were concentrated in the dorsal and dorso-lateral parts, while NS cells were concentrated in the dorso-medial and lateral sulci (Table 2).

At 4–6 months, the pleuropedal ganglia was still butterfly-shaped but increased in size from 337 × 556 × 200 μm to approximately 488 × 707 × 250 μm (Fig. 4B), and the cortex became much thicker. The number of NS cells (mostly NS_1) increased to about 20 cells per section and a larger number were found in the dorso-lateral and ventro-lateral parts (Table 2). NR cells increased in number with increasing age and were found in the ventro-medial, ventro-lateral and ventral sulci (Table 2).

At 7 months, the ganglia were H-shaped and increased in size to about 544 × 1615 × 315 μm (Fig. 4C). The number of cell layers increased and NS cell (mostly NS_1) number was about 30–40 cells per section; these cells were distributed in all areas (Table 2). NR cells (mostly NR_1) increased in number in comparison to earlier stages. From 8 to 10 months, pleuropedal ganglia were similar in shape to those of 7-month-old abalone (Table 2).

Figure 1. Diagramatic drawing of the gross anatomy of adult abalone showing the ganglia and their peripheral nerves (modified from Crofts, 1929).

At 11 months, the ganglia increased in size to 589 × 2508 × 470 μm; the ventral and dorsal horns were elongated (Fig. 4D). The number of cell layers in the cortex increased. The number of NS cells was about 60 cells per section (Table 2). NR cells and NG cells were distributed in all areas; their numbers increased with increasing age. At 12 months, the pleuropedal ganglia (589 × 2543 × 500 μm in size) were fully developed and appeared similar to those of the adult abalone (Fig. 2B).

Visceral Ganglia

In 1-month-old abalone, the visceral ganglion was as small as 37 × 72 × 30 μm and bean-shaped (Fig. 5A). The cortex had only one layer of cells (Table 3). NS cells and NR_1 cells had not yet appeared. In contrast, the remaining types of NR (NR_{2-4}) were present but still few in number (Table 3). All types of NG were observed.

From 3 months onwards, the ganglion was dumbbell-shaped (Figs. 5B–5D) and its size increased with increasing age (Table 3). The cortex was thicker, especially the lateral part. NS_1 cells first appeared in 2-month-old abalone, and their number was about 1–2 cells per section (Table 3). They were present in the left lateral, left latero-dorsal and left latero-ventral parts. There were all types of NR, but NR_1 and NR_4 were rarely observed.

At 3–10 months, the visceral ganglion increased in size from 118 × 488 × 50 μm to about 160 × 770 × 110 μm (Fig. 5B). The number of cell layers in the cortex increased. The number of NS cells increased to about 20 cells per section, and they were distributed in the right lateral part (Table 3). NR cells were similar in number and distribution to those at 3 months (Table 3).

At 11 months, the ganglion (160 × 889 × 110 μm) increased in length, but still had a similar width to that of 10-month old abalone (Fig. 5C). NS cells (mostly NS_1) increased in number and were

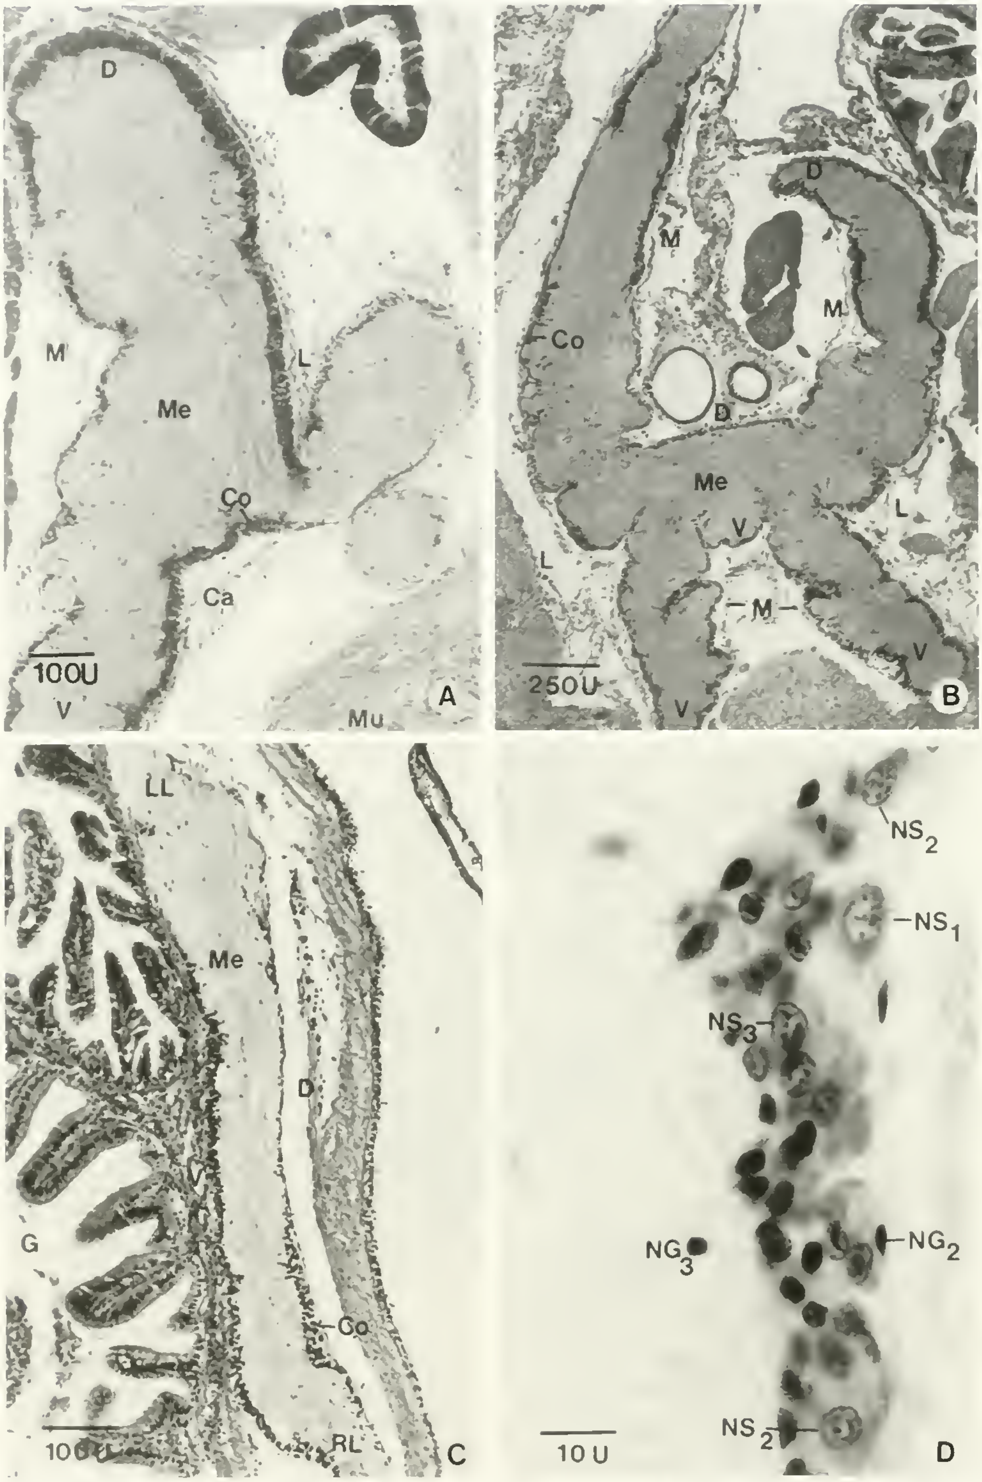

Figure 2. Photomicrographs of the frontal sections of ganglia of *H. asinina.* (A) A low-power micrograph of a cerebral ganglion, showing thick cell layers on the ventral (V) and dorsal (D) sides. Ca-capillary, Co-cortex, L-lateral, M-medial, Me-medulla, Mu-muscle. (B) A low-power micrograph of a pleuropedal ganglion showing thick cell layers on the dorsal (D) and lateral (L) sides. Co-cortex, M-medial, Me-medulla, V-ventral. (C) A low-power micrograph of a visceral ganglion showing thick cell layers on the ventral side. LL-left lateral, RL-right lateral, G-gill, Co-cortex, Me-medulla. (D) A high-power micrograph of a pleuropedal ganglion showing various types of nerve cells in the cortex region. NG_2-type 2 neuroglia, NG_3-type 3 neuroglia, NS_1-type 1 neurosecretory cell, NS_2-type 2 neurosecretory cell, NS_3-type 3 neurosecretory cell.

distributed in all areas of the ganglia (Table 3), but were concentrated mostly in the right lateral part (Fig. 5D). At 12 months, the ganglion (165 × 939 × 150 μm in size) appeared similar to those of adult abalone (Fig. 2C).

DISCUSSION

During postembryonic development of the nervous system of gastropods, the nerve cells and neurosecretory cells increase in size

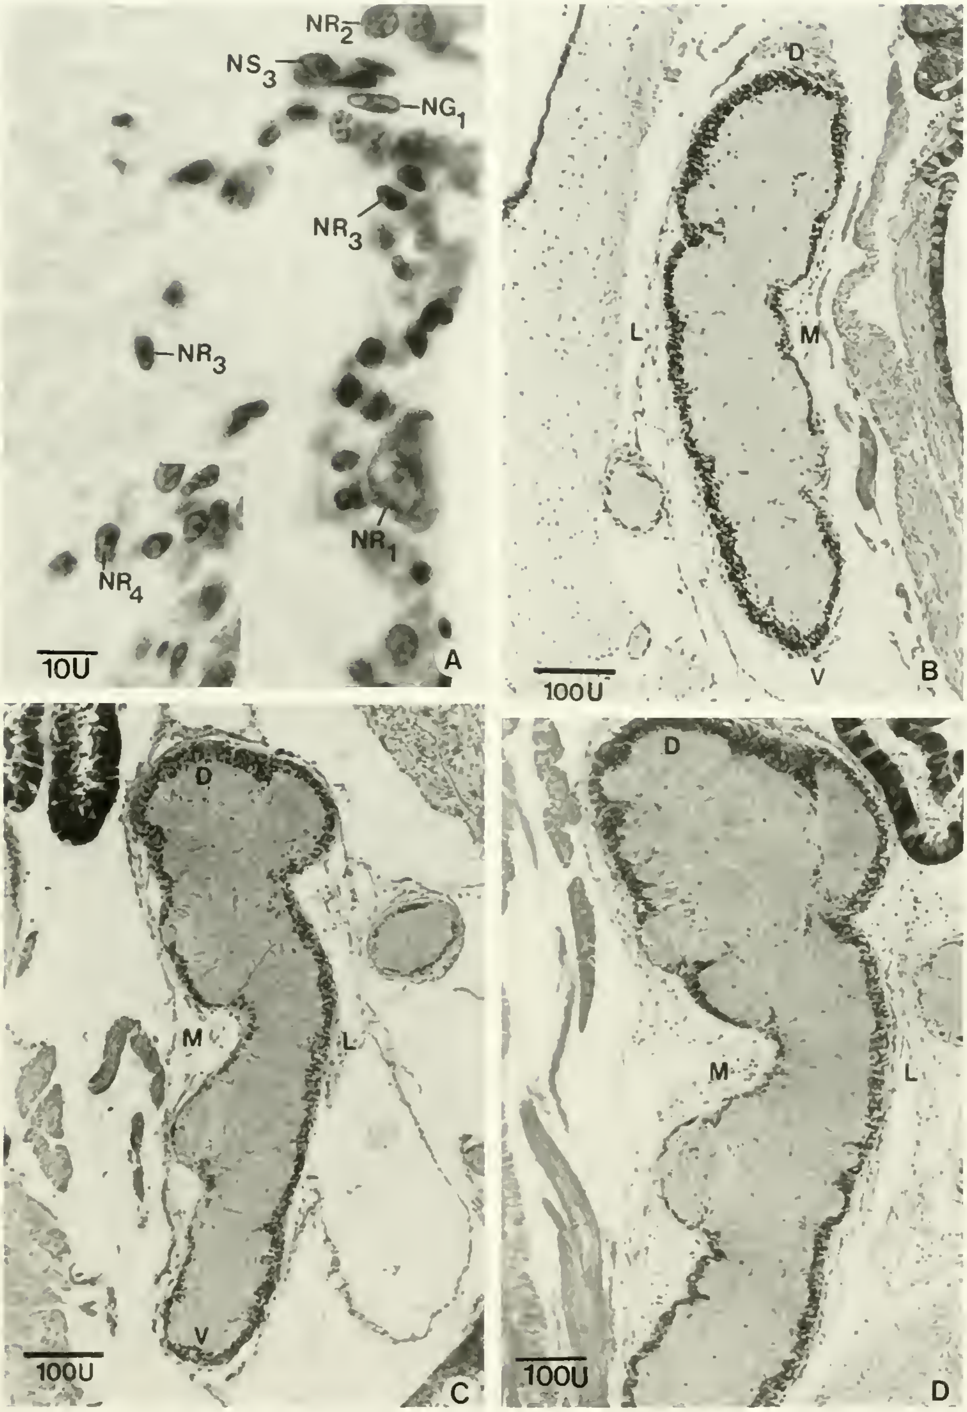

Figure 3. (A) High-power micrograph of cerebral ganglia showing type 1 neuroglia (NG_1), types 1-4 neurons (NR_{1-4}) and type 3 neurosecretory cell (NS_3). (B) Frontal sections of cerebral ganglia in 1- to 4-month-old abalone that appeared bean-shaped. (C) In 5- to 10-month-old abalone, the ganglion appeared as a sickle shape. (D) In 11-month-old abalone, the ganglion greatly increased in size. D-dorsal, L-lateral, M-medial, V-ventral

and number (Bullock & Horridge 1995), for example, the neuroendocrine cells of *L. stagnalis* increase in number and size with increasing shell length (Roubos et al. 1988). In addition, Lever et al. (1965) showed the same result in the cerebral and parietal ganglia of *Biomphalaria glabrata* (Say). Similarly, Kruatrachue et al. (1994) reported that the number and size of neurosecretory cells in the cerebral ganglia of *A. fulica* increased with increasing age. A similar trend was observed in *H. asinina* in the present study. Furthermore, our histological study indicates that the cerebral, pleuropedal and visceral ganglia appeared as definite organs with specific shapes in 1-month-old abalone. Later there were changes in the size but not so much shape of these ganglia; and the numbers of neurons and neurosecretory cells in all ganglia markedly increased with increasing age.

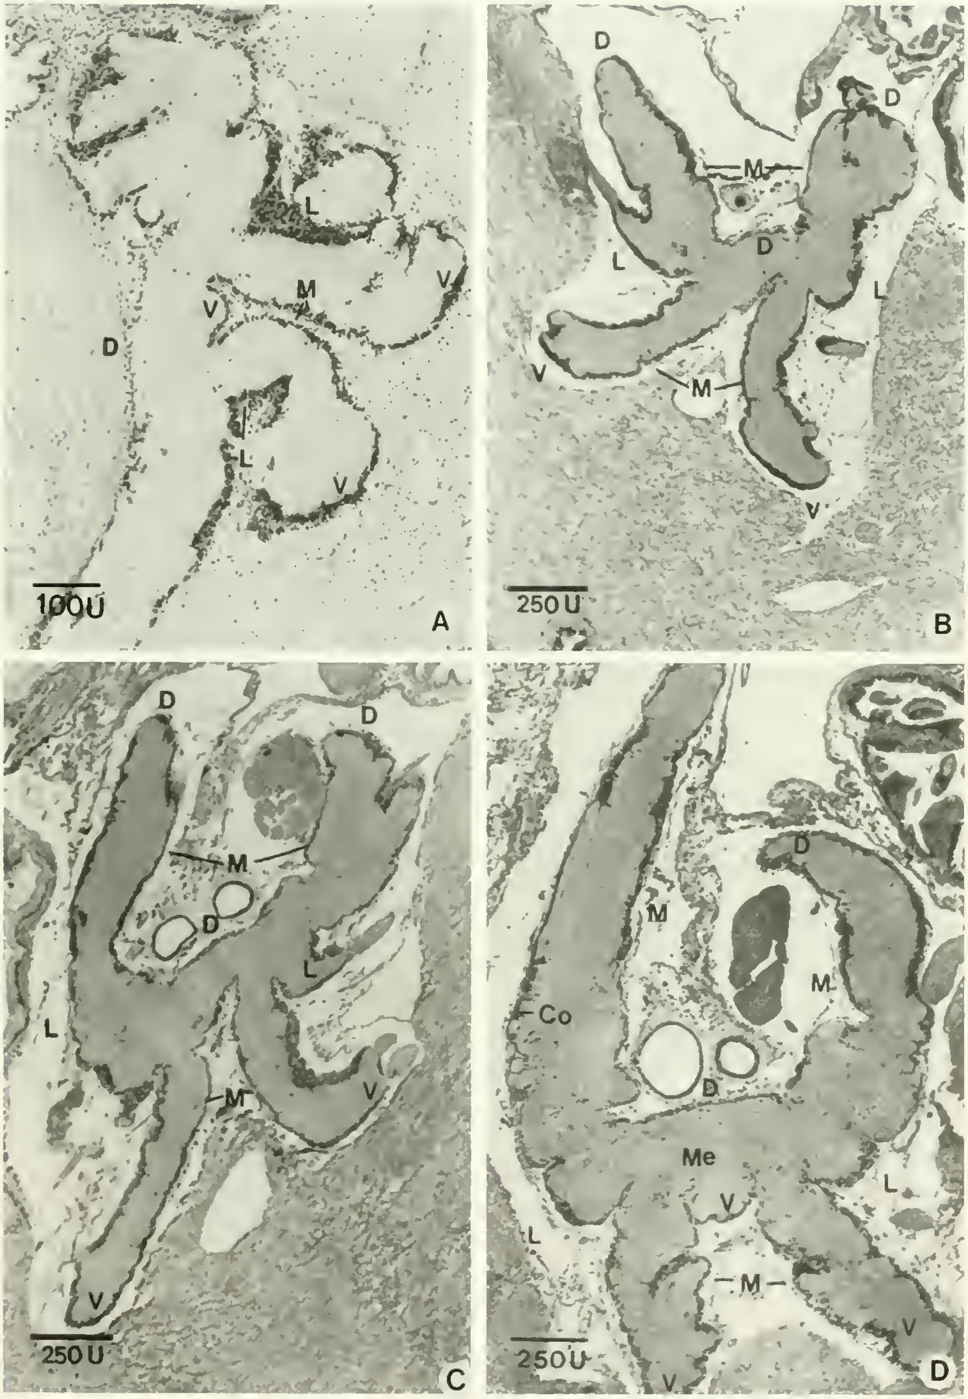

Figure 4. Low-power micrographs of frontal sections of pleuropedal ganglia. (A) In 1- to 2-month-old abalone, the pleuropedal ganglion had a butterfly shape. (B) In 3- to 6-month-old abalone, the ganglion still had a butterfly shape. (C) In 7- to 10-month-old abalone, the ganglion had an H shape. (D) In 11-month-old abalone, the ganglion was larger in size but still had an H shape. Co-cortex, D-dorsal, L-lateral, M-medial, Me-medulla, V-ventral

There have been many reports on the functions of neurosecretory cells in the cerebral ganglia of snails. It has been found that some snails have factors that stimulate growth rate (Geraerts & Algera 1976) and shell regeneration (Dillaman et al. 1976). Thongkukiatkul et al. (1998) reported that neurosecretory cells in the cerebral ganglia of *H. asinina* were positively stained with anti-human GH and anti-human insulin. In this study, it was observed that the neurosecretory cells in the cerebral ganglia first appeared in 1-month-old abalone and increased in number with increasing age. A large number of neurosecretory cells were found in 5- and 10-month-old abalone that are assumed to be juvenile and pre-adult stages, respectively. They formed maximum numbers that were observed and appeared adult-like in 12-month-old abalone that reached the adult stage. It seems, therefore, that the increase in the number of NS cells is correlated with the increase in abalone growth.

Similar studies of other species of gastropods suggest that the number and staining properties of neuroendocrine cells in ga-

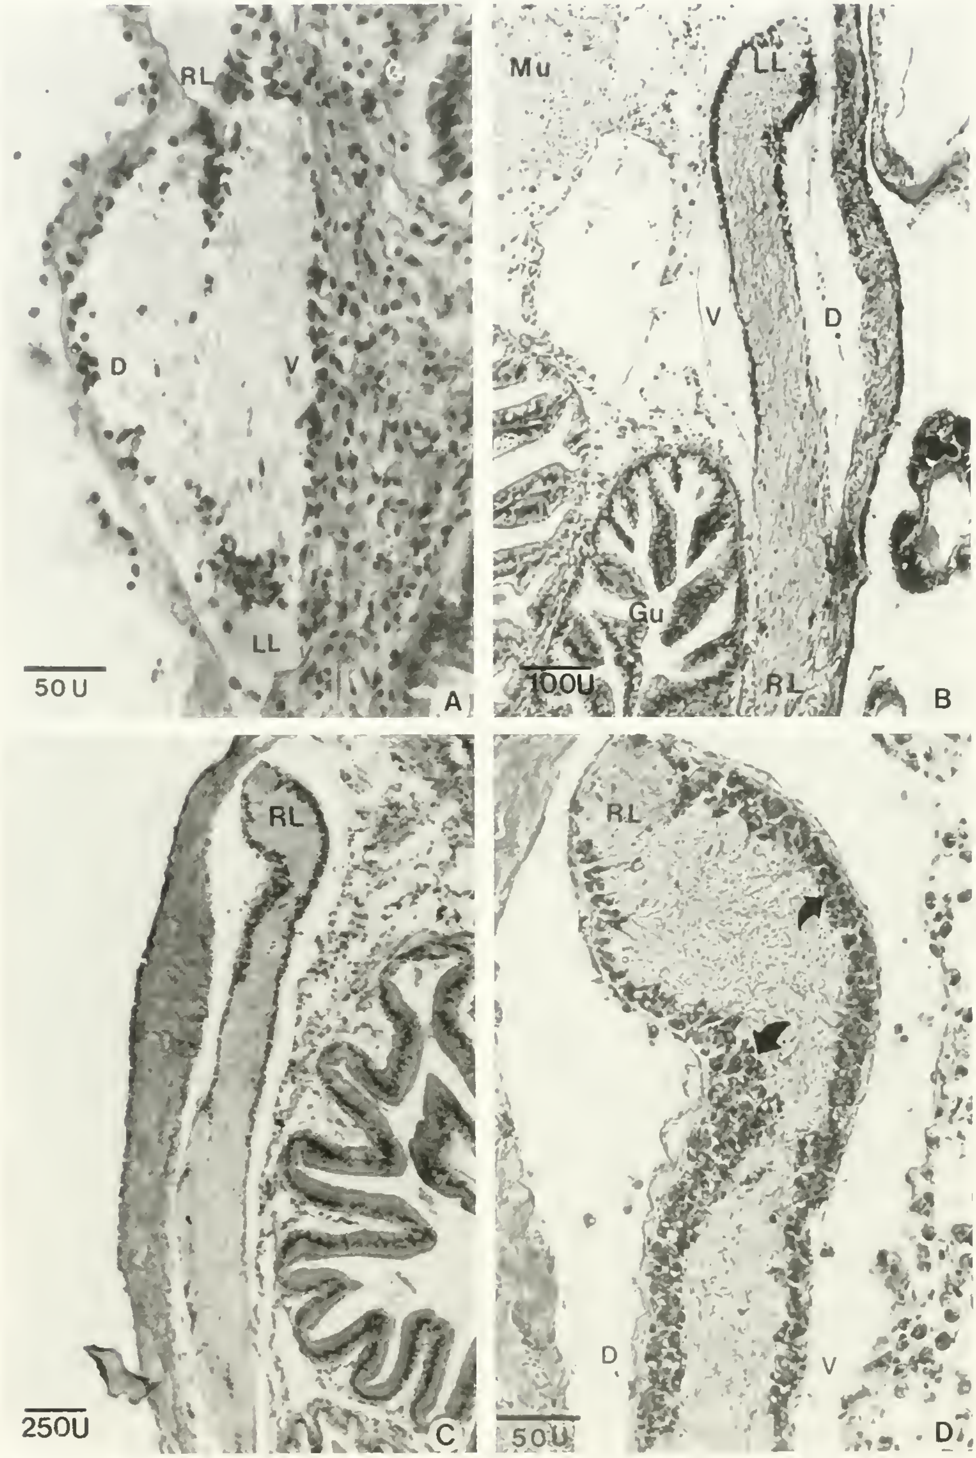

Figure 5. Frontal sections of visceral ganglia. (A) In 1- to 2-month-old abalone, the visceral ganglion was small and had a bean shape. (B) In 3- to-10-month-old abalone, the ganglion was large and assumed a dumbbell shape. (C) In 11-month-old abalone, the ganglion increased only in length. (D) High magnification of (C) showing thick cortex containing all types of nerve cells (arrows). D-dorsal, Gu-gut, LL- left lateral, RL-right lateral, Mu-muscle, V-ventral

ropedal and visceral ganglia are related to the gonadal maturation (Coggeshall 1967; Dogterom et al. 1983; Van Minnen & Sokolove 1984; Smith 1967). In our study it was observed that the neurosecretory cells in the pleuropedal and visceral ganglia first appeared in 1-month old-abalone. The number of neurosecretory cells in the pleuropedal ganglia increased in 4- and 7-month-old abalone, while in the visceral ganglia it increased in 4-month-old abalone. They reached a maximum number in 11-month-old abalone. The development of these neurosecretory cells may correlate with the development of the reproductive organs. Thongkukiatkul et al. (1998) reported that neurosecretory cells in the pleuropedal and visceral ganglia of *H. asinina* were stained by anti-human LH, while only those in the pleuropedal ganglion were stained by anti-human FSH.

It was reported that early spermatocytes and spermatids of *H. asinina* appeared at 4 months, and early oocytes (OC_{1-2}) at 6–7 months (Sobhon et al. 1999), while fully mature spermatozoa appeared in the gonads as early as 6–7 months. At this age, there were already a large number of neurosecretory cells in the visceral and pleuropedal ganglia of the abalone. Moreover, Sobhon et al. (1999) showed that a large number of mature oocytes of the reproductive cycle of *H. asinina* occurred at 10 to 11 months, the age at which the neurosecretory cells in the pleuropedal and visceral ganglia reached a maximum number and appeared adult-like. Our observations were supported by Yahata (1973) who demonstrated that the pleuropedal and visceral ganglia might produce and release factors that could induce spawning.

In the present study, the number of giant neurons (NR_1) increased following the development of the ganglia. In the cerebral ganglia, they increased in number in 5- and 10-month-old abalone that were assumed to be the juvenile and pre-adult stages. They reached a maximum number and appeared adult-like in 12-month-old abalone. NR_1 first appeared in the dorsal horn of the pleuropedal ganglia, later they were regularly found in both dorsal and ventral horns. Thus, NR_1 may proliferate relatively later than the other types of neurons (NR_{2-4}) that are abundant at an early age. This may be related to active movement due to muscular activity exhibited by abalone, as they become older.

NR_1 were more abundant in the pleuropedal ganglia than in the cerebral ganglia of *H. asinina* (Upatham et al. 1998). These cells are very large, multipolar and pyramidal in shape. Compared with the classification of neurons in the nervous system of higher vertebrates, NR_1 are similar to such large motor cells as the ventral horn motor cells of the spinal cord and Purkinje cells of the cerebellum in vertebrates. As such, they may be involved in controlling and coordinating motor activities, especially that of the pedal muscle.

ACKNOWLEDGMENTS

This research was supported financially by the Thailand Research Fund (Senior Research Scholar Fellowship to Prasert Sobhon) and BRG/04/2543. We thank Dr. Padermsak Jarayabhand of the Marine Biological Station, Chulalongkorn University, Chonburi Province, Thailand, for providing the abalone specimens.

INDUCTION OF SPAWNING AND EARLY DEVELOPMENT IN *Fissurella picta* (MOLLUSCA: ARCHAEOGASTROPODA) FROM SOUTHERN CHILE

INGRID BAHAMONDES-ROJAS[1] AND MARTA BRETOS[2]

[1]*Instituto de Biología Marina, Universidad Austral de Chile, Casilla 567, Valdivia, Chile;*
[2]*Departamento Ciencias Básicas, Facultad de Medicina, Universidad de La Frontera, Casilla 54-D, Temuco, Chile*

ABSTRACT Specimens of *Fissurella picta* were collected from the rocky intertidal coast near Valdivia, southern Chile, and used for studies of spawning. Males responded to artificial stimuli more frequently than females. Potassium chloride was the most effective agent for inducing spawning, whether injected into the mantle cavity, added to the seawater, or a gonad macerate, or combined with a period of exposure to air. Injection of hydrogen peroxide or addition of prostaglandin to ultraviolet-irradiated seawater in the experimental containers also induced males and females to spawn. Oocytes of *F. picta* (mean diameter 178 μm) were surrounded by two membranes, the vitelline and albumen membranes, and a gelatinous outer coat, which was lost a few minutes after spawning. The first polar body was released 15–20 minutes after fertilization, and various cleavage stages were observed during the following 7 hours. Trochophore larvae were observed after 15 hours and early veligers 21 hours after fertilization (temperature 17.5 ± 1°C, salinity 29–30‰). The hatched veliger larva began torsion and a free-swimming mode of life after 40 hours. The results showed the possibility to obtain the larval development in *F. picta* under laboratory conditions, providing a significant progress for its future culture.

KEY WORDS: development, spawning, gastropod, *Fissurella*, induction, reproduction

INTRODUCTION

Species belonging to the genus *Fissurella* (Bruguière 1789), known locally as "lapas", sustain a multispecies artisanal fishery in Chile. In spite of the economic importance of this resource, there is very little published information about the biology of the genus. During the last years, research on *Fissurella* species in Chile has been directed to establish the scientific and technological foundations to culture them, by studying their reproductive biology and embryo-larval development. In this sense, trials of gamete release under laboratory conditions have been conducted in view of culture. Spawning induction in *F. cumingi* (Vega & Osorio 1995; Vega et al. 1996) has had relative success in males, by using low concentrations of hydrogen peroxide. Huaquín et al. (1998) obtained gamete emission in *F. crassa* by intravisceral injection of KCl. The spawning induction methods used in *F. picta* (thermal, electric, and osmotic shock) have not produced positive results (González et al. 1999). Considering the ecological (Moreno & Jaramillo 1983) and economic (Bretos 1988) importance of *F. picta* at southern Chile, the objective of this study is to obtain gametes from *F. picta* Gmelin (1791) by various spawning induction techniques, and to describe embryonic and larval development in this species, in a population from southern Chile. Such information will greatly facilitate attempts to grow this species in culture, and contribute to efficient management of aquaculture sites in the future.

MATERIALS AND METHODS

A total of 451 specimens of *Fissurella picta* were collected from a wild population from the rocky intertidal shore at Playa Rosada and La Misión, near Valdivia (39°48′S, 73°24′W; Fig. 1), when gonads were fully mature, between October 1996 and December 1997. Only individuals of shell length greater than 40 mm were taken, to ensure that most of them were sexually mature (Bretos et al. 1988).

In the laboratory the shells were scrubbed and thoroughly washed with filtered seawater to remove epibionts, and the limpets were transferred to 30-liter plastic tanks containing continuously aerated filtered seawater (0.45 μm). The tanks were maintained under ambient conditions of photoperiod, temperature (10–20°C) and salinity (29–30‰), according to the season. In order to keep the temperature constant, the plastic tanks were placed in a 500-liter fiberglass container filled with circulating, temperature-controlled freshwater.

The experimental animals were fed ad libitum with the algae *Macrocystis pyrifera* (Linnaeus) C. Agardh 1820 and *Ulva lactuca* Linnaeus 1771, collected from the same place as the limpets. These algae are known to support growth in *F. picta* (Castro & Iglesias 1995). Occasionally *Mazzaella laminarioides* (Bory) Fredericq 1993, was also added, because it forms part of the natural diet of the limpet.

In order to determine the sex of the specimens of *F. picta*, a sample (0.1 ml) of gonad tissue was removed by aspiration through an intravisceral-pedal puncture. The sex of the individual is easily established from the color of the gonad tissue (Bretos et al. 1983).

The stage of gamete development was determined by optical microscopy and characterized as follows: oocytes mature or undergoing vitellogenesis, presence of gelatinous coat, amount of yolk, motility and appearance of sperms. The diameter (μm) of the oocytes was measured with an ocular micrometer (Carl Zeiss) in 4–7 females taken at random from each sample within the size range collected. The counting of sperms and estimation of motility was done with a blood-cell counting camera (Malassez).

Induction of Spawning

Limpets were maintained for 7 days in the laboratory, without food for 24 hours before the following stimuli were applied:

Temperature Stimuli

The animals were submitted to water temperatures from 10–24°C in increments of 3°C (12-15-18-21°C) each 15–20 min.

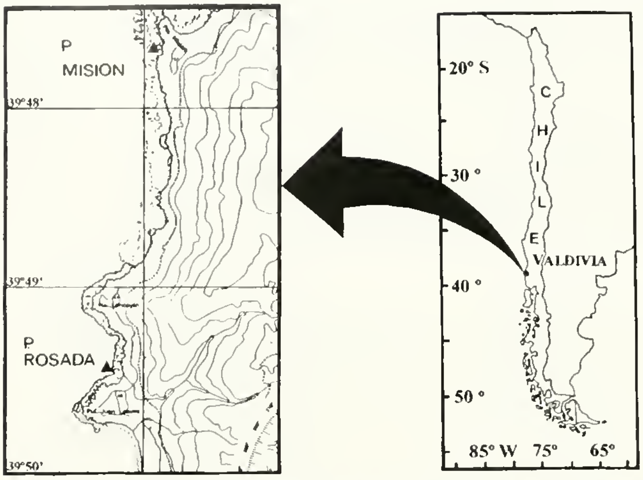

Figure 1. Map of Valdivia region, showing the locations of the two sites used to collect *Fissurella picta* during this study.

Chemical Stimuli

(a) Potassium chloride: an intravisceral-pedal injection (0.5 ml of 0.5, 10, 20, and 100 mM), or added to the seawater (concentration 10 mM).
(b) Hydrogen peroxide: an intravisceral-pedal injection (0.5 ml of a 50 mM solution) or added to the seawater (concentration 8 mM).
(c) Dopamine: an intravisceral-pedal injection (0.5 ml of a 2-mM solution).
(d) Dopamine plus hydrogen peroxide: added to the seawater (concentrations 2 mM and 8 mM, respectively).
(e) Dopamine plus seawater treated with UV radiation: added to the seawater (concentration 1 and 2 mM; irradiation period 40 minutes).
(f) Synthetic prostaglandin (α postrol, PG): an intravisceral-pedal injection (0.5 ml of a 0.04 mg/ml solution).
(g) Synthetic prostaglandin plus seawater irradiated with UV light: added to the seawater (concentration 0.04 mg/ml; irradiation period 40 minutes).

Physical Stimulation

The animals were exposed to air for 15–20 minutes.

Other Stimuli

A combination of chemical and physical stimulation was used, together with the addition of macerated gonad tissue to the seawater. Stimuli for the induction of spawning were applied to groups of 4 to 10 limpets, males and females separately, each group being maintained in 4 liters of filtered seawater gently circulated (0.5 l/min).

Any limpet failing to respond to a spawning stimulus within two or three days was replaced. The nonparametric Wilcoxon test ($P <$ level 0.05) was used to compare responses of male and female limpets to the various spawning stimuli, using the program Statistica (Windows version 4.2).

Fertilization and Development

After the initiation of spawning, individual limpets were placed in small containers with 1 liter filtered seawater. Triplicate samples of 1 ml were taken from each suspension of gametes. Oocytes were

counted under a stereomicroscope, a mean value obtained, and the total number of gametes calculated. Sperms were counted with a Malassez camera.

Sub-samples of oocytes taken during spawning were fixed in 3% glutaraldehyde, washed in phosphate buffer and distilled water, and mounted under cover slips for examination and photomicrography (Zeiss Axiomat microscope).

The remaining oocytes were screened (150 μm mesh), washed several times in sterile filtered seawater and maintained in the 1-liter containers to await fertilization. The sperm suspensions were also screened (45 μm) before use to get fertilization, gamete suspensions from individual limpets were used in ratio 10–15 sperms per oocyte.

After fertilization had been confirmed by the appearance of the first polar body, each batch of eggs was washed several times in sterile seawater to remove the excess of sperms, then transferred to a 2 liter container of sterilized filtered (0.45 μm) seawater and kept in darkness with constant aeration. Every 24 hours afterwards, two thirds of the water was replaced. Temperature was maintained at 17.5°C ± 1°C and salinity at 29–30‰. Replicate samples were taken every 15 minutes for the first 3 hours after fertilization, every 30 minutes from 3 to 24 hours post-fertilization, and every hour thereafter until the liberation of the larvae.

The embryos and larvae were screened with different mesh sizes appropriate for their size. The samples were examined under a light microscope (Olympus) and obtained from a camera (Samsung NF-E80SN) which replaced one of the eyepieces of the microscope. Selected images were captured (ATI program), digitized (BMP format) and processed by image analysis (Scion Image PC).

The criterion for determining the stage of development for any given sample was that at least 60% of the individuals should have attained the stage in question.

RESULTS

Induction of Spawning

Data from the 57 spawning induction trials, undertaken principally in October and November 1997 are presented in Table 1. More males responded than females (Wilcoxon test; $N = 16$; $Z = 2.201$; $P < 0.05$). Potassium chloride was the most effective inducing agent (10 mM), whether administered by injection, added to the medium with macerated gonad tissue, or combined with air exposure. A combination of UV-irradiated seawater with either dopamine or prostaglandin (PG) also induced spawning in males.

On one occasion with hydrogen peroxide injection, and on another with PG added to the medium together with UV-irradiation of the seawater, as many males responded as females did. Only once did a male spawn in response to PG. Dopamine was not effective for inducing spawning in males, except when combined with UV-irradiated water.

Characteristics of Gametes

Mature oocytes had two external membranes, the vitelline membrane and the albumen membrane, outside which was a gelatinous coat (Fig. 2A). The gelatinous coat was often lost, but when it was present the micropyle originating from the albumen membrane was clearly visible (Fig. 2B). The albumen membrane, which in Figure 2B had yet to expand, was derived from the oocyte and had the appearance of a clear gelatinous fluid.

Oocyte diameter varied from 117–327 μm (mean 178 μm), but those with a gelatinous coat reached a diameter of 385 μm.

Fertilization and Development

During December 1996, October and November 1997, a total of 10 trials of artificial spawning were successfully completed (Table 2); these were of three types: (a) use of gamete suspensions obtained by dissecting the gonads (OT) of 10 *F. picta* individuals; (b) oocytes from dissected ovaries together with sperm from induced spawning (OI) of 10 animals; and (c) oocytes and sperm both obtained from spontaneous spawning (SS) in 10 specimen.

The spawned oocytes of *F. picta* frequently required several seconds before complete hydration and expansion of the albumen membrane. During this time eggs were observed to be surrounded by large numbers of sperm, and occasionally the sperm head could be seen within the micropyle.

At 17.5°C, fifteen to twenty minutes after fertilization the first polar body was visible, having the appearance of a small, translucent, refringent granule (Fig. 3A). The polar body was located immediately adjacent to the vitelline membrane within the extraembryonic fluid of the albumen membrane of the egg.

After 90 minutes the first two holoblastic segmentation divisions had given rise to four blastomeres of equal size (Fig. 3B,C

The third oblique plane of division resulted in the formation eight blastomeres (Fig. 3D), of which four were very large macromeres, located at the vegetative pole of the embryo and containing yolk reserves, and the remaining four were small micromeres located at the animal pole.

After 4 to 7 hours successive divisions of the blastomeres had given rise to a blastula, a compact, multicellular sphere that gently rotated within the membrane, suggesting the presence of cilia on the external surfaces of the blastomeres. Embryonic development was highly synchronized, but became less so during the larval stages. Fertilized eggs obtained by OT and OI (Table 2) developed only until blastula stage.

The trochophore larva, exhibiting a ring of prototroch cilia, appeared 15 hours after fertilization, and was completely enveloped by the albumen membrane (Fig. 4A). Survivorship was about 50% of fertilized eggs in SS trials (Table 2).

Larvae became an early veliger, turning round within the albumen membrane, 21 hours after fertilization. Forty hours after fertilization, the albumen membrane had disappeared and the veligers had emerged (Fig. 4B) to spend a short period moving through the water column. The pretorsional larva exhibited the protoconch, an expanded velum, the foot, and the rudimentary

TABLE 2.

Fissurella picta. Stages of development obtained in laboratory at 17.5 ± 1°C and 29–30 ‰ salinity.

Fertilization	Stages	Time	Diameter (µm)
OT	Egg	First minutes	180
OT	First polar body	15–20 min.	180
OT	2 Blastomeres	<60 min.	180
OT	4 Blastomeres	80–90 min.	180
OI, SS	4–8 Blastomeres	80–90 min.	180
OI	Blastula	4–7 hours	180
SS	Trochophore	15 hours	180
SS	Early veligers	21 hours	180
SS	Hatched veligers	40 hours	200

OT = Dissected ovary and testicle
OI = Dissected ovary plus sperm from induced spawnings
SS = Spontaneous spawning in females and males.

retractor muscle. The visceral mass was well developed and the yolk reserves and velar cilia diminished.

About a 30–40% of embryos obtained by SS trials survived to veliger stage. Development did not continue, and larvae ultimately died.

DISCUSSION

Induction of Spawning

The spawning stimuli used in this study were similar to those used by other authors (Morse et al. 1977; Morse & Morse 1984; Uki & Kikuchi 1984; Pechenik 1986; Martínez et al. 1996) to obtain gametes from various marine invertebrates. In the case of *F. picta*, the maximum maturity condition in the gonads detected in this study during the spring (September to December) would facilitate the spontaneous gamete release to get fertilization and development in a more successful way.

Our results suggest that induction of spawning in *F. picta* was successful, but more effective with males than with females. Similar data have been obtained in previous studies on *F. maxima* and *F. cumingi* (Vega & Osorio 1995). The artificial spawning induction methods tested (thermal, electric, and osmotic shock) by González et al. (1999) in *F. picta* did not produce positive results; this report suggests that a combination of various inductive stimuli should be required to obtain positive responses, as has been shown in the present study.

Potassium chloride injections, either alone or combined with other stimuli (exposure to air, gonad maceration), and hydrogen peroxide induced spawning in *F. picta*. Potassium chloride acts at the cellular level and has been extensively used to induce metamorphosis in marine invertebrate larvae (Yool et al. 1986; Bahamondes-Rojas & Tardy 1988; Bahamondes-Rojas 1990) as well as for the induction of spawning.

Hydrogen peroxide induces spawning in gravid male and female abalones *Haliotis rufescens* and *Nordotis gigantea*, the mechanism possibly being direct stimulation of the enzymatic synthesis of prostaglandin endoperoxidase (Morse et al. 1977; Tanaka 1979; Hahn 1989). Our data support those of Vega et al. (1996), who successfully induced spawning in male *Fissurella cumingi* with low concentrations of hydrogen peroxide (3 mM when added to the medium, and 5 mM when combined with gonad maceration).

It is also known that seawater irradiated with ultraviolet light induces spawning in many mollusks (Kikuchi & Uki 1974; Kagawa & Nagahama 1981), but our data are not in agreement. Nevertheless, we found ultraviolet irradiation to be effective when combined with PG or dopamine, presumably as a result of synergistic action. Moss et al. (1995) induced spawning in Haliotis iris with two agents, hydrogen peroxide and seawater irradiated with ultraviolet light, the former being more effective.

The role of prostaglandin remains unclear, although its presence and biosynthesis have been established (Ogata et al. 1978; Nomura & Ogata 1976). We found PG to be a successful agent for inducing spawning in male *F. picta*, but in females the mechanism may be different. Thus Martínez et al. (1996) suggested that in the hermaphrodite scallop *Argopecten purpuratus*, dopamine and PG may be involved in the release of oocytes.

The fact that most of the trials were successful only in males may be attributable to different mechanisms or maturation rates in male and female gonads. Our microscopic observations demonstrated that gonad maturation was almost continuous in males, whereas in females there was a latent period during the vitellogenic phase.

One outcome from this experiment should nevertheless be emphasized. Spawning inducers such as KCl and H_2O_2 are inexpensive, easy to use and are widely used for the control of reproduction in molluscs such as fissurellids.

Sex and Gametes

Fissurella picta is an archaeogastropod which, like all fissurellids, does not exhibit external sexual dimorphism (McLean 1984). There is no evidence for hermaphroditism or sex reversal (Bretos et al. 1983). The technique we used for determining the sex of each specimen was non-invasive, successful and simple.

There have been few studies of the life cycle (e.g., spawning, fertilization, and age of sexual maturation) in fissurellids. Ward (1966) described the reproductive cycle of *F. barbadensis*, and demonstrated the presence of oocytes of 80–180 μm in diameter (including gelatinous coat). This species is known to have a pelagic phase of two to three days duration (Lewis 1954; Lewis 1960). In *Diodora aspera* spawned eggs are 160–198 μm in ameter, without the gelatinous coat (Hadfield & Strathmann 1996). In *F. maxima* (Bretos et al. 1983) the oocyte diameter lies between 120 and 280 μm, and that of *F. crassa* is approximately 300 μm, excluding the gelatinous coat (Huaquín et al. 1998). Our values for oocyte diameter in *F. picta* are similar to the maximum values recorded for other Chilean species. Nevertheless, differences observed from tropical little sized species such as *F. barbadensis* and *Diodora apertura* may be related to differences in reproductive strategy e.g., time to reach sexual maturity.

In *Diodora aspera* the external gelatinous coat which envelops the oocyte appears to break open only in response to a mechanical action (Hadfield & Strathmann 1996), whereas the internal membrane disappears as a result of the action of enzymes produced by the larva. In Patella (Fretter & Graham 1962) the gelatinous coat of the oocyte disappears a short time after spawning, as in *F. picta* (this study).

The presence of a canal, the micropyle, in the gelatinous coat of the oocyte, and the presence of sperm cells within it, has been observed in *F. crassa* (Huaquín et al. 1998), *Diodora aspera* (Hadfield & Strathmann 1996) and *F. picta* (Fig. 2B of this article).

Fertilization and Development

Knowledge of larval development of Chilean fissurellids is limited mainly to a few unpublished observations; all of them obtained by spontaneous gamete release and fertilization at the laboratory. Vega and Osorio (1995), and Vega et al. (1996) determined that the duration of the pelagic larval phase in *F. cumingi* is 3–5 days under controlled conditions (16–19.8°C), whereas in *F. latimarginata* at 13°C the veliger stage and metamorphosed larva occur 6–7 days after fertilization (Pereira & Quezada 1996).

According to González et al. (1999), who also got spontaneous gamete release and fertilization, the initial trochophore stage was observed in *F. picta* at 72 hours, and swimming trochophore hatched at 96 hours at 10°C. In the present study at 17.5°C, trochophores of *F. picta* were obtained 15 hours after fertilization within the albumen coat, and veligers hatched out of this coat after 40 hours. Our data are not consistent with those of González et al. (1999), probably owing to the difference in temperature. It has been described for *Haliotis* and other species, that the temperature can hasten or delay development (Hahn 1989), and this has probably happened in *F. picta*.

The veligers which were liberated in this study showed morphogenetic movements associated with torsion before settlement and metamorphosis took place. In this regard, our observations agree with those of Page (1997) for the archaeogastropod *Haliotis kamtschatkana*, demonstrating cephalo-pedal and viscero-pallial rotation in pretorsional larvae.

The fact that development of *F. picta* took place in the laboratory during this study suggests the potential for future cultivation of this species. Nevertheless, it will be necessary to elucidate the principal biological factors and ontogenetic mechanisms required to improve survival rates and to identify the conditions required for settlement and growth of a large number of larvae.

ACKNOWLEDGMENTS

This research was supported by Canadian International Development Agency, and Memorial University of Newfoundland awards, and by the Dirección de Investigación y Desarrollo, Universidad Austral de Chile (Grant F-96/01). TYRIAN PURPLE FROM MARINE MURICIDS, ESPECIALLY FROM *PLICOPURPURA PANSA* (GOULD, 1853)

LUDWIG C. A. NAEGEL[1] AND CHRIS J. COOKSEY[2]

[1]Centro Interdisciplinario de Ciencias Marinas, InstitutoPolitécnico Nacional La Paz, B.C.S. 23000 México; [2]59 Swiss Avenue, Watford, Herts WD18 7LL, United Kingdom

ABSTRACT A review of the literature discloses that most marine snails of the family Muricidae produce in the hypobranchial gland a viscous secretion containing, besides mucus and biologically active compounds, minute amounts of chromogens. These chromogens develop enzymatically and under the influence of light and oxygen into a purple pigment known as "Tyrian Purple", "Royal Purple" or shellfish purple. In the hypobranchial gland the enzyme purpurase is kept apart from the chromogens, so that no pigments are formed under normal conditions. Different species of muricids produce different pigments, depending on the number and concentration of different chromogens and on the varying light intensity and oxygen availability during pigment formation. The main pigments obtained from the hypobranchial gland from muricids are indigoids. The pigment of *P. pansa* is mainly 6,6′-dibromindigo with smaller amounts of 6-bromoindigo and 6,6′-dibromoindirubin, similar to that of *Murex brandaris*.

KEY WORDS: "Tyrian Purple", gastropoda, muricidae, *Plicopurpura pansa*, hypobranchial gland

INTRODUCTION

A review of the hypobranchial gland of muricids, its secretions, including "Tyrian purple", seemed justified in view of the growing interest in natural dyes and marine products with pharmacological properties.

The majority of purple producing marine snails belong to the family of Muricidae and most, if not all, produce a colorless secretion in the hypobranchial gland, which turns purple on exposure to air and light (Fretter & Graham 1994).

In antiquity, the purple from the muricids *Murex trunculus*, *M. brandaris*, and *Purpura haemastoma* was produced in the eastern Mediterranean countries – now called, Crete, Lebanon, and Israel. Through the Phoenicians the art of purple production was spread from the Mediterranean to West Africa and Ireland (Jackson 1917). Purple dyes were used extensively by Egyptians and subsequently by Greeks and Romans. In view of the enormous quantity of marine snails needed to produce a minute amount of the dye, the scarcity of the animals, and the high costs of production, Tyrian purple was at that time a most expensive luxury article. In addition there was the symbolic importance of purple as a sign of royalty, power and wealth, and the belief that it could possess magic and supernatural powers (Reinhold 1970). At that time it was the only known fast vat dye, other than indigo. With the Arab conquest of Palestine in 638 A.D., and finally with the fall of Constantinople in 1453 A.D. the use of Tyrian purple became, with a few exceptions, extinct in the Old World (Herzog 1919; Born 1936b; Clark et al. 1993). Through archaeological studies it was confirmed that during the Middle Ages on the west coast of France the muricid *Nucella lapillus* was used as a source for purple (Gruet 1993). From the 16th to the 18th century the artisanal use of purple for marking linen was widespread in Ireland, South Wales and Cornwall, as well as in Scotland, France, Norway and other parts of Europe (Cole 1685; Jackson 1917).

In Japan, the muricid *Rapana bezoar* was of importance in ancient dyeing processes (Baker 1974). On the Japanese peninsula Shima, professional seafood collectors stained their diving suits, made of cotton, with the purple from marine snails believing that it contained supernatural powers (Yoshioka 1974).

The use of muricids for dyeing on the pacific coast of the Americas dates at least from pre-Columbian times. In the same way as the now extinct Mediterranean purple industry the exploitation of the dye of marine snails led also on the pacific coast of the Americas to a product of high economic value.

Today, however, there is not much general interest existing in Tyrian purple derived from marine snails, since similar pigments can be obtained from synthetic substitutes at much less cost (Born 1936c). However, two remarkable exceptions have to be mentioned: (a) the dark violet-blue tekhelet color, which is relevant to Jewish religious rituals derived from the Mediterranean muricids *Murex erinaceus* and *M. trunculus*, and b) on the Pacific coast from Peru to Mexico, the hypobranchial secretion of the muricid *Plicopurpura pansa* (Gould 1853) has been exploited since pre-Columbian times by Indians for dyeing cotton yarn, which until now is subsequently woven into traditional dresses (Martens v. 1874, 1898; Schunck 1980a; Nuttall 1909; Jackson 1917; Born 1936c; Gerhard 1964; Turok et al. 1988; Yoshioka 1974; Thompson 1994; Garay 1996; Sandberg 1997). v. Martens (1898) pointed out that the use of the pigments from *P. pansa* for dyeing in Central America must have had a very long and pre-Columbian tradition and were not brought by the Spanish conquistadors from Europe to the New World. Its presence in archaeological textiles and pictures confirmed his finding.

The carnivorous muricid *Plicopurpura pansa* (Gould 1853), according to Kool (1993) conspecific with *Purpura pansa* (Gould 1853), inhabits intertidal rocks exposed to the open sea with high impact waves. The range of *P. pansa* extends at the Pacific from the north-west coast of Mexico (Baja California Sur) (Clench 1947; Keen 1971) to northern Peru (Peña 1970; Paredes et al. 1999).

Hypobranchial or Mucous Gland

Since the mid 18th century the hypobranchial gland of muricids has attracted the interest of natural scientists, investigating its functional role, and the astonishing production of Tyrian purple. Fretter and Graham (1994) consider the main function of the hypobranchial gland to be a secretor of mucus for trapping and cementing particulate matter sucked into the mantle cavity with the respiratory water current, prior to its expulsion.

Corresponding author. Ludwig C. A. Naegel. E-mail: lnaegel@cibnor.mx

The hypobranchial or mucus gland is an elongated epithelial structure located in the dorsal mantle cavity between the gills and recto-genital organs, immediately below the shell. In the gland three distinct anatomical and functional areas have been described: two lateral regions composed of eight distinct cell types, among them many active secretory cells (mucocytes), ciliated on the ventral surface, and possessing pores through which the mucus and other secretory products are released into the mantle cavity, and a central area where the formation of the "purple" precursors takes place and where secretory products accumulate prior to their release from the snail (Bolognani Fantin & Ottaviani 1981; Roller et al. 1995). The purple precursors (tyrindoxyl sulphate) and the enzyme (aryl sulfatase = purpurase) that induce the transformation of the purple precursors into pigments are only localized in the median zone of the hypobranchial gland (Erspamer 1946) and are kept separate, so that no reaction occurs. Mollusk purple as such does not occur in the live animal, but it is formed during a sequence of chemical reactions from the secretions produced by the animal. When the animal contracts vigorously the cells are massively liberated, burst open by mechanical or osmotic pressure, and their contents dispersed into the mucus (Lacaze-Duthiers 1859). These observations were later refined by the histological work of Bernard (1890), who found a well-developed innervation in the gland, suggesting a role in perception (Verhecken 1989).

The pharmacological action by extracts of the hypobranchial gland was discovered by Dubois (1909), and he described for the first time their toxic and paralyzing action in both warm- and cold-blooded species. The secretion of the hypobranchial gland from a large number of muricids contains, besides mucus, the precursors of the purple dye, proteins (aryl sulfatase, purpurase), and toxins and narcotizing agents, like serotonin (5-hydroxytryptamine), murexine (urocanylcholine,), choline ester and biogenic amines (Erspamer 1952; Erspamer & Benati 1953; Whittaker 1960; Malaszkiewicz 1967; Huang & Mir 1971; Roseghini et al. 1996; Shiomi et al. 1998).

The secretion from the hypobranchial gland of *P. pansa* can be obtained by "milking" without harming the animals. It is a milky-white liquid, which turns on exposure to air and light, at first yellow, then greenish, bluish and finally purple ("Tyrian purple"). During personal field observations (unpublished) we observed that *P. pansa* uses the secretion to immobilize prey (*Nerita* sp., *Littorina* sp.) in the intertidal zone, and does not resort to drilling through the shells of other snails. Additionally interesting to notice is the fact that during the predation no purple color is formed on the prey, despite the presence of oxygen and intense light radiation.

The chromogens containing the hypobrancial secretions seem to be purely incidental, and their functional role, if any, is presently unknown (Clench 1947). The volume of secretion obtainable from *P. pansa* depends not only on the size and sex of the animals, the time interval between the each "milking", but also on the season. Its production and use may be in proportion to the type of food the snails feed on. From small animals of less than 2 cm shell length can be obtained about 0.5 ml of secretion, from 5–6 cm large animals up to 4 ml (Rios-Jara et al. 1994). It has to be kept in mind however, that in this volume only a minute proportion consists in the dye precursors.

Chemistry of Tyrian Purple Formation

Several preliminary studies on the chemical composition of the pigments of *P. pansa* are available. The comparison between the chemical composition of the hypobranchial secretion of other muricids will lead to a better understanding of the metabolic pathways that lead to the final production of Tyrian purple.

Since the re-discovery by Cole (1685) of "Tyrian Purple" from *Nucella (Purpura) lapillus* a number of researchers have worked on the determination of the chemical composition of the secretion of the hypobranchial gland. Most remarkable, considering the limited knowledge of organic chemistry at the beginning of the 19th century, is the analytical work by Bartolomeo Bizio about the origin and properties of Tyrian purple from the Mediterranean muricids *Murex trunculus* and *M. brandaris* (Ghiretti 1994). When collecting the glandular secretion of the snails he made the important observations, first, that as soon as the colorless fluid is exposed to light and air it becomes immediately yellow and greenish, and soon afterwards it turns into deep emerald green, blue, deep blue and finally reaches the purple color. Next, that during the production of the purple dye, a highly odorous compound is released. In comparing the color differences between the purple from *Murex trunculus* and *M. brandaris* he discovered that they are species specific. Bizio also determined that Tyrian purple is a substance with chemical properties similar to indigo. Schunck (1879) isolated and crystallized the pigment from the "ink" of *Nucella (Purpura) lapillus*, and determined the chemical properties. He called the pigment punicin. To obtain 7 mg of punicin he extracted the hypobranchial gland of 400 animals, after which he reports "my patience was exhausted". Friedländer (1909) isolated 1.4 g of the pure pigment from 12,000 hypobranchial glands from *Murex brandaris*, and showed that it was 6,6′-dibromoindigo.

Recently, using advanced analytical methods, Fouquet (1970), Baker and Duke (1973), Michel et al. (1992) and Koren (1994, 1995) among others, have confirmed that the major pigment from all studied muricids is 6,6′-dibromoindigo.

Different species of muricids produce different color qualities of the dye, depending mainly on the number and concentration of the different chromogens. Fouquet (1970) found four different chromogens in the hypobranchial gland of *M. trunculus*: I) indoxyl sulfate, II) 2-methylthio-indoxyl sulfate, III) 6-bromoindoxyl sulfate, and IV) 6-bromo-2-methylsulfonyl-indoxyl sulfate, and he described the chemical pathway leading to Tyrian purple: The first step in the purple production is hydrolysis of the sulfate group with purpurase (aryl sulfatase). Indoxyl sulfate (I) and 6-bromoindoxyl sulfate (III) are then oxidized by oxygen to give indigo and 6,6′-dibromoindigo, respectively. With 2-methylthio-indoxyl sulfate (II) and 6-bromo-2-methylsulfonyl-indoxyl sulfate (IV) oxidation is followed by dimerisation and the dimer is photolysed in light to give indigo and 6,6′-dibromoindigo respectively together with methanethiol or dimethyl disulfide. These reactions as described by Foquet (1970) are shown in Figure 1.

At the time of Fouquet's studies the possibility of cross-coupling of the indoxyls which accounts for the large percentage of 6-bromoindigo in the pigment of *M. trunculus*was was unknown.

The composition of the chromogens of other muricids is less complicated. *Thais clavigera*, *T. bronnii*, *Dicathais orbita*, *M. brandaris* and *N. lapillus* contain 6-bromo-2-methylthio-indoxyl sulfate (IV); *M. erinaceus* contains a single different chromogen and *Purpura haemastoma* and *Rapana bezoar* contain two other different chromogens, but the chemical structures are not known (Baker 1974; Hiyoshi & Fujise 1992). The reaction pathways of

6-bromo-2-methylthio-indoxyl sulfate (tyrindoxyl) to give indigoid pigments are shown in Figure 2.

The composition of the different chromogens is not only dependent on the species of muricids, but also environmental, and physiological condition of the animals. The light intensity and oxygen availability also play a role during pigment formation. According to historical reports the best seasons to exploit the purple snails in the Mediterranean are autumn and winter. During summer the animals are hidden and in spring they lay eggs, at which time the hypobranchial secretion presumably is losing its coloring power and is not suited for color production (Born 1936; Cardon & du Chatenet 1990). Fouquet (1970) cites Schaefer (1941 "Neuere Ansichten über den antiken Purpur" Chemiker Zeitung, 273) and O. von Fürth (1903 "Vergleichende chemische Physiologie der niederen Tiere". Verlag G. Fischer, Jena, page 377) who stated that there are seasonal changes in the chromogens of snails from the "trunculus" and "brandaris" types, due to age, gender, and food.

Chemistry of Tyrian Purple from P. pansa

For more than a hundred years the chemical composition of "Tyrian Purple" from *P. pansa* has attracted the interest of chemists. Edward Schunck (1880a) obtained a sample of cotton yarn dyed on the west coast of Nicaragua with the extract of *Purpura patula* (now *P. pansa*). From 24 g of dyed material he obtained 99 mg of pure crystalline pigment with all the properties of punicin, which he had earlier obtained from *Purpura capillus (Nucella lapillus)* (Schunck 1879). Thirty years later it was shown by Friedländer (1909), that Schunck's punicin was 6,6'-dibromindigo. In 1922 Friedländer obtained from Mexico a sample of yarn dyed with the excretion of *P. aperta* (the zoological description has to be *P. pansa*, since *P. aperta* does not occur on the Pacific coast of the Americas). The analysis of the dye showed no differences in solubility, color, and absorption spectrum between the dye from *M. brandaris*, which he had analyzed before and for this reason he concluded with some certainty the dye of *P. pansa* consists mainly of 6,6'-dibromoindigo (Friedländer 1922).

Saltzman (1992) showed that the reflectance spectrum of cloth dyed with the "ink" of *P. pansa* had a maximum absorption at 520 nm. Very similar results obtained Withnall et al. (1993) and Clark et al. (1993) for synthetic 6,6'-dibromoindigo. Mass spectrometry was used by McGovern et al. (1991) to confirm that the major colorant of the cotton sample from Saltzman, was 6,6'-dibromoindigo with traces of 6-bromoindigo. It was found that direct introduction of the cotton sample into the mass spectrometer led in addition to the detection of large amounts of 6-bromoindigo also to some indigo. This artifact arose from interaction of the cotton fiber and 6,6'-dibromoindigo at the high injection temperatures, leading to debromination and the formation of indigo. The problem can be avoided by extraction of the dye from the fiber with hot quinoline, or with dimethyl sulfoxide (McGovern et al. 1991). Using this extraction methodology, it was observed that apart from the major 6,6'-dibromoindigo component there were also smaller amounts of monobromoindigo and indigo which have been previously obscured by other low molecular weight materials.

The analytical technique of choice for the characterization of mixtures of indigoid dyes is the application of the High Performance Liquid Chromatography (HPLC), pioneered by Wouters and Verhecken (1991). This technique allows the characterization of pigments by retention time and absorption spectrum. Koren (1994) applied this technique to a sample of Dr. Saltzman's material containing the Mexican purple from Oaxaca. He could only detect 6,6'-dibromoindigo. A recent chemical study of the pigments of *P. pansa* confirmed the finding that the main component of the dye is 6,6'-dibromoindigo (90%); with 9% monobro

Results obtained by different authors (Wouters 1992; Cooksey et al. 1992; Koren 1995, Withnall et al. unpublished) using HPLC to determine the chemical composition of the indigoid constituents of the purple dye from various muricids are shown in Table 1.

Since the values in Table 1 were obtained using a variety of HPLC protocols, close comparison is not justified, but some trends can be noted: *P. pansa* belongs to the *M. brandaris* group containing no indigo in the pigment, some 6,6′-dibromoindirubin, and showing a higher proportion of 6-bromoindigo than the average.

Textile Dyeing with "Tyrian Purple"

In using the "ink" for dyeing materials two significant differences have to be mentioned between the Mediterranean muricids and *P. pansa*: (a) the Mediterranean snails have to be killed to obtain the chromogens, whereas *P. pansa* can be "milked" to obtain the dye without harming the animals; and (b) the "milk" from the *P. pansa* can be applied directly on textiles where the final pigments are formed in the presence of light and oxygen.

In textile dyeing, there are two methods for dyeing with mollusk purple. The most simple is to have the chromogens react in the presence of light and air to obtain directly the final pigment on the fiber, as is the case with *P. pansa*. Since the molecular structure of mollusk purple is indigoid, there exists also the possibility of starting the dyeing process with the final oxidized purple colorant by reducing it in an aqueous alkaline bath, and applying the highly water soluble, and almost colorless leuco-form as a vat dye, just like indigo. Exposure to air oxidizes the leuco-form back to the indigoid pigment (Verhecken 1993; Clark et al. 1993; Schweppe 1998). In sunlight, the brominated leuco-indigoids can be photodebrominated, leading to 6-bromoindigo or indigo after aerial oxidation and changing the purple color to blue. This chemistry of reduction and photodebromination of 6,6′-dibromoindigo, was first described by Driessen (1944), as shown in Figure 3.

DISCUSSION

Different species of muricids produce different color qualities of the ink (Born 1936a), depending on the number and concentration of different chromogens. According to Verhecken (1993) depending on the precursors and chemical reactions for the formation of the pigments, two groups of dyes from marine muricids can be distinguished: the "trunculus type" where light is not necessary, and the "brandaris type" requiring both light and oxygen. Since for the formation of the dye of *P. pansa* light and oxygen is necessary, the dye of *P. pansa* according to this definition belongs to the "brandaris type". Another fact supports this characterization: the pigments of the "brandaris type" contain mainly 6,6′-dibromoindigo. The pigments of *P. pansa* contain 90% 6,6′-dibromindigo, confirming that the snails are forming part of the "brandaris type". This is in contrast to the purple pigment derived from *M. trunculus*, which is exceptional in containing non-

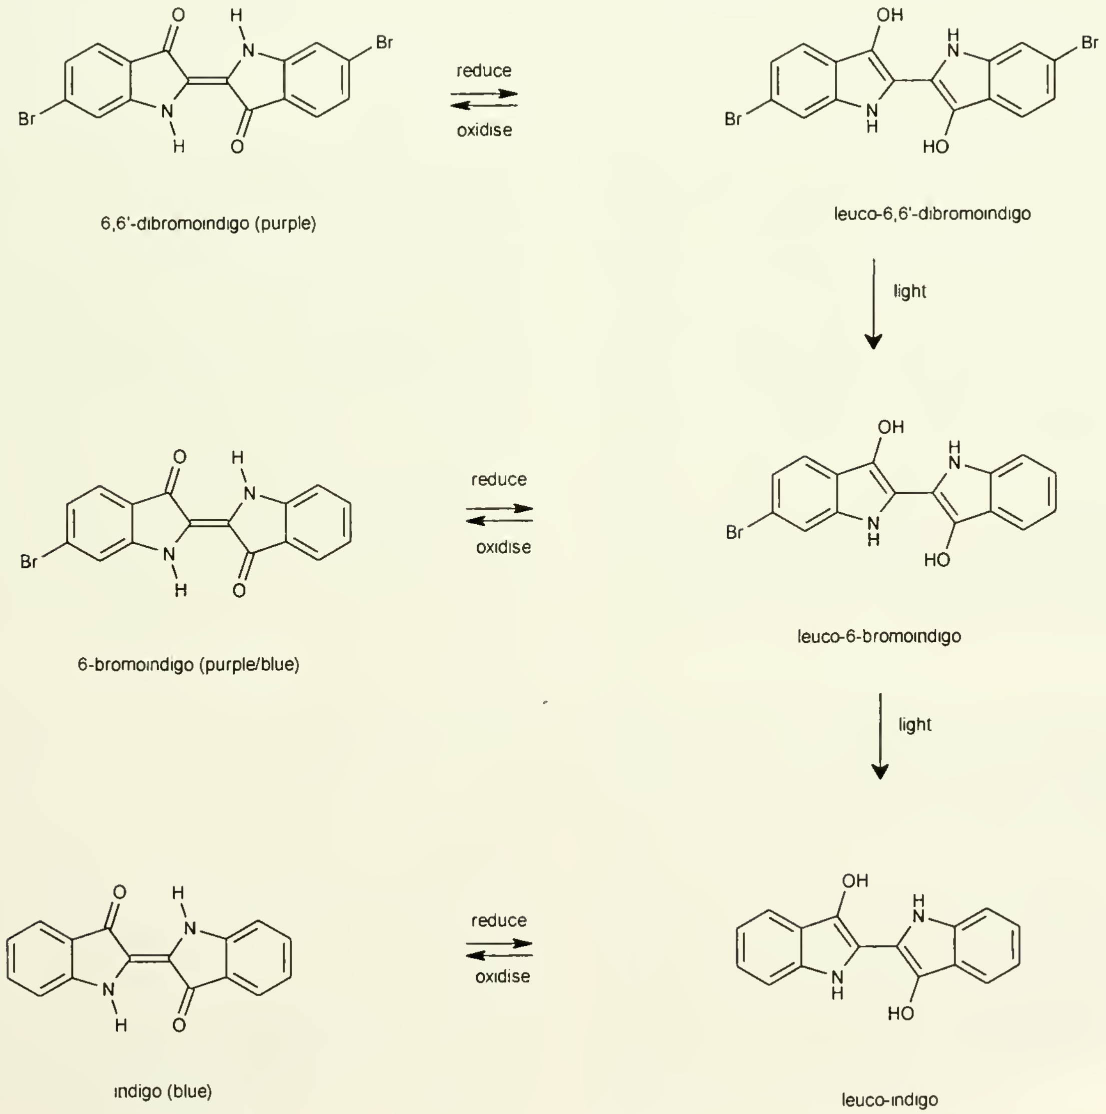

Figure 3. The reduction and photodebromination of 6,6′-dibromoindigo.

brominated precursors, leading to widely varying mixtures of indigoid pigments, including indigo and indirubin (Malaszkiewicz 1967).

The biosynthesis of the chromogens in the hypobranchial gland of muricids originates from tryptophan, an essential amino acid for animals, which is enzymatically split into indole and pyruvate. After a sequence of chemical reactions different intermediates are formed from indole, which lead finally to the colorless precursor of indigoid pigments tyrindoxyl sulfate, and subsequently through an enzymatic reaction with aryl sulfatase to give the yellowish intermediate tyrindoxyl (Fouquet 1970). In the presence of oxygen the red tyrindoleninone is formed, which reacts together with tyrindoxyl to give the greenish tyriverdin. In the presence of light tyriverdin is photolysed to give dimethyl disulfide and the purple, insoluble pigment 6,6′-dibromoindigo (Verhecken 1989). Additionally, from photolysis of tyrindoxyl or tyriverdin in the presence of oxygen, 6-bromoisatin can be formed which reacts with tyrindoxyl to 6,6′-dibromoindirubin (Withnall et al., unpublished). Oxygen and the light intensity during the chemical reactions of the intermediate substances determine the final composition of the pigments. The higher content of 6-bromoindigo than average in the pigments of *P. pansa* may result from the development of the dye under conditions of high light intensity. Under these conditions, any leuco-6,6′-dibromoindigo would be photodebrominated to give leuco-6-bromindigo, which on aerial oxidation would give 6-bromindigo. Under high intensity light conditions, the photoelimination of dimethyl disulfide from tyriverdin to yield 6,6′-dibromindigo will proceed rapidly, leading to a low concentration of tyriverdin. Consequently, oxidative cleavage of tyriverdin, a bimolecular reaction, to give 6-bromoisatin is a minor reaction pathway, leading to a low concentration of 6,6′-dibromoindirubin in the purple pigments of *P. pansa* (Withnall et al., unpublished).

The importance of the chromogens in the metabolism of the purple snails is unclear. The presence of the enzyme aryl sulfatase, which presumably occurs in all muricids (Erspamer 1946), supports the hypothesis that the chromogens could serve as a storage for the highly unstable indoxyls, which are formed enzymatically by the aryl sulfatase from sulfate esters (Fouquet 1970). Additional attention needs the question about the biological function of the indoxyls and their substituted bromo and methylthio analogs. It could be possible that these bromo and thio substituted indoxyls, like the iodine derivatives of tyrosine could act as hormones in the metabolism of the snails. Since the chromogens, besides mucus and bioactive substances, have their origin in a specialized area of the hypobranchial gland, it is feasible that the gland could have additionally inner secretory activities (Fouquet 1970).

We observed during field work that *P. pansa*, above sea level uses the secretion to immobilize their prey, without the formation of purple pigments (unpublished personal observations). This supports the finding that under normal circumstances the enzyme purpurase is kept apart from the chromogens, and therefore no pigments are formed, despite the presence of oxygen and light (Verhecken 1989). Additionally, in preliminary, yet unpublished personal studies, we could show, that the secretion from *P. pansa* is toxic to nauplii of Artemia, and has gram negative and gram positive antibacterial properties.

From snails of less than 2 cm shell length can be obtained about 0.5 ml of secretion and from large animals 5-6 cm up to 4 ml (Rios Jara et al. 1994). About one liter of secretion is required to dye about 200 g of cotton (Acevedo Garcia et al. 1993; Michel Morfin 2000). Since the average size of *P. pansa* is about 3 cm and a collection of more than 1 ml secretion per animal seems difficult, the enormous number of at least 1,000 snails has to be "milked" to obtain 1 liter of secretion to dye only 200 g of material. Since too frequent "milking" does harm to the animals it was the right decision of the Mexican government to permit only Indian communities the traditional exploitation of *P. pansa* for its pigments and to declare it a protected species.

In contrast with the Mediterranean region, where the use of purple from marine snails has long been forgotten and the craft of dyeing today cannot exactly be reconstructed, in remote Pacific regions of Mexico (in the States of Oaxaca and Michoacan) and with the Indian community of the Borucas in Costa Rica (Turok 1999) its use is continuing now and represents the survival of a knowledge of considerable antiquity. However, as Thompson (1994) observed that this old tradition will be lost in the future. As Thompson (1994) notes "In the early 20th century in Mexico shellfish purple was in much more widespread use than it is now. The beliefs, languages, and crafts of the Mexican Indians are fast disappearing. The progressive 'westernization' of rural Mexico has led people in many villages to abandon their traditional textiles and customs, in favor of factory-made cloth and western-style clothes which are readily available everywhere. Cultural and social decay is continuing to the point that the demand for traditional textiles has almost vanished. Weavers in a few villages formerly noted for their excellent textiles have turned to making more 'commercial' articles, for sale to people, such as tourists, outside their culture—a classic manifestation of the 'airport art' phenomenon."

ABSTRACT The mantle cytology and ultrastructure of the abalone *Haliotis tuberculata* were investigated and different structures are detailed in relation to shell structure. The mantle edge of the abalone (3–4 mm near the shell edge) was chosen because it corresponds to the most active area in shell formation. The mantle is composed of a thin lamella of connective tissue wrapped in monolayered epithelia, the inner epithelium (facing the body cavity) and the outer epithelium (facing the shell). At the edge, the mantle ends with the division of the edge in two folds. The main features of glandular and nonglandular cells were characterized. The inner epithelium, responsible for ion exchanges with the external environment, is composed of three glandular cell types and ciliated or unciliated nonglandular cells. The periostracal groove, where the periostracum originates, shows high metabolic activity, with many secretions inside both from glandular and nonglandular cells. Numerous cilia have been observed in relation to these secretions. The outer epithelium could be divided into two distinct areas: a first short area in the outer part surface of the outer fold at the mantle edge (approximately 250–300 μm long), called the tubular area, and a larger area which extends on the whole shell surface beyond the tubular zone. These two areas are both folded, but in the tubular area folds form tubules. Moreover, some alimentary pigments have been observed to be associated with the tubular zone. Both structural characteristics of these two distinct areas as well as features of the cells indicate that they are responsible for the formation of the two distinct layers of the shell: the tubular zone (the calcite prismatic layer) and the outer epithelium (the aragonite nacreous layer), respectively.

KEY WORDS: mantle, ultrastructural study, shell formation, marine gastropod, *Haliotis*

INTRODUCTION

The shell of the mollusc abalone, *Haliotis tuberculata*, is made up of three distinct layers (Nakahara et al. 1982; Wilbur & Saleuddin 1983): the outer layer or periostracum, which is a tanned proteinaceous layer, a middle prismatic layer (calcite), and an inner nacreous layer (aragonite). The calcified layers are a tight association of calcium carbonate minerals with organic matrix. Despite numerous studies of the mineralization processes in molluscs (reviewed by Wilbur 1964; Wilbur 1972), the precise mode of formation of shell is far from clear. The organic matrix plays an important role in mineralization, providing sites for crystal nucleation and a template for crystal growth and orientation. Each layer of the shell corresponds to a different composition of this organic matrix. The precursors of this organic matrix are first secreted by the mantle into a small cavity between the mantle and the shell (the extrapallial space). Some studies on mollusc mantle structure show that a regionalization of the mantle exists in relation with the secretion of the three shell layers (Beedham 1958; Kawaguti & Ikemoto 1962b; Wilbur & Saleuddin 1983).

Whereas the ultrastructure of the molluscan mantle edge, especially the bivalves, has been studied in great detail, the epithelium of the inner (facing the mantle cavity) and the outer (facing the shell) surface of the mantle has received considerably less attention. In molluscs, the structure of the mantle, and more particularly the mantle edge, shows a high degree of variation. In bivalves, the mantle edge is generally composed of three main folds (Jabbour-Zahab et al. 1992; Morrison 1993): an inner muscular lobe, a middle lobe believed to be sensory, and an outer lobe (Richardson et al. 1981). It is generally held that the periostracum in bivalves is secreted by the cells lining the surface of the outer lobe. In some gastropods, the mantle is also arranged into lobes, however, in numerous species the mantle lobes can be reduced in size and number (e.g., *Biomphalaria glabrata*, Bielefeld et al. 1993a; Bielefeld et al. 1993b), or are virtually lacking (e.g., *Littorina littorea*, Bevelander & Nakahara, 1970). An additional feature of gastropods is the presence of one or more groups of marginal glands embedded in the connective tissue (Bevelander & Nakahara 1970; Saleuddin 1975).

Because no study of abalone mantle has been undertaken to our knowledge, we investigated the histology and ultrastructure of the whole mantle, and more particularly near the shell edge, which is considered to be the more active part of the mantle in the biomineralization processes. Then we attempted to relate features of the cells to formation of the different shell layers: the periostracum, the calcitic prismatic, and the aragonitic nacreous layers.

MATERIALS AND METHODS

Source and Maintenance of Animals

Adult (6–7 cm in length) and juvenile (<1 cm in length) abalones, *H. tuberculata*, were purchased from a French farm (ECHINOXE, West coast of Cotentin, Manche, France). Animals were maintained at the laboratory in tanks, in artificial, aerated seawater at 18–20°C.

Histology

Pieces of the mantle (ca. 5 mm^2) were cut near the edge of the shell, after the central foot of the abalone was removed. For this study, the most active parts of the mantle were used: the two frontal lobes and the right mantle near the shell edge of the abalone. For fixation of the mantle, tissue was placed in Bouin's mixture overnight (Martoja & Martoja 1967). Sections of 5 μm in thickness were made according to the usual paraffin method. St ing with hemalum picro-indigo carmine was found to be excellent in differentiating epithelial cells, muscle, and collagen fibers.

Identification of Cell Types: Transmission Electron Microscopy (TEM)

For TEM studies, different parts of the mantle near the edge were used. Preparations were fixed in a cocktail containing 3% glutaraldehyde, sodium cacodylate buffer at pH 7.0, and 0.35 M saccharose, overnight at +4°C. Then preparations were postfixed in a solution of 2% OsO_4 for 1 h at room temperature and rinsed twice in double-distilled water (2 × 10 min). Preparations were then placed in uranyl acetate aqueous solution (1%) during 1 h at room temperature and in the dark. Preparations were then rinsed twice in double-distilled water (2 × 10 min). Preparations were dehydrated through a graded ethanol series and then embedded in Araldite. Thin sections were cut on a Reichert ultramicrotome, stained with uranyl acetate (5% in ethanol 50°C, w/v) and lead citrate, and examined in an electron microscope (Philips EM 201 under 80 kV, Centre de Microscopie Electronique de Jussieu–Pierre et Marie Curie University, Paris, France).

RESULTS

Gross Morphology of the Mantle

The mantle of abalone is a thin lamella that originates at the base of the foot muscle. The mantle covers the visceral mass and extends to the shell edge so as to cover the shell surface. As we investigated the structure of abalone mantle in relation with the biomineralization processes, we focused on the mantle near the shell edge. Indeed, scanning electron microscope (SEM) study of the shell surface has demonstrated that the more active area of shell growth (in length and in width) corresponds to a band of 2–4 mm in length near the shell edge (unpubl. data). For this study, mainly adult abalones were used, except for Figure 9, which shows a juvenile abalone.

Figure 1a corresponds to a transverse section through the mantle edge of *H. tuberculata.* At the shell edge, the mantle is composed of a thin lamella of connective tissue covered by a monolayer of epithelial cells. In the connective tissue, hemolymph lacunae are found; hemocytes are known to participate in the biomineralization processes, and more precisely in shell regeneration. A particular feature with the muscle fiber repartition is the formation of a dense network of fibers parallel to the outer epithelium (OE) mantle surface, whereas muscle fibers, mixed with collagen fibers, remain with no specific orientation near the inner epithelium (IE). Such muscle repartition is probably responsible for the tight contact with the inner shell and for the mantle's retractive ability in response to mechanical stimuli. Because the extrapallial space (between the shell and the mantle) is very thin and contact with the external medium may be limited, this particular organization of muscle fibers may contribute to the adherence of the mantle onto the shell. The epithelium is separated from the connective tissue by a basal membrane. The epithelium in contact with the shell is called the OE, whereas the IE, in contact with seawater, faces the visceral mass. The mantle edge ends with the periostracal groove (PG) separating the mantle into two folds: the inner fold (facing the visceral mass) and the outer fold (facing the shell). For a better understanding, we have divided the mantle epithelium into different functional areas (Fig. 1b).

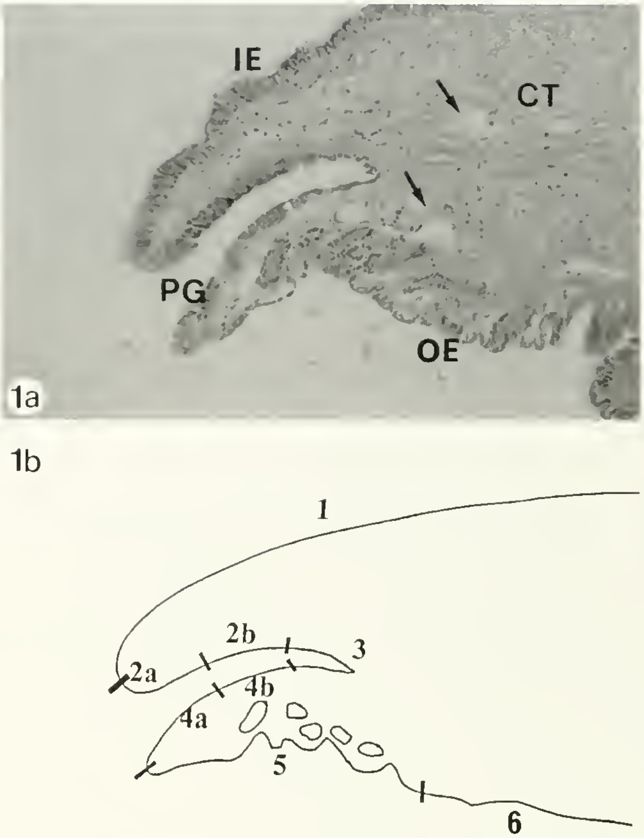

Figure 1. (a) Light micrograph of the mantle edge structure in *Haliotis tuberculata*. CT, connective tissue; IE, inner mantle epithelium (facing the body); OE, outer mantle epithelium (facing the shell); PG, periostracal groove. The hemolymph lacunae are designated by the black arrows (×160). (b) Subdivision of the mantle edge into different functional areas: 1, inner epithelium; 2, epithelium of the outer face of the inner fold; 3, bottom of the periostracal groove; 4, epithelium of the inner face of the outer fold; 5, tubular area of the outer epithelium; and 6, outer epithelium, which extends on the whole shell surface beyond area 5.

The Inner Mantle Epithelium: Area 1

The inner mantle epithelium generally consists of palisadic cells. The apical border of the cells exhibits a prominent border of microvilli, 2–5 μm high (Fig. 2a). Cells are interconnected by intercellular junctions comprising an apical desmosome and septate junctions. A distinguishing feature of the inner epithelial cells is the highly convoluted interdigitations of the plasma membranes below the apical desmosome (Fig. 2b). Under the basal lamina, a thin sheet of collagen fibers is observed (orientated parallel to the basal lamina). Two major cell types can be identified, depending on the secretions of their cytoplasm: epithelial glandular cells (where the cell cytoplasm is filled with secretory granules) and epithelial nonglandular cells.

Epithelial nonglandular cells are generally similar in size. Cilia are occasionally observed, interspersed between the microvilli (Fig. 2a), but the general characteristics of these cells remain similar along the mantle IE. These epithelial cells contain a basal nucleus in which most of the heterochromatin is concentrated in the periphery. A Golgi complex is often observed in the vicinity of the nucleus. Mitochondria are mainly located near the nucleus as well as in the apical part of the cell cytoplasm, even though some have been observed in the whole cytoplasm. Numerous vacuoles are located in the apical part of the cells. Some vacuoles contain some dark-staining contents, which are sometimes heterogeneous

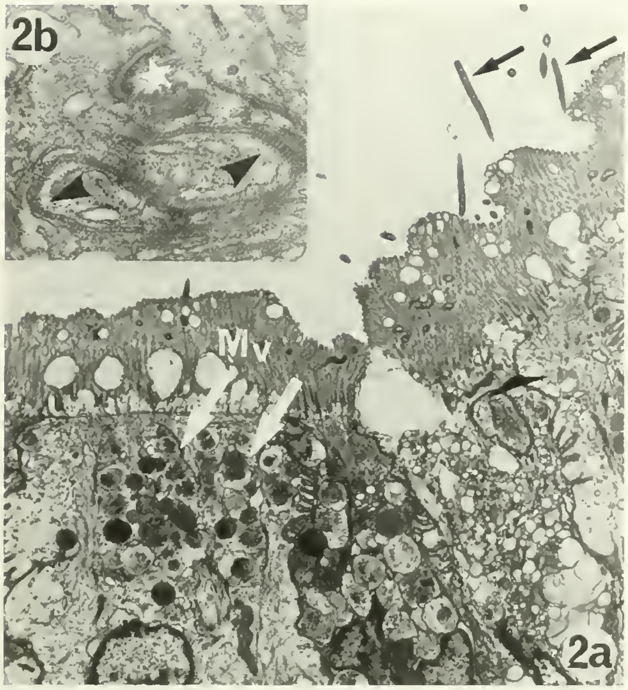

Figure 2. Area 1. (a) Inner mantle epithelium (TEM) with nonglandular cells. Cilia (black arrows) are interspersed with microvilli (Mv). Some vesicles with pigments are observed in the apex of the cells (white arrows) (×4,500) (b) Detail (TEM) of highly convoluted plasma membranes below the microvillar border. Cells are separated from each other by intercellular junctions comprising a desmosome (white star) and septate junctions (black arrowheads) (×20,000).

and could be related to some kind of pigments. Tonofilament bunches are observed mainly orientated in the axis of the cell (Fig. 2b).

A general feature of the glandular cells (or secretory cells) is their goblet shape. The narrow openings of glandular cells can sometimes be seen. The main features of these cells are the occurrence of numerous secretory granules in their cytoplasm and a basal small nucleus surrounded by a more or less developed rough endoplasmic reticulum (Figs. 3, 4, and 5). Three glandular cell types could be distinguished depending on their secretions. Type A glandular cells (Fig. 3) contain clear ovoid granules, closely packed and homogenously stained, which tend to coalesce. Type B glandular cells (Fig. 4) contain distinct, darkly staining granules, which have a denser core in some cells. The membrane of type B granules is generally still distinct when they are discharged. Type C glandular cells (Fig. 5) contain some distinct, membrane-bound granules, with rosette-like mucous granules. Type C cells have peculiar secretory granules of heterogeneous stages: in a clear and finely granular matrix an array of complex chains of electron-dense material is found. The basal nucleus is surrounded by a well-developed rough endoplasmic reticulum of enlarged cisternae filled with finely granular material. Between the rough endoplasmic reticulum and the secretory granules, Golgi stacks occur. The immature granules from the trans Golgi only contain finely granular material, then the dense complex progressively condenses and develops.

Figure 6 resumes the main features of the IE: a monolayered epithelium which constitutes ciliated (Ci), or nonciliated, nonglandular, and glandular cells (A, B, C types) with microvillous border (Mv).

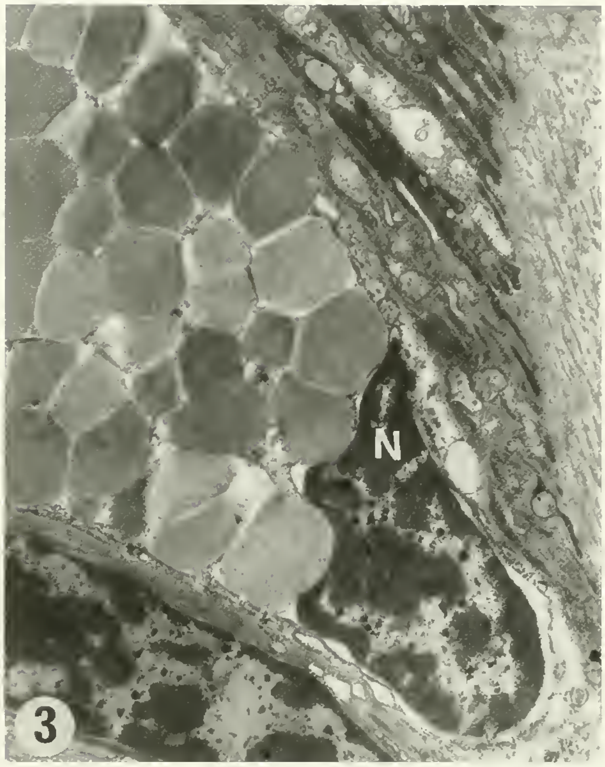

Figure 3. Area 1. Detail of type A glandular cells in the inner mantle epithelium (TEM): The cytoplasm is filled with ovoid granules, closely packed, homogeneously stained. N, nucleus (×14,000).

The Periostracal Groove: Areas 2a, 2b, 3, 4a, 4b

We divided the periostracal groove, which runs parallel to the mantle edge, into three different parts of spatial and equal importance, depending on the structure of the cells. The first part (a) corresponds to the opening of the periostracal groove directly in contact with external seawater: areas (2a) and (4a) are, respectively, the epithelium of the inner and outer folds of the periostracal groove. Principal features of the cells are very similar to those of cells of the IE: in the 4a area, characteristics of the IE are less marked (plasma membrane is not as convoluted as in the 2a area, and pigment granules are less representated than in the 2a area). The second part (b) corresponds to the middle of the periostracal groove: areas (2b) and (4b) are, respectively, the epithelium of the inner and outer folds of the periostracal groove. A principal feature of this area is the presence of a group of ciliated cells of the epithelium 4b (outer fold, Fig. 7) and the presence of numerous secretions from nonglandular cells of the epithelium 2b (inner fold, Fig. 7). All cilia are orientated to the opening of the periostracal groove and some secretions are often found associated with the cilia. Principal characteristics of the cells are quite similar to that of cells previously described.

In the periostracal groove, the microvillous border is not equivalent in the inner and outer folds. In the epithelium of the outer fold (4a, 4b), microvilli are dense and arranged in a brush border, whereas the cells of the inner fold (2a, 2b) are lined by microvilli irregularly arranged. A lot of material seems to be discharged by these cells, as clear vesicles with a fine granular content. We can also observe some secretions from nonglandular cells in the microvilli in area 2b (in the inner fold).

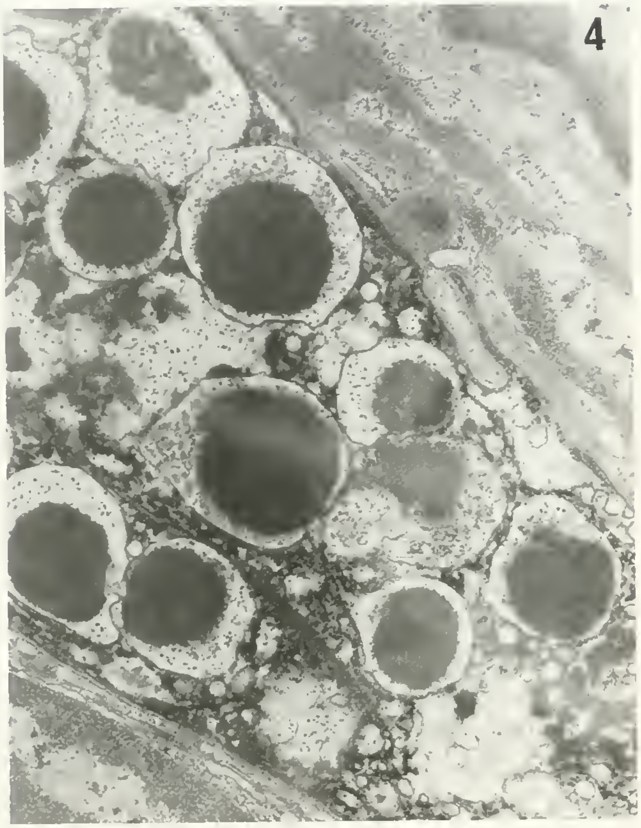

Figure 4. Area 1. Detail of type B glandular cells in the inner mantle epithelium (TEM): The cytoplasm is filled with distinct, darkly staining granules, which have a denser core in some cells (×30,000).

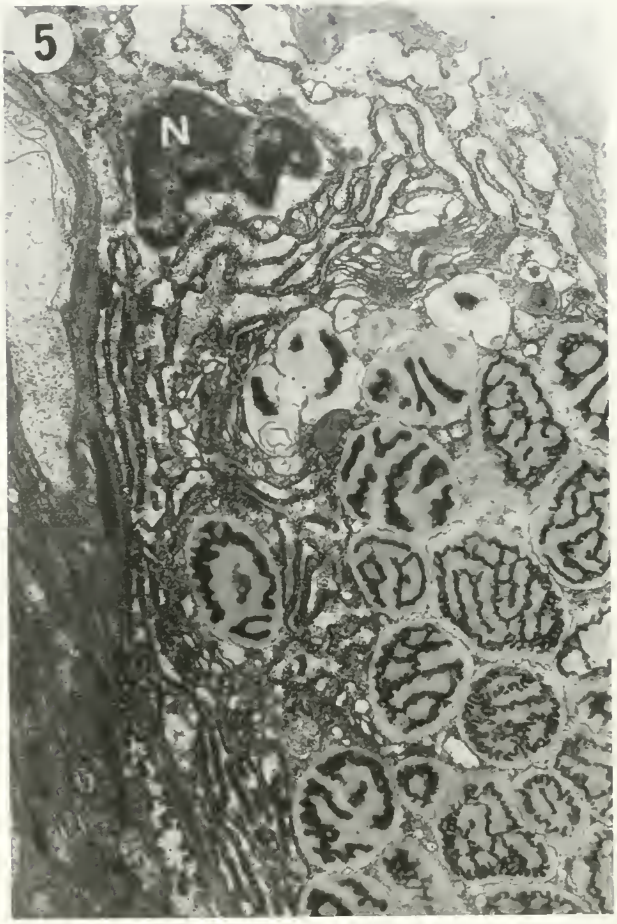

Figure 5. Area 1. Detail of type C glandular cells in the inner mantle epithelium (TEM): The cytoplasm is filled with distinct, membrane-bound granules, which have a heterogeneous content. N, nucleus (×14,000).

In areas (a) and (b) of the inner and outer fold, we can notice the presence of numerous B-type glandular cells. A-type glandular cells have been observed in some sections in the epithelium of both outer and inner fold. However, C-type glandular cells have only been found in the epithelium of the inner fold.

At the bottom of the periostracal groove (area 3), the cells become gradually cuboidal. Essentially, nonglandular cells are observed. Cilia and cell secretions could not be observed (Fig. 8). The inner and outer folds appear morphologically equivalent.

Fine Structure of the Outer Mantle Epithelium: Areas 5 and 6

In *H. tuberculata*, two distinct areas of the outer mantle epithelium can be distinguished: a short area near the periostracal groove (area 5) and the other part of the outer mantle epithelium (area 6). The structure of the cells and the structure of the folds in the OE determine this separation. Area 5 corresponds to a very folded epithelium, which forms some tubules when this area is quite developed. In scanning electron micrographs of the outer mantle epithelium, this area corresponds to an alveolous structure in external view: this area has been called the tubular zone (TA, Fig. 9). In area 6, the OE displays folds that are quite parallel to the mantle margin (Fig. 9).

In area 5 the tubular zone is more or less developed, depending on the collected specimens in a same size class. To observe the well-developed tubular zone, some juveniles have been observed by TEM (Fig. 10). The principal features of these cells are their cuboidal shape, a high nucleoplasmic ratio, and numerous round-shaped mitochondria. In Figure 10, tubules are cut transversally, and we can observe in the lumen of each tubule some small microvilli and some secretions. In this area, pigments are found travelling from hemolymph lacunae to tubules: they correspond to an obvious red and/or green line along the border of the OE in live specimens. The pigments are carried by "migrating cells" (likely hemocytes), which have a central nucleus and a cytoplasm filled with four or five vacuole sites containing a large central core of heterogeneous granules (Fig. 11).

Figure 12 summarizes the main features of the tubular zone: a monolayered epithelium (which is very folded) composed of cuboidal cells and tubules (T) containing microvilli (Mv), alimentary pigments (Pi) in vacuoles, and some secretions in the lumen (Lu).

In area 6, a different structure than the OE has been observed: cells are low columnar (<10 μm) (Fig. 13) to very high columnar (>15 μm) (Fig. 14), depending on studied specimens in the same size class. Meanwhile, the OE is always folded. In some specimens with low columnar cells (Fig. 13), numerous "empty" cells have been observed and the other cells have a cytoplasm where few organelles are present, corresponding to low cell activity. In other specimens, the OE is very high and narrow columnar (Fig. 14): numerous mitochondria, Golgi apparatus, and inclusions are found in the cytoplasm of these cells (Fig. 15). In such cells, all organelles, and in particular, all Golgi complexes, are found orien-

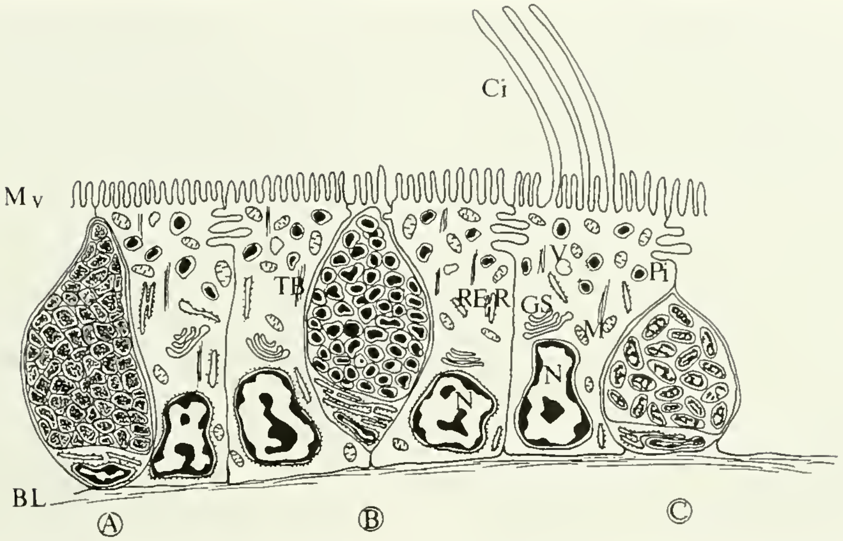

Figure 6. Area 1. Schematic drawing of the main features of the cells of the inner epithelium. In this area, three types of glandular cells are present: types A, B, and C (encircled A, B, C), with nonglandular cells, with or without cilia (Ci). BL, basal lamina; Ci, cilia; GS, Golgi stacks; M, mitochondria; Mv, microvilli; N, nucleus; RER, rough endoplasmic reticulum; Pi, pigments; TB, tonofilament bunches; V, vesicle (not to scale).

tated in the longitudinal axis of the cells (Fig. 15). The microvillous border is well developed in very high columnar cells and numerous protruding cell processes are found associated with this microvillous border (Fig. 14). In low columnar cells the microvillous border is quite nonexistent excepted in fold of the IE; however, in the cells of the OE, some distensions of the membranes are generally observed and they are often associated with mitochondria (Fig. 15).

The schematic Figure 16 resumes the main characteristics of the OE far from the periostracal groove: very high columnar cells containing numerous mitochondria (Mi), Golgi apparatus (G), and microvillar border (Mv) with protruding processes, orientated in the longitudinal axis of cells.

DISCUSSION

Many publications describe shell formation in molluscs and some of them reported the structure of the mantle and its role in shell formation. But the majority of these studies dealt with bivalves (Kawaguti & Ikemoto 1962a; Kawaguti & Ikemoto 1962b; Neff 1972; Bubel 1973a, 1973b, 1973d; Garcia-Gasca et al. 1994). Most of the work on gastropods has been done on the terrestrial snail *Helix* and on freshwater gastropods (Zylstra et al. 1978, Bielefeld et al. 1993a, Bielefeld et al. 1993b); only one reference to a marine gastropod was found: *Littorina littorea* (Bevelander & Nakahara, 1970). Although shell production is often assumed to be quite similar among molluscs, there are important morphologic

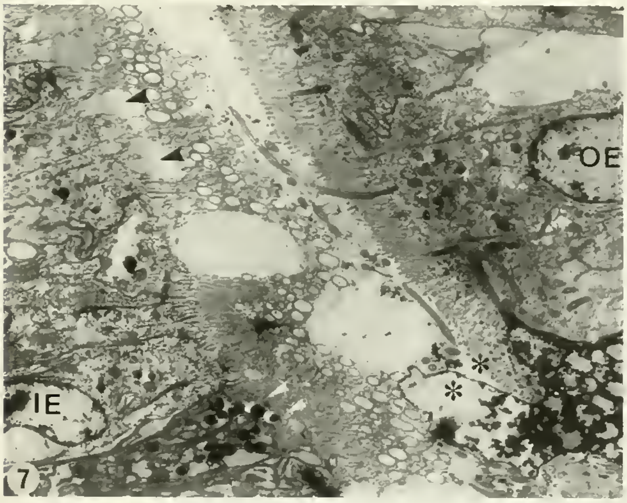

Figure 7. Area 2b–4b of the periostracal groove (TEM): Numerous cilia are interspersed in the microvillar border of the epithelium of the outer fold (4b). The microvillar border of the inner fold (2b) is irregular and some cell protruding processes can be observed (black or white arrowheads). Some secretions of the B type glandular cells are associated with cilia (*). IE, inner mantle epithelium; OE, outer mantle epithelium (×9,000).

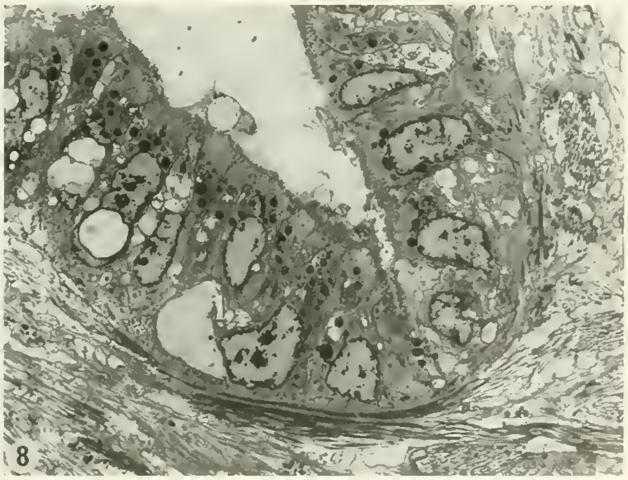

Figure 8. Area 3. Bottom of the periostracal groove (TEM). The cells are cuboidal. Only few secretions and no cilia can be observed in this part of the periostracal groove (×4,000).

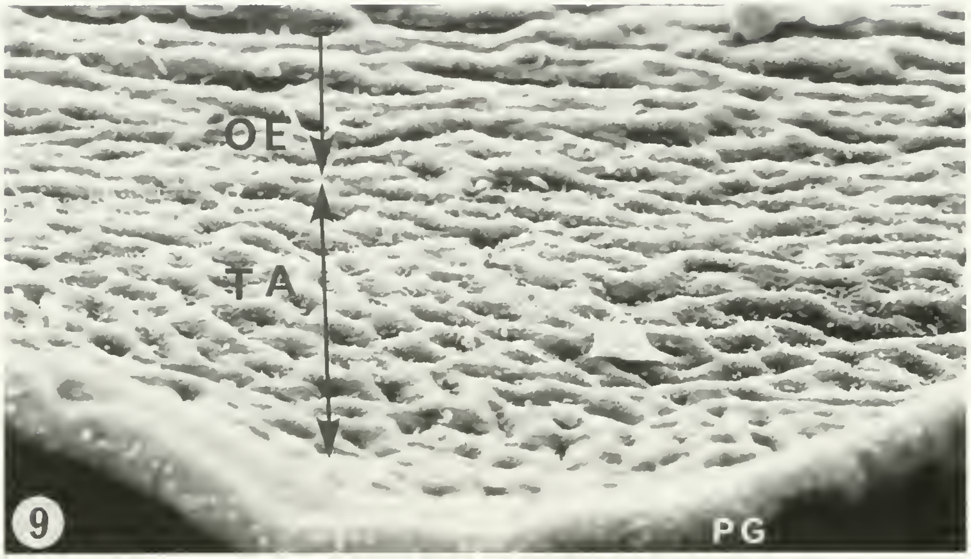

Figure 9. Areas 5 and 6. External structure of the outer mantle epithelium (SEM). Near the periostracal groove (PG), the tubular area (TA) (area 5) appears as honeycomb lobe at the surface of the mantle (double black arrow), whereas the outer epithelium (OE) beyond area 5, covering the whole shell surface (area 6) (single black arrow) have some folds parallel to the periostracal groove. This tubular area (area 5) can be distinguished from the outer epithelium covering the remainder of the mantle (area 6) (×350).

differences of the mantle between bivalves and gastropods due to different shell structure and morphology (Hedegaard, 1997).

As Martin et al. (1983) have demonstrated with their study of the gonads in *Haliotis rufescens*, two cell types can be defined depending on their cytoplasm content: glandular (or secretory) cells and nonglandular cells. In *H. tuberculata*, ultrastructural studies have allowed us to determine three types of glandular cells with regard to their secretion vesicles content. Type A and B glandular cells are present in the whole epithelium, whereas type C cells only occur in the IE and in the inner fold epithelium of the periostracal groove. Type A glandular cells correspond to a typical mucous cell. Type A and B glandular cells are present in various species (for example: *Lymnaea stagnalis*, Zylstra et al. 1978). Type C glandular cells are rarely represented in molluscs and have already been described in the gastropod *Rhodope* sp. (Haszprunar & Künz 1996). Glandular cells, and notably type B, are highly represented in the periostracal groove. While in the IE glandular cells play a role in the protection of the mantle (Lemaire-Gony & Boudou 1997), various authors report the presence of glandular cells, which might facilitate the movement of the periostracum out of the groove or protect the site of periostracum formation against invading water (Bielefeld et al. 1993a; Bielefeld, 1993b; Garcia-Gasca et al. 1994). Some ultrastructural studies demonstrated that glandular cells play a role in periostracum formation (Tsujii 1968a; Tsujii 1968b; Bevelander & Nakahara 1969a; Bevelander & Nakahara 1969b; Nakahara & Bevelander 1971): this role is to be assumed in *H. tuberculata*. The role of glandular cells in mineral deposition is controversial in the studies: Tsujii (1960) suggests that in *Pinctada martensii*, glandular cells in the OE do not participate in shell formation, whereas Beedham (1958) (studying *Anodonta cygnea*, *Mytilus edulis*, and *Ostrea edulis*) believes that secretion may be incorporated in the organic matrix of the shell.

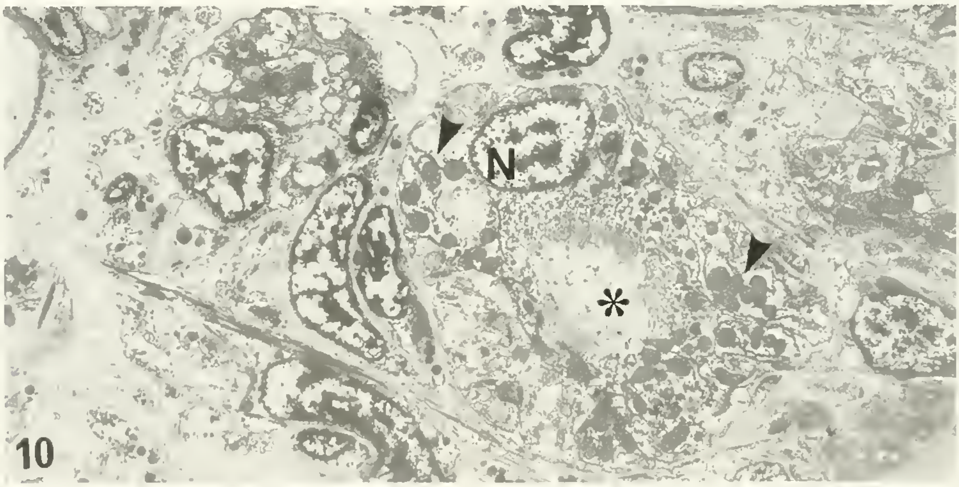

Figure 10. Area 5. Tubular area of the outer mantle epithelium (TEM) in a juvenile abalone. Structure in tubules are shown transversally cut. Cells contain a central nucleus (N) and numerous mitochondria can be observed (arrow heads). In the lumen of the tubule some secretions are present (*) (×4,000).

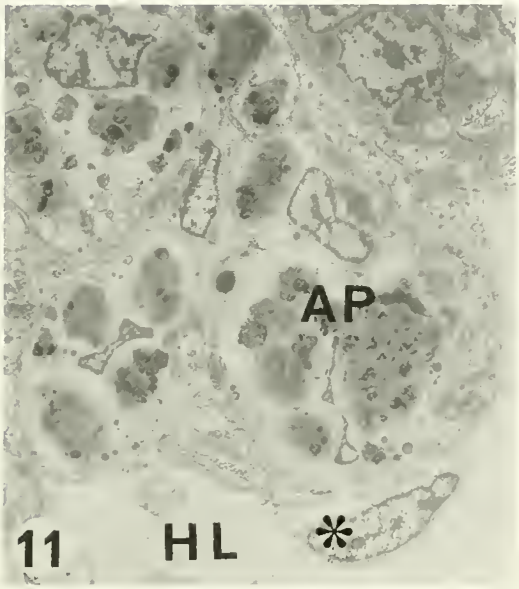

Figure 11. Area 5. Tubular area of the outer mantle epithelium (TEM). Alimentary pigments (AP) are found in vacuoles of wandering hemocyte-like cells. HL, hemolymph lacunae; hemocyte (*) (×3,000).

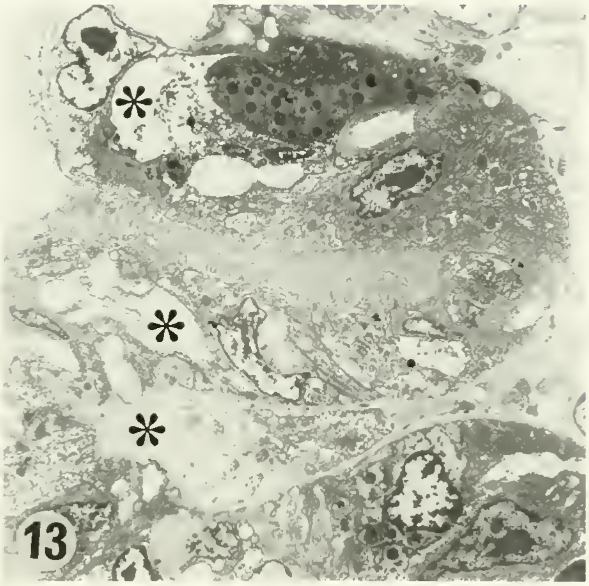

Figure 13. Area 6 of the outer mantle epithelium (TEM). Detail of one fold: Numerous empty cells can be observed (*) (×3,000).

Hillman (1961) suggests that not all glandular cell types could interfere with the biomineralization processes. The organic matrix of the shell mineral layers (which are calcite and aragonite) contains some mucopolysaccharides (Garcia-Gasca et al. 1994). As a consequence, the participation of glandular cells in shell formation could not be ruled out in *H. tuberculata*, and further studies need to be undertaken to determine the nature of each glandular cell and the role of glandular cells in shell formation.

In *H. tuberculata*, the mantle edge ends with a periostracal groove, parallel to the mantle surface, which divides the mantle into two folds: the inner and outer folds. In all molluscs, the periostracum is secreted by the mantle edge, but the mode of formation and the morphological structure of the mantle edge vary from species to species. Generally, in molluscs, the periostracal groove divides the mantle into folds, although it is virtually lacking in some species such as the gastropod *L. littorea* (Bevelander & Nakahara 1970). The mantle edge of bivalves generally consists of three folds compared with the usual two folds among (freshwater or terrestrial) gastropods. In bivalves, the periostracum originates from epithelial cells lining the inner surface of the outer fold of the periostracal groove and/or from a row of basal cells at the bottom of the groove (Kawaguti & Ikemoto 1962a; Dunachie 1963; Neff 1972; Bubel 1973a; Bubel 1973c; Bubel 1973d; Saleuddin 1974; Petit et al. 1979). In some gastropods, such as *Helix* sp., the periostracal groove is described as a single layered, flattened

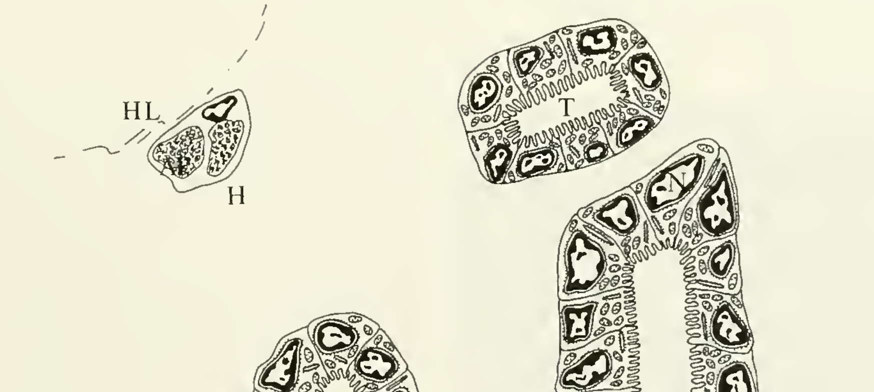

Figure 12. Area 5. Schematic drawing of the tubular area of the outer epithelium (OE). The epithelium is folded and when well developed, it forms tubules (T). Some alimentary pigments (AP) are observed near the hemolymph lacunae (HL). H, hemocyte; M, mitochondria; Mv, microvilli; N, nucleus (not to scale).

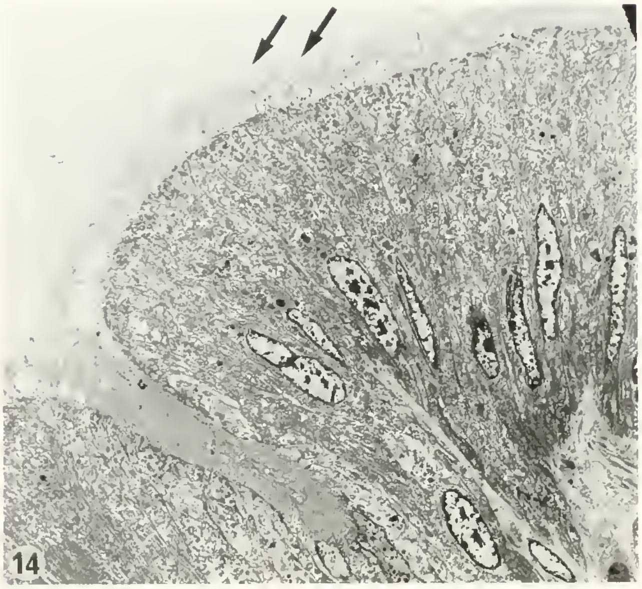

Figure 14. Area 6 of the outer mantle epithelium (TEM). Very high columnar cells are seen; numerous protruding processes (arrows) can be observed within the microvillar border (×2,000).

glandular epithelium called the "periostracal gland" (Beedham 1958), although it does not form a compact body or have a duct. The cells forming the gland seem to be equivalent to the basal cells described in other bivalves (Saleuddin 1974). In some gastropods (*L. stagnalis* and *Biomphalaria pfeifferi*), some different types of gland cells are found which have their cell bodies sunken into the underlying connective tissue at the base of the groove (Zylstra et al. 1978).

In gastropods, the periostracal groove is generally shallow, but it is deeper in *H. tuberculata* and morphologically similar to that in the bivalves: this could be due to the primitive status of this gastropod (Stasek & McWilliams 1973). Periostracal gland and basal cells, described respectively in gastropods and in bivalves (Hillman 1961; Kawaguti & Ikemoto 1962a; Kawaguti & Ikemoto 1962b; Bubel 1973a; Bubel 1973b; Petit et al. 1979), have not been found in *H. tuberculata*. Secretions of material have been observed in the outer surface of the inner fold, whereas it is generally accepted that, in bivalves, the cells lining the inner surface of the outer fold contribute to the periostracum (Bubel 1973b). A group of ciliated cells have been observed in the inner surface of the outer fold of the periostracal groove of *H. tuberculata*. Such cilia have been described in some bivalves (*Pinctada margaritifera*, Jabbour-Zahab et al. 1992), but are generally located at the bottom of the groove. These cilia may help to conduct and aggregate the periostracum material outside the periostracal groove as well as microvilli in the brush border along the inner surface of the outer fold.

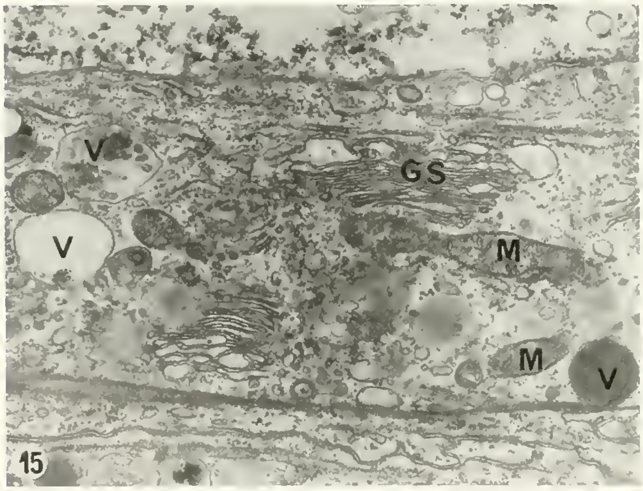

Figure 15. Area 6 of the outer mantle epithelium (TEM). Detail of one very high columnar cell: Inclusions of different content are present in vesicles (V). GS, Golgi stacks; M, mitochondria (×40,000).

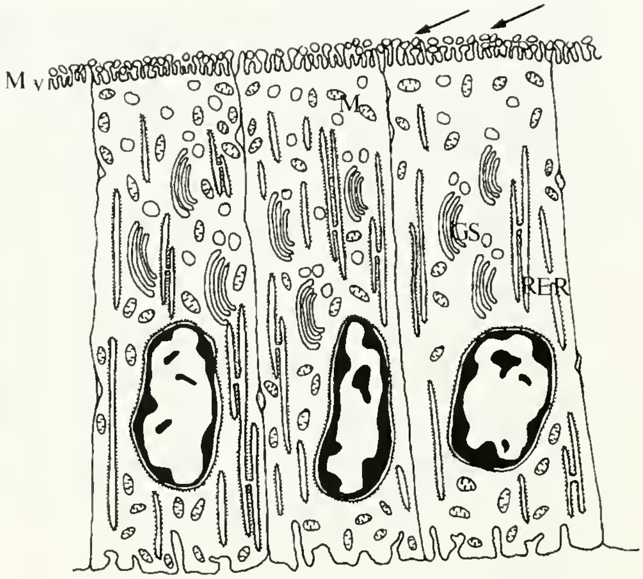

Figure 16. Area 6. Schematic drawing of an active outer epithelium. Palissadic cells are tall and narrow, filled with numerous organites arranged in the longitudinal axis of the cells: Golgi stacks (GS), mitochondria (M), rough endoplasmic reticulum (RER). The microvillar border (Mv) is well developed and some protruding processes (black arrows) are observed (not to scale).

A distinct membrane-like lamellar layer has not yet been observed in any preparation or fixation in *H. tuberculata* periostracal groove, although such a membrane-like layer is reported for other gastropods and bivalves (Saleuddin 1979; Saleuddin & Petit 1983). This could be explained by the fact that animals have not been anesthetized and mantle contractions could tear up the periostracum. Nevertheless, the periostracum has also not been found in juveniles fixed *in toto* with their shell. Anesthetized animals with 3-aminobenzoic acid ethyl ester (MS222) or 7% $MgCl_2$ could be useful to answer this question. Moreover, no periostracal units described in other bivalves or gastropods (Saleuddin 1976; Bielefeld et al. 1993b; Schaefer & Haszprunar 1997) have been observed in cells of *H. tuberculata*. It seems that the secretions and the formation of the periostracum differ from those previously described, and a more detailed study of periostracum formation must be undertaken to determine how the periostracum is secreted.

In *H. tuberculata*, two distinct areas have been identified in the OE. These two areas are morphologically different: both epithelia are folded, but in the outer surface of the outer fold, the epithelium can form tubules, whereas beyond this, the OE folds are quite similar and are almost orientated parallel to the periostracal groove side. In the first area (5), located in the outer surface of the outer fold, cells are cuboidal, and numerous mitochondria have been observed. According to Istin and Masoni (1973), in bivalves, the number of mitochondria underlying the epithelial border of the outer fold indicates a metabolic activity for such cells. This activity is not linked only with calcium movements, but may be linked with matrix components synthesis. In the vicinity of this area, in the connective tissue, and near the hemolymph lacunae, some accumulations of partially digested pigments have been found. These pigments originate from the algae diet, giving red or green color of the prismatic layer, depending on the algae consumed as food. In Haliotidae, these pigments are incorporated into the calcitic layer of shell (Leighton 1961). Thus, this particular area called here the tubular zone (5), can be related to the secretion of the calcitic layer in *H. tuberculata*. This area has already been described by Crofts (1929) as the "glandular acini." This tubular area is always present in juveniles of *H. tuberculata*, but it could be less developed or even absent in adult specimens. A lower development of tubular area in adult specimens could be related to a decrease in shell growth rate compared to juveniles. The presence or the absence of this area may be considered as a cyclic shell secretion, whereas the other area (6) of the OE is likely related to the formation of the aragonitic (nacreous) layer.

This regionalization of the outer mantle epithelium exists in other molluscs: according to Nakahara and Bevelander (1971), in *P. radiata*, the prismatic layer of the shell is derived exclusively from the tall columnar cells lining the outer surface of the outer mantle fold. Although some authors found a distinction between the secretion of the different shell layers (Beedham 1958, *Ostrea edulis*; Kawaguti & Ikemoto 1962b, *Musculus senhousia*; Jabbour-Zahab et al. 1992, *Pinctada maxima*; Schaefer & Haszprunar 1997, *Laevipilina antarctica*), other authors found this distinction not to be effective (Petit et al. 1980 – *Amblema* sp.). In *H. tuberculata*, this regionalization is in accordance with the differences in the organic matrix components of each shell layer and with the presence of alimentary pigments incorporated into the calcitic layer.

In area 6 of the OE in relation with the nacre secretion, two different structures of these epithelia have been found: a tall columnar and a very high, narrow columnar epithelium, depending on the activity of the mantle. These two epithelial structures have been observed, depending on studied specimens. Such morphological differences may be correlated with seasonal and/or individual variations. In the tall columnar epithelium, organelles are not in great number and numerous "empty" cells have been observed, whereas in the very high, narrow columnar epithelium, numerous organelles are found (mitochondria, Golgi complexes, rough endoplasmic reticulum, numerous inclusions of various types). It seems that the last epithelium is much more active than the first. A large number of cytoplasmic vesicles as well as numerous mitochondria were found, indicating an involvement in the mechanisms of shell formation attributed to this epithelium (Wilbur 1964; Istin & Masoni 1973). Moreover, the very high, narrow columnar epithelium is associated with protruding cell processes, which can be related to the secretion of the organic matrix components of the shell (Wilbur 1964; Jabbour-Zahab et al. 1992). In the very high, narrow OE, some distensions of the intercellular spaces have been found: these could act as ion pumps, particularly for calcium (Zylstra et al. 1978; Richardson et al. 1981).

The structure of the mantle margin in *H. tuberculata* is very peculiar and could not be related morphologically to the mantle of other gastropods and bivalves. A spatial organization of the mantle exists in relation with the secretion of the different shell layers: the periostracal groove in relation with the secretion of periostracum, the tubular area (in the outer surface of the outer fold) in relation with the deposition of the prismatic layer, and the OE (beyond the previous area) in relation with the secretion of the nacreous layer. This spatial organization can be related to a temporal variation, because the OE seems to have different structure depending on the stage of secretory activity of the mantle. This temporal variation could be related to the incremental bands deposited annually, monthly, daily, or during another shorter period (Wilbur 1972), because shell formation is incremental rather than continuous.

DIETARY BIOTIN REQUIREMENT OF JUVENILE ABALONE, *HALIOTIS DISCUS HANNAI* INO

GETIAN WU, KANGSEN MAI, BEIPING TAN, AND WEI ZHU
Mariculture Research Laboratory, College of Fisheries, Ocean University of Qingdao, Qingdao 266003, Shandong, People's Republic of China

ABSTRACT The experiment was conducted to quantify the biotin requirement of juvenile abalone, *Haliotis discus hannai* Ino. The possible biotin-synthesizing capacity of intestinal microflora was also examined. Seven purified diets were formulated to provide a series of biotin (0, 0.5, 1.0, 3.0, 6.0, 12.0, 20.0 mg/kg diet). An antibiotic diet was supplemented with tretracycline hydrochloride (4-g/kg diet) in basal diet to suppress possible intestinal bacteria synthesis. To reduce leaching, dietary biotin and other water-soluble vitamins were encapsulated by calcium alginate. Abalone juveniles of similar size (initial mean weight 175.1 ± 3.6 mg; mean shell length 11.66 ± 0.14 mm) were distributed in a flowing-through system using a completely randomized design with eight treatments and three replicates per treatment. They were fed the appropriate diet once every day for a 110-day period. Results of this study clearly showed the necessity of dietary biotin for juvenile abalone as the daily increment in shell length (DISL), visceral pyruvate carboxylase and acetyl-CoA carboxylase activities were significantly influenced by the dietary biotin levels (ANOVA, $P < 0.05$). However, the survival, specific growth rate (SGR) and carcass proximate compositions were not significantly influenced by dietary biotin at the end of the experimental period. The viscera biotin concentration (VBC) of abalone increased as the biotin supplementation level increased ($r = 0.91$). Compared to those of other groups, SGR, DISL, VBC and two carboxylase activities of antibiotic group were obviously depressed. It indicated that the intestinal microflora probably contribute to biotin nutrition for juvenile abalone. Based on measurements of DISL and two carboxylase activities, the optimum biotin requirement was estimated to be 0.42 mg/kg and 0.67–0.70 mg/kg for maximum growth and carboxylase activities, respectively.

KEY WORDS: *Haliotis discus hannai*, biotin, carboxylases, microflora, bio-synthesis, mollusk, nutrition

INTRODUCTION

Biotin is a water-soluble vitamin included in vitamin B complex. As a coenzyme for several carboxylases, such as pyruvate carboxylase (EC 6.4.1.1), acetyl-CoA carboxylase (EC 6.4.1.2), propionyl-CoA carboxylase (EC 6.4.1.3), and methylcrotonyl-CoA carboxylase (EC 6.4.1.4), biotin participates in the reactions of relevant enzymes, and affects the metabolism of amino acids, carbohydrates, nuclear acids and lipids.

Since biotin is one of the most expensive vitamins to add to artificial feed rations, it is necessary to quantify the minimum requirement for the vitamin in order to reduce feed cost. However, several factors have been proven to influence the need for dietary biotin in animals, for example, dietary factors such as the presence of high dietary fat has been shown to obscure the effects of biotin in rats, chicks, brook trout, and rainbow trout (Jacobs et al. 1970; Marson & Donaldson 1972; Poston & McCarteney 1974; Walton et al. 1984). In addition, biotin was found to be synthesized by intestinal bacteria in considerable amounts in some land animals (Victor & Rachel 1945) and freshwater fishes (Sugita et al. 1992). Thus, these factors should be taken into account during estimation of biotin requirements.

Until now, the quantitative requirement of dietary biotin for maximum growth has been studied in only a few species of aquatic animals. Kitamura et al. (1967) reported that 0.01-mg biotin/kg diet was sufficient to support optimum weight gain in rainbow trout fry. The biotin requirement of lake trout appears to be lower than 0.1 mg/kg (Poston 1976). Shiau and Chin (1998, 1999) reported that grass shrimp and tilapia require 2.0–2.4 mg/kg and 0.06 mg/kg of diet, respectively. Günther and Meyer-Buorgdorff (1990) concluded that optimum biotin supply for mirror carp was 2.0–2.5 mg/kg of diet. The deficiency signs of biotin included anorexia, poor food conversion, poor growth, "blue slime" disease, light skin and lower carboxylase activity (Phillips et al. 1950; Ogino et al. 1970; Halver 1972; Poston & McCartney 1974; Robinson & Lovell 1978; Halver 1979).

Abalone is a large algivorous marine mollusk of genus, *Haliotis* (*Gastropoda, Prosobranchia, Archaeogastropoda, Haliotidae*). They are the most commercially important gastropod in aquaculture. At present, limited information has been reported on the essentiality or quantitative requirements of vitamins for abalone. Only the effect of dietary vitamin C on the growth, survival and level of ascorbic acid in the tissues of the abalone *H. tuberculata* and *H. discus hannai* had been investigated (Mai 1998a). For the sake of safety, biotin is generally supplemented in excess to diets for abalone at levels of about 12 mg/kg of diet (Ogino & Kato 1964; Uki et al. 1985; Viana et al. 1993; Mai et al. 1995a; Mai et al. 1995b; Mai 1998a). This dietary level of biotin may not provide maximum efficiency of nutrient utilization and maximum profit margins.

The objective of this study was to quantify the biotin requirements for juvenile abalone, *H. discus hannai* Ino. The possible biotin-synthesizing capacity of intestinal microflora was also investigated.

MATERIALS AND METHODS

Preparation of Vitamin Microsphere

To reduce leaching from diets, dietary biotin, and other water-soluble vitamins were encapsulated with sodium alginate. The method of preparation was modified from Bodmeier and Wang (1993). One hundred milliliters of sodium alginate solution (2%, w/w) containing 2% (w/w) of water-soluble vitamins were mixed with 150 ml of oil containing 6.74 g/L Span80, stirred at 400 rpm for 15 min. The emulsified solution was slowly poured into 1% (w/w) $CaCl_2$ solution, with continuously stirring for 1 min, then filtered below normal pressure. Harvested microcapsules were washed with cyclohexane and absolute alcohol, in turns, to rem

Feed Formulation and Manufacture

The basal diet formulation is given in Table 1. The basal diet contained negligible intrinsic biotin. Dietary treatments were prepared by replacing the dextrin with graded levels of biotin, 0–20 mg biotin/kg diet, in the form of crystalline biotin encapsulated with sodium alginate, was used to prepared seven experiment diets. These diets were designated D0, D0.5, D1, D3, D6, D10 and D20, respectively. The biotin concentrations of the seven diets were determined by HPLC method (Hudson et al. 1984). They contained 0, 0.51, 0.91, 3.04, 6.03, 10.11, and 19.89 mg/kg diet, respectively. A treatment with tetracycline hydrochloride (A. P., Japan) (4 g /kg of diet) was included to ascertain the biotin-synthesizing capacity of intestinal microflora.

Procedures for diet preparation were modified from those described by Mai et al. (1995a, 1995b). Casein, gelatin and some minerals that were in the form of small grains were ground individually using a Pascal Mill and then passed through a mesh with 200-μm pore size. Dry ingredients were weighed on an electronic balance and thoroughly mixed. After adding water (about 120%, v/w) to the mechanically mixed ingredients containing 20% sodium alginate, a paste was made. The paste was shaped into 0.5-mm thick sheets, which were cut into 1-cm^2 flakes. The flakes were dipped into an aqueous solution of $CaCl_2$ (5%, w/v) for 1 min. By this treatment, sodium alginate was converted to an insoluble calcium alginate gel, in which the nutrients were bound (Uki & Watanabe 1992). The surplus solution was drained naturally, then the flakes were sealed in a sample bag and stored at −20°C until use.

TABLE 1.

Composition of the basal diet (g/kg, dry weight basis).[a]

Ingredients	Content
Casein (vitamin-free, Sigma Chemical, St. Louis, MO, USA)	260.0
Gelatin (Sigma Chemical, St. Louis, MO, USA)	65.0
Dextrin (Shanghai Chemical Co., Shanghai, China)	300.0
Carboxymethylcellulose (Sigma Chemical, St. Louis, MO, USA)	50.0
Sodium alginate (Shanghai Chemical Co., Shanghai, China)	200.0
Vitamin mix (biotin-free)[b]	20.0
Choline	5.0
SO/MFO (Food grade)[c]	35.0
Mineral mix[d]	40.0
Filler[e]	25.0

[a] The basal diet contained (dry weight basis): crude protein, 29.67%; crude lipid, 3.68%; gross energy, 18.48 kJ/g.

[b] Vitamin mix, each 1,000 g of diet contained: thiamin HCl, 120 mg; riboflavin, 100 mg; folic acid, 30 mg; PABA, 400 mg; pyridoxine HCl, 40 mg; niacin, 800 mg; Ca pantothenate, 200 mg; inositol, 4,000 mg; ascorbic acid, 4,000 mg; vitamin E, 450 mg; menadione, 80 mg; B_{12}, 0.18 mg; vitamin A, 100 000 IU; vitamin D, 2,000 IU; ethoxyquin, 400 mg. All water-soluble vitamins coated with calcium alginate.

[c] Soybean oil and menhaden fish oil (1:1) with 0.001% ethoxyquin.

[d] Mineral mix, each 1,000 g diet contained: NaCl, 0.4g; $MgSO_4 \cdot 7H_2O$, 6.0g; $NaH_2PO_4 \cdot 2H_2O$, 10.0g; KH_2PO_4, 12.8g; $Ca(H_2PO_4)_2 \cdot H_2O$, 8.0g; Fe citrate, 1.0g; Ca-lactate, 1.4g; $ZnSO_4 \cdot 7H_2O$, 141.2 mg; $MnSO_4 \cdot H_2O$, 64.8 mg; $CuSO_4 \cdot 5H_2O$, 12.4 mg; $CoCl_2 \cdot 6H_2O$, 0.4 mg; KIO_3, 1.2 mg; Na_2SeO_3, 0.4 mg.

[e] Dextrin replaced with biotin supplements.

Leaching

The leaching test of dietary biotin was modified from the method used by Marchetti et al. (1999). Ten-gram aliquots of each feed, stored in nylon bags (mesh size, 149 μm), were immersion in a beaker containing 2 L of sea water maintained at 20.0 ± 1°C and mechanically stirred. Thimerosal was added at 100 ppm to reduce bacterial activity. At the end of allotted time (3, 6, 12 hours, respectively), the remained food was removed from the bags and dried overnight at 60°C in an oven. Dried food was submitted for analysis of total dietary biotin by HPLC. The leaching of dietary supplemented biotin was reflected as retention efficiency (RE), which defined as:

$$\mathrm{RE} = \left[\frac{\text{(Biotin retained in diet after immersion)}}{\text{(Biotin contained in diet before immersion)}}\right] \times 100$$

Animal Rearing

Juvenile abalone (*H. discus hannai* Ino.) used in this experiment was derived from a spawning in June 1999, at Mashan Fisheries Co., Shandong, China. Before the trial, shell lengths were measured with calipers to the nearest 0.02 mm and the animals were weighed to the nearest 0.1 mg using an electronic balance.

Animals were kept in acrylic square cages (35 cm × 28 cm × 20 cm). Each rearing unit was stocked with 40 abalone juveniles. Similar sized juveniles (mean weight 175.1 ± 3.6 mg; mean shell length 11.66 ± 0.14 mm) were assigned to the rearing system using a completely randomized design with eight treatments and three replicates per treatment. The system was flow-through, with water filtered to 30-μm by primary sand filters, then to 10-μm by secondary composite sand filters. The flow rate was about 0.5 L per min per cage. Cages were kept in dim light by screening with black plastic drapes. During the experimental period, water temperature ranged from 18.2 to 22.0°C, salinity 30–34‰, pH 7.6–7.9. Dissolved oxygen was not less than 7.0 mg/l, and there were negligible levels of free ammonia and nitrite (AOAC, 1995).

Prior to initiation of the experiment, the abalone underwent a 1-week conditioning period during which they readily acclimated to environmental conditions. The feeding trial was run for 16 weeks. Abalone were hand-fed with the test diets at a rate equaling 5–10% of abalone wet body weight once daily at 17:00. Every morning, uneaten food and feces were cleaned to maintain the water quality.

Sample Collection and Analysis

At the termination of the feeding trials, to deplete the digestive canal, animals were not fed for 3 d, then all abalone were removed from the rearing system, weighed, measured and counted. Then, 30 abalone from each replicate were quickly frozen (−70°C) for subsequent analysis. Growth was reported as specific growth rate (SGR, %/day) and daily increment in shell length (DISL, μm/d). The formulae are as follows:

$$\mathrm{SGR}\ (\%/\mathrm{d}) = [\,(\ln Wt - \ln Wi)/t] \times 100$$
$$\mathrm{DISL}\ (\mu\mathrm{m/d}) = [\,(\ln SLt - SLi)/t] \times 1000$$

Where, Wt, Wi are final and initial mean weights (mg), respectively; SLt, SLi are final and initial mean shell lengths (mm), respectively; t is the feeding trial period (days).

The frozen samples were finely cut. Then, an aliquot of the whole visceral tissues was hand homogenized with 18 ml of ice-cold phosphate buffer (pH 3.5). The homogenate was centrifuged for 20 min at 3,000 rpm. Then, the biotin was estimated using HPLC method (Hudson et al. 1984). Another aliquot of viscera was homogenized on ice in 5 volumes of Tris-HCl (pH 7.5) buffer. The homogenate was pre-centrifuged (2,000 rpm, 10 min) to reduce the foam and sediment debris. A subsequent centrifugation was carried out at 20,000 rpm for 30 min. The protein concentration of supernatant was assayed following the method of Lowry et al. (1951) using bovine serum albumin as the standard. Then, pyruvate carboxylase (EC 6.4.1.1), and acetyl-CoA carboxylase (EC 6.4.1.2) activities were measured as described by Zempleni et al. (1997). The NaH[^{14}C]O$_3$ (specific radioactivity, 30.1 MBq/mmol; NEN, USA) was used as substrate. Preliminary work with each assay also ensured that enzyme-saturating conditions were achieved. ^{14}C were counted in 5 ml of Ultima Gold XR scintillation fluid (Packard Instrument, Meriden, CT) in a liquid scintillation analyzer Winspectral-1414 (Wallac). Pyruvate carboxylase activity was expressed as units per milligram of protein, where 1 unit equals 1 μmol of H[^{14}C]O$_3$ incorporated into oxaloacetate per minute at 30°C. Similarly, acetyl-CoA carboxylase activity was expressed as 1 unit equaling 1 pmol of H[^{14}C]O$_3$ incorporated into malonyl-CoA per minute at 37°C.

Proximate analyses to determine carcass protein, lipid, and moisture contents were conducted using conventional procedures (AOAC, 1995).

Statistical Analysis

All percentage data were arcsine square-root transformed prior to analysis. Data from each treatment were subject to one-way ANOVA. When overall differences were significant at less than 5% level, Tukeys' test was used to compare the mean values between individual treatments. Statistical analysis was performed using STATISTICA™ package (StatSoft, Inc., USA).

RESULTS

Leaching

The results of the 12-h leaching test of the biotin-supplemented diets are presented in Figure 1. The supplemented biotin contents in all diets decreased with the increasing of the immersion time. After 3 and 6-h of immersion in seawater, the retention efficiencies (RE) were approximately 90.3–96.1% and 76.8–84.2%, respectively; and this value decreased to 42.5–69.2% after 12-h of immersion in all diets. In the first 6-h, there were no differences in the RE among all levels of the biotin supplementation (ANOVA, $P >$ 0.05). After 12-h immersion, the retention efficiencies of all biotin-supplemented diets were significantly different and showed a negative correlation with the biotin supplemental content (r = 0.87). By taking into account the leakage rates in the first 3-h immersion and the amount initially encapsulated, the real amounts of biotin delivered to the abalone were about 0, 0.49, 0.87, 2.88, 5.75, 9.37, and 17.96 mg biotin/kg diet for D0, D0.5, D1, D3, D6, D10, and D20, respectively.

Survival and Growth

Survival, specific growth rate (SGR) and daily increment in shell length (DISL) data are shown in Table 2. During the 110-day experimental period, there were no significant differences in survival (89.2–96.2%.) with any of dietary treatments (ANOVA, $P >$ 0.05). The SGR of the antibiotic group (0.83%/day) was significantly lower than those of biotin treatment groups (1.10–1.28%/day) (P < 0.05). There were no differences observed in SGR among biotin treatment groups during the experimental period (ANOVA, P > 0.05).

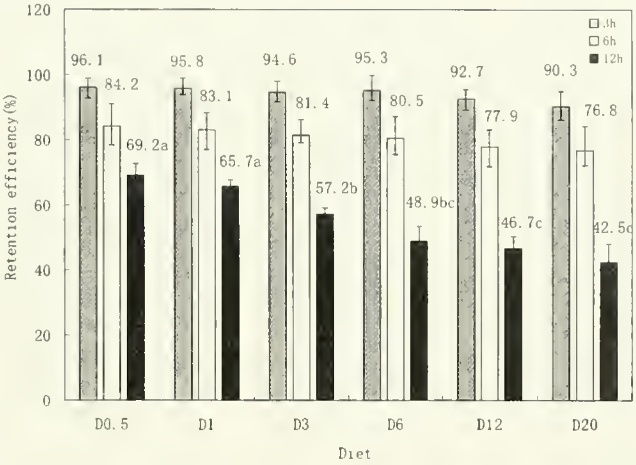

Figure 1. The retention efficiency (RE) of dietary biotin in six biotin supplemented diets at different interval (3, 6 and 12h, respectively) immersed in seawater in triplicate. Error bars are SE. Means with the same letter are not significantly different (P > 0.05). In the first 6h immersion, RE were not significantly different among all diets. After 12h, the values were significantly different and show a negative relationship with the biotin supplemental content (r = 0.87).

Similarly, DISL were significantly higher for dietary biotin treatment groups (60.0–69.1 μm/d) than for the antibiotic group (50.9 μm/d) (P < 0.05). Among all dietary biotin treatments, dietary biotin levels influenced DISL significantly (ANOVA, P < 0.05). DISL increased from 60.0 to 69.1 μm/d with dietary biotin levels increasing to 1mg/kg. There was a decline in DISL observed in abalone fed diets with biotin supplementation higher than 3 mg/kg. Thus, the broken-line regression model (Robbins et al. 1979) was used in this study to express the relationship between DISL and dietary biotin content. The regression equations are shown in Figure 2. As the break point at 0.42 mg/kg gave the least mean square error, the adequate amount of dietary biotin for juvenile abalone is estimated to be 0.42 mg/kg.

Carcass Composition and Biotin Concentration

As seen in Table 3, all the moisture (75.30–77.91%), crude protein (55.87–58.35%), and crude lipid content (5.16–6.37%) of abalone were not affected by dietary treatments (ANOVA, $P >$ 0.05). However, the visceral biotin concentration (VBC) significantly responded to dietary treatments (ANOVA, P < 0.05). The differences among the eight groups were all significant. By addition of 0.4% tetracycline hydrochloride in the basal diet, the VBC was significantly lower than those of other groups were. A linear increase in the VBC was observed when the biotin supplementation level increased (r = 0.91).

Carboxylase Activity

The activities of pyruvate carboxylase (EC 6.4.1.1) and acetyl CoA carboxylase (EC 6.4.1.2) in abalone fed test diets are presented in Table 4. Both enzyme activities showed similar trends

TABLE 2.

dietary treatments. Compared to the basal group, two carboxylase activities in viscera were significantly depressed when animals were fed the antibiotic diet (93.8 U/mg protein and 7.31 U/mg protein for the activity of pyruvate carboxylase and acetyl-CoA carboxylase, respectively). Apart from the antibiotic diet, the activities of pyruvate carboxylase activity (155.9 U/mg protein) and acetyl-CoA carboxylase (8.33 U/mg protein) of basal group were the lowest among the biotin treatment. The activities of both enzymes generally increased with increasing dietary biotin up to 3-mg/kg diet then leveled off. The differences between the lowest group and the groups fed diets with biotin higher than 1 mg/kg diet were significant ($P < 0.05$). It is obvious that the relationships between both enzyme activities and dietary biotin levels were in accord with the broken-line regression model (Robbins et al. 1979). Based on pyruvate carboxylase and acetyl-CoA carboxylase activities, the regression equations were $Y = 8.97 + 0.03 \times (X - 0.70)$ ($r^2 = 0.93$) and $Y = 171.1 + 0.38 \times (X - 0.67)$ ($r^2 = 0.85$), respectively. Therefore, the biotin requirements were estimated to be 0.67–0.70 mg/kg that based on two carboxylase activities.

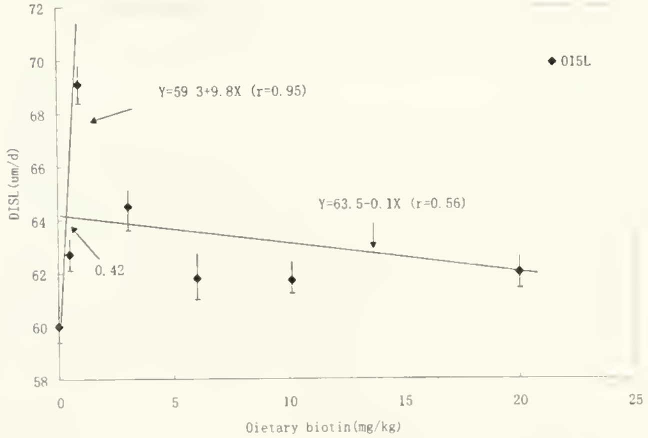

Figure 2. The effect of dietary biotin on daily increment in shell length (DISL) of abalone. Each point represents the mean of three groups o abalone (n = 3), with thirty abalones per group. Based on the broken-line model, the biotin requirement is estimated to be 0.42 mg/kg.

DISCUSSION

Abalone are known to be slow feeders or nibblers. They can take several hours before consuming one feed flake. Thus, it is necessary to reduce leaching to precisely quantify the requirement of water-soluble micronutrients including water-soluble vitamins. Microencapsulation is one of the most potential methods to reduce leaching by sheltering encapsulated materials from outer environment (Louis 1970; Gupta & Rao 1985; Shun et al. 1988). According to Marchetti et al. (1999), the retention efficiencies of lipid-walled vitamin B_1 in pelleted food were 87.5% and 72.5% for 1 and 2-h immersion, respectively. In the present study, the RE of biotin was up to 90.3–96.1% after 3-h immersion. It is evident that leaching out of biotin from the experimental diets was reduced in a great degree. A previous study indicated that the guts of most

abalone were full of food after 2 to 3-h feeding with premium quality diets (Mai et al. 1998b). There were no significant differences observed in retention efficiency when all diets immersed in seawater for 6-h (ANOVA, $P > 0.05$). Thus, in this study, the leaching may not influence the result of biotin requirement for abalone by encapsulating biotin and other water-soluble vitamins. On the other hand, wall-forming material calcium alginate is apt to be digested by abalone as high level of alginase appears in the digestive tract of abalone (Oshima 1931; Nakado & Sweeny 1967; McLean 1970; Toshio 1985; Hugo & Maria 1998). In comparison to those reported by other authors (Uki et al. 1985; Uki & Watanabe 1992; Mai et al. 1995a; Mai et al.1995b), the satisfactory abalone growth indicates encapsulated vitamins can be efficiently utilized by abalone and supports our conclusions as follows.

Until now, the essentiality of dietary biotin for any mollusk species was unknown. Results of this study clearly show that dietary biotin is necessary for juvenile abalone as the shell growth (DISL) was significantly influenced by dietary biotin. The shell growth of abalone fed lower levels of dietary biotin was depressed implying that biotin probably affects the course of biomineralization of shell. This is in accord with the findings of Bain et al. (1988) that biotin deficiency affects bone growth in broiler chick. During the 110-day experimental period, dietary biotin did not significantly affect SGR. However, there still was an obvious trend that lower biotin levels reduced SGR. As we know, biotin is a type of micronutrient in diets and the signs of biotin deficiency are usually produced under specific conditions. Thus, a 110-day experimental period is probably not long enough to significantly affect SGR in abalone. In juvenile animals, body length growth is usually faster than the body weight gain. This agrees with DISL being a more sensitive parameter to dietary biotin than SGR, and DISL may be a responsive criterion for estimating dietary biotin requirement for other mollusk juveniles. Based on the daily increment in shell length (DISL), the optimum biotin requirement for the maximum growth is estimated to be 0.42 mg/kg diet by the broken-line regression analysis. Compared with other reports, the optimum requirement for juvenile abalone is higher than that of brook trout (0.05 and 0.25 mg/kg) (Poston & McCartney 1974), lake trout (0.1 mg/kg) (Poston 1976), rainbow trout (0.05–0.14 mg/kg) (Woodward & Frigg 1989; Castledine et al. 1978), common carp (0.02–0.03 mg/kg) (Ogino et al. 1970), tilapia (0.06 mg/kg) (Shiau & Chin 1999), but less than the requirements reported for the mirror carp (2.0–2.5 mg/kg) (Günther & Meyer-Buorgdorff 1990) and grass shrimp (2.0–2.4 mg/kg) (Shiau & Chin 1998). The different biotin requirements probably attribute to the differences of experimental procedures and species.

The presence of high dietary fat has been shown to obscure effects of biotin in rats, chicks, brook trout, and rainbow trout (Jacobs et al. 1970; Marson & Donaldson 1972; Poston & McCarteney 1974; Walton et al. 1984). In the present study, 3.68% of lipid was measured in the basal diet. According to Mai et al. (1995a), optimum dietary lipid content was 3–5% to maintain maximum weight gain for abalone. Therefore, 3.68% of lipid is just sufficient to meet requirements of the abalone and lipid effects on biotin requirements can be omitted here.

As a coenzyme for several carboxylases, biotin affects the metabolism of amino acids, carbohydrates, and lipids. Thus, some studies have demonstrated that the proximate composition of animals usually respond to dietary biotin treatment. Poston (1970) reported the carcass fat content of lake trout was depressed when animals were fed biotin-free diets. The crude ash, fat and protein contents of mirror carp were significantly affected by dietary biotin (Günther & Meyer-Buorgdorff 1990). Similar results were also obtained with common carp (Ogino 1970) and tilapia (Shiau & Chin 1999). However, in the current study, the crude protein and lipid contents in the soft body tissues, which consist of mantle, foot muscle, and viscera that include all inner organs, of juvenile abalone remained independent of biotin supplementation. This effect may be manifested by a longer experimental duration. It is also generally believed that carboxylase activities are depressed in biotin deficient animals such as mammals, fishes and shrimp (Deodhar & Mistry 1969; Arinze & Mistry 1971; Poston & McCarteney 1974; Castledine et al. 1978; Walton et al. 1984; Shiau & Chin 1998, 1999). In the present study, the pyruvate carboxylase and acetyl-CoA carboxylase activities of abalone visceral tissues positively responded to dietary biotin levels. This implies that abalone did experience biotin deficiency, which would lead to depressed enzyme activities. Thus, both carboxylase activities are useful criteria in estimating dietary biotin requirements for abalone. Based on two carboxylase activities, the optimum biotin requirement for the maximum enzyme activities is estimated to be 0.67–0.70 mg/kg diet by the broken-line regression analysis. In the present study, the recommended biotin requirement for maximum carboxylase activities is higher than that for maximum growth (0.42 mg/kg diet). This means that the biotin level resulting in maximum enzyme activities and the level resulting in maximum growth are not necessarily the same.

In some species of land animals, such as calves and cows, biotin has been found synthesized in considerable amounts by intestinal bacteria (Victor & Rachel 1945). In the present study, when tetracycline was incorporated into basal diet as an antibiotic group, a deficiency developed. The SGR DISL of antibiotic group were significantly lower than those of the basal group ($P < 0.05$). Similarly, the visceral biotin concentration (VBC) and the carboxylase activities were also obviously depressed by addition of tetracycline. Sugita et al. (1992) examined the biotin-producing ability of intestinal microflora in freshwater fishes and proved requirement of freshwater fishes for biotin was significantly influenced by intestinal microflora. Thus, we believe that the poor growth of the abalone in the treatment with antibiotics could attribute to the suppression of intestinal microflora that can probably synthesize biotin. Further investigation is needed to provide direct evidence.

Another interesting phenomenon is that VBC increased from 292.3 to 1208.7 ng/g with increasing biotin supplemental levels (r = 0.91). Theses results indicate that biotin can be stored in abalone viscera in amounts corresponding to the dietary supply. Therefore, the VBC can be used to monitor biotin status in abalone. To our knowledge, the toxicity of biotin in animals is still uncertain, however, depressed growth was observed when abalone were fed high levels of dietary biotin and this would require further studies.

ACKNOWLEDGMENTS

This study has been supported by grant No. 39925029 from National Science Foundation for Talented Youths of the People's Republic of China and the Excellent Young Teachers Program of MOE of the P. R. China. We thank Dr. Q. F. Ye (Institute of Nuclear Agriculture, University of Zhejiang, China) for his excellent technical assistance.

ABSTRACT Illegal fishing and species-substitution of abalone (genus *Haliotis*), a highly valuable marine gastropod, are of worldwide concern. A mitochondrial DNA PCR-RFLP analysis of fragments of the cytochrome oxidase I (mtCOI) and II (mtCOII) genes was developed for the identification of 11 Southern Hemisphere species of abalone. These included five temperate and one tropical species from Australian waters, three temperate species from New Zealand and two temperate species from South Africa. All species, with the exception of the *Haliotis rubra*/*H. conicopora* complex, can be unequivocally identified using the combined profiles from four individual restriction enzyme digests (*DdeI*, *HhaI*, *HinFI* and *HpaII*) on a 193 base pair fragment of mtCOI. Six species each displayed a unique profile for a single restriction enzyme. A one hundred and fifty-nine base pair fragment of mtCOII allowed individual identification of six of the species using the combined profiles from five individual restriction enzyme digests (*DdeI*, *EcoRV*, *HhaI*, *HpaII*, and *RsaI*). These primers failed to amplify in *H. iris*. Again *H. rubra* and *H. conicopora* could not be separated, and neither could *H. australis* and *H. spadicea*. No DNA sequence variation in either fragment was observed between *H. rubra* and *H. conicopora*; the latter may be a subspecies of *H. rubra*. The use of both fragments and a minimum of two restriction enzymes is recommended for species differentiation. DNA was successfully extracted, PCR amplified and identified from canned tissue and mucous samples of *H. rubra*. A conformational mutation in the mtCOI fragment was observed in *H. midae*, but in no other species nor in the mtCOII fragment.

KEY WORDS: *Haliotis*, abalone, mitochondrial DNA, identification

INTRODUCTION

Abalone, genus *Haliotis* Linnaeus, are a highly valuable commercial marine univalve mollusk. There are over 55 recognized species worldwide (Geiger 1998), of which nearly half are exploited by commercial or recreational divers. Abalone generally inhabit rocky reefs to depths of 65 m, but more are usually found in shallower waters to 30 m. The foot muscle of abalone attracts high prices in Asian markets, with species differential. Once the distinguishing shell and mantle tissue have been removed, it is very difficult to differentiate the commercial product of one species from another. The high price, market demand, ease of harvest and similarity of processed product between species makes abalone very suitable targets for illegal marketing and both highly organized and small scale poaching.

Abalone poaching and species-substitution of abalone products is of concern to many countries, including the USA (Daniels & Floren 1998), Mexico (Ponce-Díaz et al. 1998), South Africa (Sweijd et al. 1998) and Australia. The value of the illegal trade is difficult to quantify. Conservative estimates in Australia alone are over $US25M annually. The legal Australian abalone fisheries, dominated by *Haliotis rubra*, account for about half the annual world abalone harvest of ca. 10,500 mt (FAO 2000) and is worth around $US80M per year. The South African abalone fishery (*H. midae* ca. 500 mt/year) is worth approximately $US15M with legal sales of confiscated (poached) abalone from just one area fetching over $US1m (Sweijd et al. 1998). In New Zealand the main commercial species is *H. iris* and the illegal harvest is estimated at about 33% of the annual commercial catch of 1,300 mt (Roberts et al. 1999). The high but unknown level of illegal harvesting of abalone creates major problems for fishery managers endeavoring to maintain viable and economic fisheries.

Whilst *H. rubra* is the dominant commercial species within temperate Australian waters, both *H. laevigata* and *H. roei* are subject to significant levels of commercial fishing under independent quota systems, and a *H. scalaris* fishery is under consideration. A problem for fisheries enforcement is the overlapping ranges of these and non-commercial species. Such species richness is common with abalone (Geiger 1999), and after removal of the characteristic shell and mantle species identification of the foot muscle is obscure. The need exists for a definitive means of identifying tissue and by-products (e.g., mucous in instances of suspected poaching when tissue has been disposed) of individual abalone species.

Identification of plant and animal species when morphological characters have been removed is possible using either protein or DNA-based methods (Palumbi & Cipriano 1998; Toro 1998; Johannesson & Stenlid 1999; Hare et al. 2000; Sweijd et al. 2000). The protein based methods are very dependent on tissue quality; generally requiring fresh or frozen material. Often identification for commercial needs may require analysis of processed (dried or canned) tissue or degraded tissue. DNA-based methods are relatively independent of tissue quality, and those that rely on amplification of small DNA fragments are less likely to be affected by degradation (Mackie et al. 1999). A number of techniques are available for species identification including: random amplification of polymorphic DNA (RAPD) (Martinez & Malmheden Yman 1998), restriction fragment length polymorphism (RFLP) analysis (Innes et al. 1998; Wolf et al. 2000), direct DNA sequencing (Quinteiro et al. 1998) and single-stranded conformation poly

---

Corresponding author. Nicholas G. Elliott. CSIRO Marine Research, GPO Box 1538, Hobart, Tasmania 7001, Australia. E-mail: nick.elliott@marine.csiro.au morphism (SSCP) (Mackie et al. 1999) of PCR (polymerase chain reaction) amplified fragments.

A PCR-RFLP analysis of a 1,300 base-pair (bp) fragment of the nuclear lysin gene was devised for identification of two South African abalone species, *Haliotis midae* and *H. spadicea* (Sweijd et al. 1998). Generic PCR primers that amplify across the intron differentiated between species based on the size of the intron. Preliminary analyses found that the size of the lysin intron varied greatly between other *Haliotis* species (generally 500 to 1,100 bp), but the intron in the Australian greenlip abalone *H. laevigata* was over 4,000 bp (unpublished data). Products of such size are not ideal for species identification tests with the likelihood of unreliable PCR products due to tissue and DNA degradation.

To differentiate between the more common Southern Hemisphere abalone species a PCR-RFLP method was developed using short fragments (less than 200 bp) of the mitochondrial DNA (mtDNA) molecule. To satisfy potential legal scenarios in Australia and South Africa, 11 species were included. Within species variation and potential non-*Haliotis* amplification of our designed primers were examined in addition to testing the primers with canned abalone tissue and abalone mucous samples.

MATERIALS AND METHODS

Sample Collection and DNA Extraction

Whole individuals (live or frozen) or alcohol preserved tissues were obtained for 11 purported *Haliotis* species: *Haliotis asininal* Linnaeus, Queensland, Australia (30 individuals); *Haliotis australis* Gmelin, New Zealand (10); *Haliotis conicopora* Péron, Western Australia, Australia (11); *Haliotis iris* Gmelin, New Zealand (10); *Haliotis laevigata* Donovan, Tasmania & Victoria, Australia (62); *Haliotis midae* Linnaeus, South Africa (10); *Haliotis roei* Gray, Western Australia, Australia (10); *Haliotis rubra* Leach, Tasmania, Victoria & New South Wales, Australia (50); *Haliotis scalaris* Leach, Tasmania & Western Australia, Australia (22); *Haliotis spadicea* Donovan, South Africa (10); *Haliotis virginea* Gmelin, New Zealand (10).

Total genomic DNA was extracted from ca. 25 mg of foot muscle or gill tissues using a modified CTAB (hexadecyltrimethlammoniumbromide) protocol (Grewe et al. 1993). Tissue was incubated overnight at 50°C instead of 30 to 60 min at 60°C.

To verify the use of our PCR primers on processed product, DNA was extracted from commercially canned *H. rubra*. Approximately 0.5 g tissue was digested for 30 min at 65°C in 5 mL digestion buffer (100 mM Tris, 50 mM EDTA, 400 mM NaCl, 1% SDS). 50 µL proteinase K (10 mg/mL) was then added and the solution was incubated overnight at 55°C. 150 µL NaCl (5 M) and 520 µL of 10% CTAB were added and the solution incubated at 65°C for 1 h with regular mixing. Samples were then extracted once with equal volumes of chloroform/isoamyl alcohol (24:1) and precipitated with 2 volumes of 100% ethanol. Precipitated DNA was washed twice with 70% ethanol, once with 100% ethanol, air-dried and re-suspended in 200 µL TE.

PCR amplification was also tested using DNA extracted from *H. rubra* mucous. Two mucous samples were obtained by placing individual freshly captured *H. rubra* in separate plastic bags for approximately 2 h, removing the abalone and placing the bag and fluid contents at 4°C. Tissue samples were taken from the individual abalone as positive controls for DNA extraction. DNA was extracted from mucous swabs taken from the sides of the bags and from the control tissue samples using the modified CTAB protocol described above. In addition, a 600 µL sample of fluid (mixture of seawater and mucous) from the bottom of each plastic bag was taken, incubated overnight in 20 µL proteinase K (10 mg/mL) and 5% SDS, and then genomic DNA extracted using the same modified CTAB protocol.

Genus specificity of the PCR amplification was tested on total genomic DNA extracts (using above CTAB protocol) from a variety of marine organisms. These consisted of an alga (unidentified red alga), an anemone (unidentified), a crustacean (Antarctic krill *Euphausia superba*), mollusks (unidentified chiton and Pacific oyster *Crassostrea gigas*) and teleosts (bigeye tuna *Thunnus obesus*, southern bluefin tuna *T. maccoyii*, pink ling *Genypterus blacodes*, Patagonian toothfish *Dissostichus eleginoides*, school shark *Galeorhinus galeus* and gummy shark *Musteleus antarcticus*).

PCR Primers and Amplification

Generic PCR primers were designed for the mitochondrial cytochrome *c* oxidase subunit I gene (mtCOI) by alignment of either our own unpublished or published *Haliotis* sequences (Metz et al. 1998). DNA sequences used for the design of the mitochondrial cytochrome *c* oxidase subunit II gene (mtCOII) were either our own or other unpublished sequences (Sandy Degnan, University of Queensland).

The primers designed to amplify a 193 bp fragment of the mtCOI gene were designated HALCO1-NG1 (5′-CIGACATRGCITTYCCICGACT-3′) and HALCO1-NG2 (5′- CCGGCTARGTGIAGIGARAAAAT-3′). Those designed for a 159 bp fragment of the mtCOII gene were designated HALCO2GENA (5′-CAATYTGAACYATTCTMCCAGC-3′) and HALCO2GENB (5′-CCTTAAARTCTGAGTATTCGTAGCC-3′). (Degenerate nucleotide IUB codes: I, Inosine = A, C, G or T; M, aMino = A or C; R, puRine = A or G; Y, pyrimidine = C or T).

PCR reactions consisted of 50 to 100 ng of total genomic DNA, 2.5 mM $MgCl_2$, 200 µM each dNTP, 10 pmoles of each primer, and 0.55 U *Taq* DNA polymerase (Biotech) in a buffer supplied by the manufacturer. PCR amplifications were carried out in a 50 µL final volume using a Perkin Elmer GeneAmp® System 9600 with hotlid. The cycling parameters were as follows: denaturation at 95°C for 3 min, 10 initial amplification cycles (94°C for 30 s, 60–55°C for 30 s, 72°C for 1 min, with a decrease in the annealing temperature of 0.5°C per cycle), a further 25 amplification cycles (94°C for 30 s, 55°C for 30 s, 72°C for 1 min) and final extension at 72°C for 5 min. Negative controls, without DNA template, were prepared for each series of amplifications to exclude the possibility that PCR reagents and buffers were contaminated with template DNA. Amplification products were examined by electrophoresis through a 2% agarose gel (GIBCOBRL) made up in 1 X TBE. Gels were stained in ethidium bromide at a concentration of 0.5 µg/mL and visualized under UV light. A one-hundred bp ladder (GIBCOBRL) was run concurrently to facilitate sizing of amplification products.

DNA Sequencing

PCR products were sequenced to confirm variation in restriction fragments and sizes, and to improve PCR primer design. PCR products were purified using Wizard™ PCR purification columns (Promega) according to manufacturers instructions, and sequenced using an ABI Prism™ BigDye™ Terminator Cycle Sequencing Ready Reaction Kit (Perkin Elmer). Cycle sequencing reactions were electrophoresed on an ABI377 automated DNA sequencer (Perkin Elmer) and analyzed using ABI Prism™ Sequencing Analysis Version 3.3 (Perkin Elmer).

RFLP Analysis

For each individual of the 11 species, four separate restriction digestions of the mtCOI fragment were performed using the four enzymes *DdeI, HhaI, HinFI* and *HpaII* (New England Biolabs, Genesearch). For the mtCOII fragments five separate restriction digestions were performed for each species individual using the enzymes *DdeI, EcoRV, HhaI, HpaII* and *RsaI* (New England Biolabs, Genesearch). Restriction digestions were carried out in a 15 μL total volume consisting of 5 μL of PCR product, 1.5 μL digestion buffer supplied by the manufacturer, 0.5 μL enzyme, and 8 μL ddH$_2$0 for all enzymes except *HhaI*. Digestions for *HhaI* were carried out in a 15 μL total volume consisting of 5 μL of PCR product, 1.5 μL digestion buffer supplied by the manufacturer, 0.5 μL enzyme, 1.5 μL 10 X Bovine serum albumin (BSA) and 6.5 μL ddH$_2$0.

Mitochondrial haplotypes were scored by electrophoresis of 10 μL of digested PCR product in a 3% agarose gel made up in 1 X TBE at 100V for 3 h, stained in ethidium bromide (0.5μg/mL) and visualized under UV light. Electrophoresis of restriction digestions was also performed on 12% polyacrylamide (Austral Scientific) gels made up in 1 X TBE and run for 2 h at 100 V.

RESULTS

DNA Extraction and PCR Amplification

DNA extractions from fresh, alcohol preserved and canned tissue, resulted in high yields of high molecular weight total genomic DNA. Amplification of these extracts consistently produced high quality PCR products.

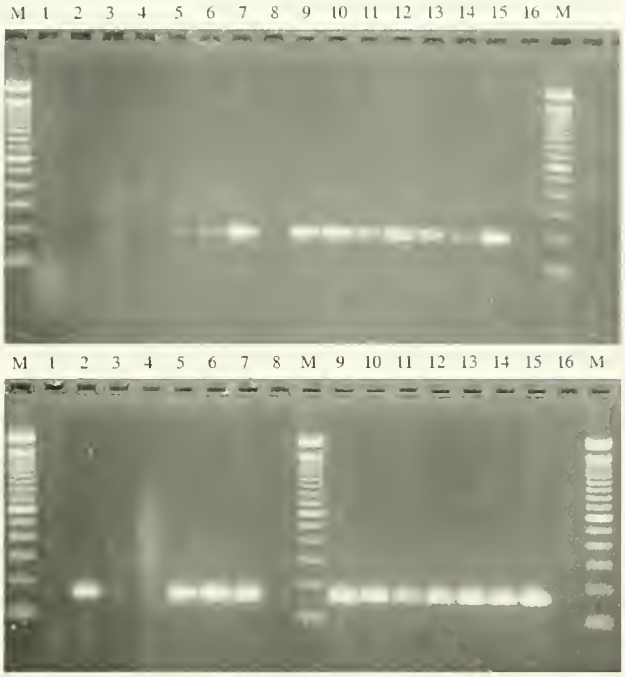
Extractions from mucous scrapings and fluid samples from plastic bags produced a small amount of high molecular weight genomic DNA. PCR amplification of these extracts failed at times to yield a product when undiluted, however when diluted 10 fold, produced a strong PCR product in all samples (Fig. 1).

PCR amplification of non-*Haliotis* DNA with the designed primers was only observed in the tuna samples. Both tuna species amplified (160 bp fragment) with the mtCOI primers. Sequencing of the tuna mtCOI products confirmed that the observed product was not contamination from abalone DNA. While nucleotide differences and RFLP cut site differences existed to separate these teleost products from abalone products, high levels of nucleotide sequence conservation suggests that the amplified product was part of the tuna COI gene.

Restrictian Digests mtCOI

The expected 193 bp fragment was generated in each abalone species following PCR amplification with the HALCOI-NG1/HALCOI-NG2 primers. Comparison of the DNA sequences indicated suitable restriction sites for discrimination between species using four restriction enzymes (Fig. 2).

Intraspecies restriction digest polymorphisms were observed in four species, but in each case for a single individual for only one enzyme (Table 1). Two of the observed polymorphisms were the result of a loss of a restriction site and two the result of a gain. All individuals showing a different restriction fragment profile for the species were sequenced to confirm the profile. All other digestions returned a single restriction pattern in all individuals examined for each species.



M 1 2 3 4 5 6 7 8 9 10 11 12 13 14 15 16 M
M 1 2 3 4 5 6 7 8 M 9 10 11 12 13 14 15 16 M

Figure 1. Electrophoretic analysis of undiluted (lanes 1 to 6) and diluted (x10, lanes 9 to 14) 193 bp mtCOI (upper image) and 159 bp mtCOII (lower image) PCR fragments for *H. rubra* tissue and mucous samples. M = 100 bp ladder. Samples in lanes are as follows: 1, 2, 9 and 10 muscle tissue; 3, 4, 11, and 12 fluid sample from plastic bag; 5, 6, 13, and 14 mucous swab from plastic bag; 7 and 15 positive *H. rubra* DNA (x20 dilution) control; 8 and 16 negative H$_2$O control.

At this 193 bp fragment, six of the eleven species had a unique species-specific restriction pattern for at least one enzyme, and so could be individually identified (Table 1). With the exception of the *H. rubra* and *H. conicopora* pairing, all species are discernible from each other using the four restriction enzymes, regardless of all but one observed polymorphism. The exception polymorphism was a single *H. rubra* individual that had gained a *DdeI* cut site, and therefore had a profile similar to *H. scalaris*. The restriction profiles for the canned tissue, mucous and fluid samples all matched that expected for *H. rubra*.

One purported *H. scalaris* individual returned a different profile at three enzymes to all other *H. scalaris* individuals. This particular individual displayed the expected cut pattern for *H. laevigata* for all four enzymes; three of which are diagnostic between the two species for all other specimens analyzed. Laboratory contamination was ruled out and the results confirmed with repeated tissue sampling, DNA extraction and PCR amplification for this one individual.

The observed fragment lengths produced in this study were all examined on agarose and (non-denaturing) polyacrylamide gels and confirmed by sequence analysis. A fragment mobility change was observed in the mtCOI fragment for *H.midae* when run on a polyacrylamide gel (Fig. 3). This assumed conformation-induced mutation was only observed in *H. midae*.

Restriction Digests mtCOII

The expected 159 bp fragment was generated in each abalone species following PCR amplification with the HALCOIGI N[illegible]

Figure 2. Sequence alignment of the 193 bp mtCOI fragment for eleven abalone species. Primer sequences and cut sites for the four restriction enzymes *DdeI*, *HhaI*, *HinFI*, and *HpaII* are included. (N = sequence data unclear whether C or T).

TABLE 1.

Expected restriction fragment lengths for eleven *Haliotis* species for the 193 bp mtCOI fragment when cut with restriction enzymes *DdeI*, *HhaI*, *HinFI* and *HpaII*. The number in parenthesis represents the total number of individuals examined for each species that displays the given restriction pattern. Unique restriction profiles are shown in bold. *H. laevigata* numbers include the misidentified *H. scalaris* individual.

	COI Restriction Digestion Patterns			
	DdeI	*HhaI*	*HinFI*	*HpaII*
H. asinina	**7,50,137** (29) 7,187 (1)	193 (30)	34,159 (30)	3,42,72,76 (30)

H. conicopora	193 (11)	42,151 (11)	34,159 (11)	3,42,51,97 (11)
H. iris	193 (10)	42,151 (10)	**19,174** (10)	3,190 (10)
H. laevigata	193 (63)	193 (62) 94,99 (1)	34,159 (62) 193 (1)	3,42,148 (63)
H. midae	193 (10)	42,151 (10)	34,159 (10)	3,42,148 (10)
H. roei	29,164 (10)	193 (10)	**6,34,97** (10)	45,51,97 (10)
H. rubra	193 (49) 29,164 (1)	42,151 (50)	34,159 (49) 193 (1)	3,42,51,97 (50)
H. scalaris	29,164 (21)	42,151 (21)	34,159 (21)	3,42,51,97 (21)
H. spadicea	193 (10)	42,151 (10)	**15,19,159** (10)	3,190 (10)
H. virginea	193 (10)	**42,57,94** (9) 42,151 (1)	193 (10)	3,190 (10)

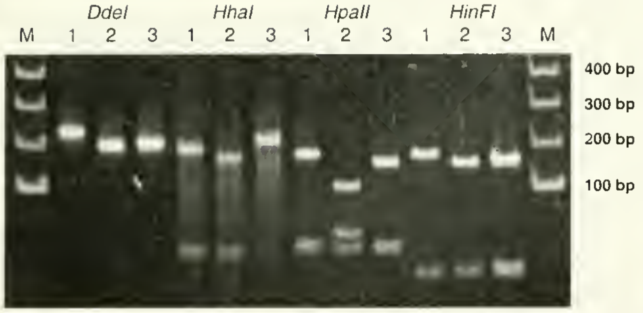

Figure 3. RFLP patterns on a non-denaturing polyacrylamide gel of the 193 bp mtCOI fragment for three abalone species produced with four restriction enzymes. Species 1 – *H. midae*, species 2 – *H. rubra*, species 3 – *H. laevigata*, M – 100 bp DNA ladder. Reduced mobilty in *H. midae* fragments suspected to be due to a conformational mutation.

HALCO2GENB primers, except *H. iris* that failed to amplify for all ten individuals examined. Comparison of the DNA sequences for the other species indicated suitable restriction sites for discrimination between species using five restriction enzymes (Fig. 4).

All restriction digestions for the five enzymes resulted in a single restriction pattern for each species, except for two enzymes for *H. rubra* (Table 2). The two polymorphisms were each observed in two different individuals, all were sequenced to confirm the observed RFLP. None of these four individuals was responsible for the polymorphisms observed at the mtCOI fragment, and the individual *H. rubra* with a mtCOI profile similar to *H. scalaris* was clearly identified as *H. rubra* at this fragment. The restriction profiles for the canned tissue, mucous and fluid samples all matched that expected for *H. rubra*.

As with the mtCOI RFLP analysis, an unusual species profile was observed for three enzymes with a single *H. scalaris* individual (the same individual), and again all three profiles match that recorded for *H. laevigata*. Sequence data showed a 100% similarity to *H. laevigata* across the 159 bp fragment, while three other *H. scalaris* samples each differed at 9 nucleotides from the *H. laevigata* sequence.

At this 159 bp fragment, three of the ten species (excluding *H. iris* that did not amplify) had a unique restriction pattern for the enzyme *DdeI* and so could be individually identified (Table 2). In addition to the *H. rubra/H. conicopora* complex it was not possible to separate *H. australis* and *H. spadicea* using the five enzymes on this fragment. All remaining species combinations were separable from each other using one to five of the enzymes (Table 2).

Fragment mobilities on polyacrylamide gels were all consistent with known fragment lengths; no conformation induced mutations were observed in the mtCOII fragment.

DISCUSSION

The ability to identify abalone species from tissue samples and/or mucous is important to the continued survival of significant abalone fisheries. The tests described in this article will provide one more tool in the fight against illegal fishing, which has the potential, along with commercial over-fishing and environmental variables (Davis et al. 1998, Shepherd et al. 1998), to lead to the decline and collapse of fisheries. The methods are straightforward

Figure 4. Sequence alignment of the 159 bp mtCOII fragment for ten abalone species. This fragment did not amplify for *H. iris*. Primer sequences and cut sites for the five restriction enzymes *DdeI*, *EcoRV*, *HhaI*, *HpaII*, and *RsaI* are included. (1 = sequence data unclear whether C or T; 2 = sequence data unclear whether C or A).

TABLE 2.

Expected restriction fragment lengths for 10 *Haliotis* species for the 159 bp mtCOII fragment when cut with restriction enzymes *DdeI*, *EcoRV*, *HhaI*, *HpaII*, and *RsaI*. *H. iris* did not amplify with these primers. The number in parenthesis represents the total number of individuals examined for each species that displays the given restriction pattern. Unique restriction profiles are shown in bold. *H. laevigata* numbers include the misidentified *H. scalaris* individual.

and suitable for use in any laboratory with basic DNA analytical equipment. The PCR-RFLP tests utilize short DNA fragments that can be amplified from processed products and slightly degraded material, and therefore are of potential forensic use.

Care has been taken in this study to include examination of intraspecies variation as well as possible non-*Haliotis* amplification with our PCR primers. Samples from different geographic locations were examined for the two main Australian commercial species (*H. rubra*, five locations and *H. laevigata*, three locations). While not exhaustive, the results suggest that what limited intraspecies variation exists can be accounted for using the two fragments and multiple restriction enzymes. Both PCR primer sets devised for the test are relatively degenerate and so cross genus amplification was not unexpected. However, of the groups we have examined only DNA from the tunas (*Thunnus* spp.) amplified, and it was possible to easily differentiate these from *Haliotis* species.

The restriction patterns produced by *DdeI* for the mtCOII fragment would discriminate three of the species, while five other species would be differentiated by a single restriction pattern at the mtCOI fragment. Such species-specific patterns are useful, however as rare polymorphisms may exist it would be wise to confirm identification with multiple enzymes and/or both short fragments. None of the rare polymorphisms observed occurred in more than a single individual, and no individual displayed more than one variation. With the exception of the *H. rubra/H. conicopora* pairing, all other combinations of the 11 abalone species can be differentiated from each other using two or more of the restriction profiles shown in this study. We therefore recommend using both fragments and at least two of the restriction enzymes included here to differentiate species.

The ability of our test to differentiate between species was inadvertently put to the test during the intraspecies examinations. Of 20 purported *H. scalaris* individuals, one was found to display a different restriction profile at six of the nine profiles examined. The combined profile of this individual matched completely the expected profile for *H. laevigata*; and was confirmed by DNA sequence analyses. Although occupying different microhabitats, these two species have overlapping distributions and co-occur in the same area (Shepherd 1973). Shell and mantle morphology did not separate the aberrant individual from other *H. scalaris* individuals. This individual is either a *H. laevigata* and morphological characters between the two species are more plastic than currently recognized, or a hybrid between the two species.

Naturally occurring hybrids between abalone species with overlapping ranges, although relatively rare, have been reported (e.g., Talmadge 1977; Sasaki et al. 1980; Arai et al. 1982; Messier & Stewart 1994). The two Australian species *H. rubra* and *H. laevigata*, also show evidence of backcrossing and introgression (Brown 1995). There are no records of hybrids between *H. laevigata* and *H. scalaris*, but *H. laevigata* is more closely related to *H. scalaris* than to *H. rubra* (Brown & Murray 1992), and hybrids would not be unexpected. Allozyme analysis of the aberrant individual could not confirm nor refute its putative hybrid status as there are no known diagnostic loci between the two species (Brown 1991).

The possible existence of hybrids, albeit at low frequencies, does not minimize the validity of our mtDNA-based test for abalone. However, the possibility of hybridization and backcrossing between species does question the legal "species identity" of an individual. If hybrids were infertile and only F1 hybrids were possible, then a single diagnostic nuclear DNA marker would confirm the individual as a hybrid, and the mtDNA marker would confirm the maternal species. Such individuals could be legally classed as hybrids. However at least some abalone hybrids appear to be fertile and backcrossing occurs (Brown 1995), and identifying the "nuclear lineage" of a potential backcross offspring would require multiple nuclear DNA markers. Even then it could never be proved that an individual was not the offspring of a backcrossing event, except based on probability. A suite of nuclear DNA markers could never disprove a claim of backcrossing, although making it improbable. On the other hand using a mtDNA-based test, the maternal lineage of the individual can always be validated. We suggest that for legal purposes where hybrid backcrossing may exist between abalone species that the genetic "species identity" of an individual be classified as its maternal lineage, which can be confirmed from its mtDNA. Hybrid individuals (those with mtDNA of one species and nuclear DNA wholly or partly of another species) while biologically acknowledged should not be legally recognized as the existence of backcross hybrids cannot be disproved except by probability based on a large number of diagnostic nuclear DNA markers. Mitochondrial DNA in abalone as in most organisms appears to be only maternally inherited (Conod 2000). The aberrant individual in our study therefore is classed as *H. laevigata*.

The advantage of the tests described here to previous studies (Sweijd et al. 1998) for abalone is the smaller size of the DNA fragment; an advantage when examining processed or slightly degraded material (Mackie et al. 1999). The lysin gene protocol described by Sweijd et al. (1998) did aim for fragments less than 300 bp, but the presence of an intron increased this at least three times, and for *H. laevigata* by about ten fold (unpublished data). The authors did however successfully use PCR primers for a smaller 146 bp fragment to discriminate between canned *H. midae* and *H. rubra* products.

PCR inhibition was observed when testing our primers on the mucous samples of *H. rubra*. Dilution (10 fold) to a lower concentration did not have the same inhibitory effect. Similar PCR inhibition due to high levels of polysaccharides is common in plant tissue extracts (Fang et al. 1992), and inhibition due to mucopolysaccharides in the abalone mucous may have caused the observed PCR failure.

No DNA sequence variation was observed between *H. rubra* and *H. conicopora* in either short mtDNA fragment examined in this study. In an assessment of all recent taxa in the family Haliotidae, Geiger (1998) concluded that there was some justification for sub-species recognition of *conicopora* under *H. rubra*. Allozyme data suggested conspecifity but shell and geographic distributions indicated distinct taxa. Fifteen of 22 DNA microsatellite primers developed for use in *H. rubra* amplified a similar product in *H. conicopora* (Evans et al. 2001). This compares to the conservation of only 12 of the 22 markers in other temperate Australian species (*H laevigata, H.scalaris* and *H. roei*). Our short DNA sequences lend some support to the possibility of sub-species status for *conicopora*, however further research is required to resolve the issue.

The altered mobility of the *H. midae* mtCOI fragment run on polacrylamide gels is most likely due to a conformation change. Conformational mutations attributed to sequence-specific variations are restricted to polyacrylamide gels and not seen on agarose gels (Singh et al. 1987). The location and conservation of this conformation variant requires further investigation. Its presence, however, raises a note of caution when using RFLPs as mobility variation of fragments seen on polyacrylamide gels may be misleading as they can be length or conformation polymorphisms. It is therefore recommended that species differentiation using the RFLP tests described here be run only on agarose gels.

The test described here fulfills the aim of our study to provide a relatively straightforward and cost-effective means for identifying several abalone species of commercial importance to Australia. Costs for any DNA-based analyses are not insignificant, but the PCR-RFLP technique is generally considered more cost-effective for routine species identification than alternatives such as direct DNA sequencing of the PCR product (e.g., Asensio et al. 2000). The opportunity to sequence a PCR product is of course still available for differentiation of individuals if problems arise following PCR-RFLP analysis.

To increase the potential value of this study to the sustainability and protection of abalone fisheries worldwide, additional species, particularly from Northern Hemisphere waters, need to be incorporated either into this test or a modified one, so that a single test is available for discrimination of all abalone species.

ACKNOWLEDGMENTS

This study was funded in part by the Australian Fisheries Research and Development Corporation (Project 1999/164), with additional financial assistance from the Tasmanian Abalone Council and the Tasmanian Marine Police. The authors are grateful for their support as well as that provided by the South African Police Services, Phil and Audrey Critchlow, Sandy Degnan, Greg Maguire, Elizabeth O'Brien, Rodney Roberts and Tasmanian Seafoods Pty Ltd. Sharon Appleyard, Malcolm Haddon and Bob Ward provided useful comments on an earlier version of this paper.

DISTRIBUTION AND ABUNDANCE OF *STROMBUS COSTATUS* (GMELIN, 1791) LARVAE AND ADULTS AT THE BIOSPHERE RESERVE: BANCO CHINCHORRO, QUINTANA ROO, MEXICO

ALBERTO DE JESÚS NAVARRETE

Departamento de Pesquerías Artesanales, El Colegio de la Frontera Sur, Unidad Chetumal, A.P. 424, Chetumal Q. Roo, México. C.P.: 97000

ABSTRACT In order to study the distribution and abundance of *Strombus costatus*, larvae and adults, samples were collected bimonthly from August 1997 to July 1998 at six sites at Banco Chinchorro. To collect larvae, replicate surface plankton tows were made with a conical net. Larval density ranged from 0.0018 ± 0.026 veligers/10 m^3 to 4.77 ± 3.50 veligers/10 m^3. Presence of all larval stages suggested a complete development of veligers from egg stage to metamorphic competence in the reef lagoon; 8.52% of the larvae corresponded to stage II veligers, 18% to stage III and 72.65% to stage IV. At the bottom, all conch found within three 100-m^2 replicate areas were counted, shell lengths were measured and egg masses recorded. Conch density varied from 0.0025 to 0.22 conch/m^2 with a dominance of juveniles. The total population in Banco Chinchorro was estimated at 1.3×10^6 conch, but only 8% were estimated to be of legal size. Larvae and adults were more abundant in Cayo Centro, the principal distribution site. Egg masses were abundant from May to October with a greater abundance in May. Banco Chinchorro is an important source of *S. costatus* veligers and sustains an adult and juvenile population within the reef lagoon. Nevertheless, this *S. costatus* population is not large enough to support a commercial fishery. It is necessary to protect the reproduction sites to maintain larval supply downstream.

KEY WORDS: Caribbean, distribution, larvae, *Strombus costatus*

INTRODUCTION

In 1997, Mexico harvested 140,021 tons of mollusks, with a total value of US$39.79 million. This harvest represents 10.06% of the country's total fish and invertebrate catch and corresponds to 4.15% of the total economic value (SEMARNAP, 1998).

In the Yucatan Peninsula, the mollusk fishery is multispecific; catches principally consist of queen conch (*Strombus gigas* Linnaeus, 1758), and on a minor scale, milk conch (*Strombus costatus* Gmelin, 1791), and the fighting conch (*S. pugilis* Linnaeus, 1758). Other gastropods are also caught, such as the red conch, (*Pleuroploca gigantea*, Kiener, 1840) and the black conch, (*Xancus angulata*, Lightfoot, 1786) (Sosa–Cordero et al. 1993; Perez 1997).

The milk conch (*S. costatus*) is widespread in the Caribbean, but it is commercially caught only off the Yucatan (Stoner 1997) where it has the same market value and demand as the queen conch (Aldana-Aranda & Patiño-Suárez 1998). In the South of Quintana Roo fishing regulations only allow harvesting mollusks in Banco Chinchorro. The queen conch is the targeted species and the milk conch are not harvested.

The decline of *S. gigas*, between 1985 and 1990 in the Yucatan Peninsula, led to the closure of the conch fishery off Yucatan State and a ban in some areas off Campeche State and northern Quintana Roo State. In addition, a system of capture quotas was established in sourthern Quintana Roo.

With the descend of the queen conch fishery, alternative sources such as milk conch could be caught to meet the growing demand for conch meat earmarked for the local markets and the Costa Maya's tourism industry in southern Quintana Roo. The potential for the non-exploited resource milk conch, *S. costatus*, needs to be evaluated.

There are only a few studies on milk conch in the Caribbean. Percharde (1968) studied the distribution of the genus *Strombus* in Trinidad and Tobago. Brownell (1977) reported that *S. gigas* was the most important fishery resource in Los Roques, Venezuela, but that other mollusks such as *S. costatus* and *S. pugilis* also contributed to the fishery. Appeldoorn (1985) studied the growth, mortality and dispersion of laboratory reared *S. gigas* and *S. costatus* in Puerto Rico, and Berg et al. (1989) described the abundance and distribution of *S. costatus* in Bermuda. In Mexico, Aldana-Aranda et al. (1989) studied the effect of temperature and algal food on larval growth of milk conch. Recently, Aldana-Aranda and Patiño-Suárez (1998) reviewed algal diets used in larviculture, of several Strombid species, including the milk conch, and Shawl et al. (in press) reared *S. costatus* juveniles raised from egg masses laid in captivity.

There are no studies related to the milk conch at Banco Chinchorro. Consequently, the objective of this work is to describe the distribution and abundance of *S. costatus* adults, determine their reproduction sites, and evaluate larval abundance. This study tests the following hypotheses: (1) the lagoon reef is an important site for reproduction and distribution of milk conch; and (2) there is complete larval development (egg to metamorphosis competence) of this specie in Banco Chinchorro.

MATERIALS AND METHODS

Study Area

Biosphere Reserve Banco Chinchorro is a false atoll on Quintana Roo's South coast, within the Mexican Exclusive Economic Zone (18°23'; 18°47'N, 87°14'; 87°27'W) (Jordán and Martín 1987) (Fig. 1). Chinchorro is 46 km long and 19 km at its maximum width, with a reef lagoon area of 560 km^2. The reef lagoon has an extensive sand bottom with patches of sea grass. In the North these species are most abundant, *Thalassia testudinum* Banks ex Köning, *Halodule wrigthii* Ascherson, and *Syringodium filiforme* Kützing. Reef patches are common in the South region of the lagoon.

Banco Chinchorro has four keys; in the north there are two small keys known as Cayo Norte. In the central area, there is Cayo Centro, which is the largest, and in the southern area, Cayo Lobos which is the smallest (Fig. 1).

E-mail: alberto@ecoosur-qroo.mx

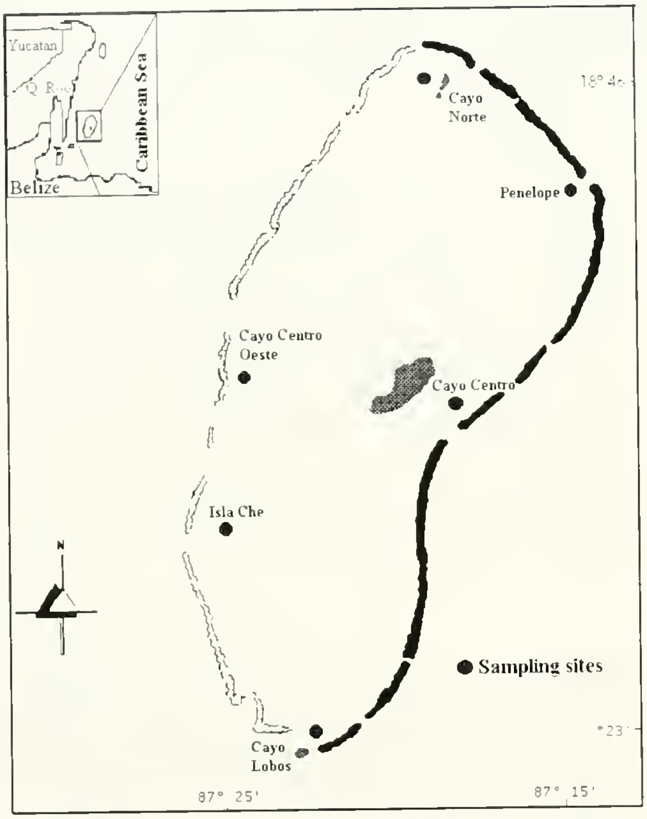

Figure 1. Map of Banco Chinchorro showing six sampling sites within the reef lagoon.

The dry season extends from March to June, while the rainy season is from July to October, and the cold season, characterized by strong northerly winds ("nortes"), is from November to February.

Sampling Methods

Samples were collected bimonthly from August 1997 to July 1998, within the reef lagoon, in six traditional queen conch fishing sites: Cayo Lobos (18°23′45. 0′N, 87°21′ 20.9′W), Isla Che (18°30′ 12.3′N, 87°26′13. 1′W), Cayo Centro (18°33′ 32.7′N, 87°18′ 24.5′W), Cayo Centro Oeste (18°33′24. 1′N, 87°24′; 56.6′W), Penelope (18°42′ 47.6′N, 87°14′55.5′W), and Cayo Norte (18°45′28. 1′N, 87°47′01.1′W) (Fig. 1). At each site, temperature (°C) and dissolved oxygen (mg/l) were measured at surface level using an oxygen meter (YSI model 58). Salinity was measured with a thermoconductivity meter (OHALUS model 50).

Replicate surface plankton tows were made at each site using a conical net, 0.50-m dia, with a 202-μm mesh size. Plankton tows were conducted for 15 min at a velocity of −1.0 m/min. Water volume was measured with a flow meter (General Oceanic model 2031H) attached to the net. Plankton were fixed with a mixture of neutralized 5% sea water-formalin (Stoner & Davis 1997a). Tows were conducted diurnally and additional night collections were made at Cayo Centro and Cayo Lobos.

Gastropod larvae were sorted from other plankton using a dissecting microscope (×20). Identification and developmental stages (I to IV) were assigned following the descriptions of Davis et al. (1993), and larvae were counted and measured for maximum shell length. Total larval abundance was standardized to larvae/10 m^3.

To determine the abundance of juvenile and adult conch, bimonthly samples were conducted at each site. All conch found in each of the three circular unit replicates (100 m^2) were counted. The shell length and lip width were measured to the nearest mm using calipers, after measurements all conch were returned to the sea bottom. Egg masses within the unit samples were counted.

Conch abundance was compared among months and sites sampled using a two-way Analysis of Variance (ANOVA), on Log (x + 1) transformed data. The procedure considered independence between sites and months.

RESULTS

Maximum mean temperatures were recorded during August and October, 28.9 ± 0.55 and 29.3 ± 0.28°C ($n = 6$), respectively, whereas lowest temperature occurred in December (26.3 ± 0.94 $n = 6$). Dissolved oxygen varied between 5.87 ± 0.37 mg/l in July and 7.01 ± 0.56 mg/l ($n = 6$) in August. Salinity ranged from 35.9 ± 0.12% in October to 37.0 ± 0.9‰ ($n = 6$) in March.

A total of 245 larvae were collected over the 12 months. Most larvae were collected in July during night tows (158 veligers at Cayo Lobos and 75 veligers at Cayo Centro). Diurnal tows contained a very low number of veligers. Six larvae were collected in October; one at Isla Che, one at Cayo Centro, and four at Centro Oeste. In May, six larvae were collected at Penelope. No veligers were found in August, December, and March. Larvae were categorized into the following stages, 8.53% of larvae were stage II (451–750 μm), 18.77% corresponded to stage III (751–950 μm) and 72.65% were stage IV at Cayo Centro in October, to 4.77 ± 3.50 veligers/10 m^3 at Cayo Lobos in July (Table 1).

A total of 280 juvenile and adult conch were collected during the sampling period. Conch abundance was significantly different between sites ($P = 0.0036$), Cayo Centro had the highest density and Isla Che had the lowest (Tables 2 and 3). A total 184 individuals were found at Cayo Centro; 89 conch were collected in

Milk conch adults density (no. conch/m^2) at Banco Chinchorro.

	Cayo Lobos	Isla Che	Cayo Centro	C. Centro Oeste	Cayo Norte
August	0.0075	0	0.0075	0.0025	0.0100
October	0.0050	0.0025	0.0825	0.0025	0.0200
December	0.0125	0.0025	0.0025	0	0
March	0.0725	0	0.2225	0.0125	0.0125
May	0	0	0.1400	0	0.0025
July	0.0125	0.0025	0.0050	0.0050	0.0550

March, 56 in May, 33 in October, 3 in August, 2 in July, and 1 in December. Juvenile and adult density varied from 0.0025 conch/m^2 to 0.222 conch/m^2. Despite significant differences between sites (Table 3), a uniform conch distribution was used to calculate the population size at Banco Chinchorro. Based on the lowest conch density (0.0025 ind/m^2), and a lagoon area of 560 km^2 for Banco Chinchorro, a total of 1.3×10^6 conch were estimated. However, only 100,000 conch were estimated to be harvest size (8%). This low population size does not appear sufficient to support a commercial fishery.

The highest numbers of conch found in Banco Chinchorro were collected in March, with a total of 128 organisms. Fifty-seven conch were collected in May, 45 in October, 32 in July, 11 in August, and 7 in December. The size-frequency distribution varied from 30 to 180 mm shell length with 92% of total sample of conch in the range of 81 to 160 mm shell length (Fig. 2).

Reproductive activity, copulation, and the presence of egg masses in medium sands, were observed from March to December. A total of 113 egg masses were counted with the majority at Cayo Centro (39 egg masses in October, 58 in May, and 1 in December). Fifteen egg masses were counted at Cayo Lobos in March.

DISCUSSION

Temperature has a direct influence on the beginning and cessation of conch reproductive activity, egg-hatching time, and on the duration of the larval phase (Berg et al. 1989; Appeldoorn et al. 1983; Stoner et al. 1992; Stoner & Davis 1997a; Pechenik 1999).

At Banco Chinchorro, egg masses of *S. costatus* were first observed in March and were found until December when bottom water temperature decreased to 26.3°C. In Banco Chinchorro, the reproductive season of *S. costatus* is during a ten-month period, with a peak in copulation and egg laying in May. This period is longer than in Trinidad and Tobago where mating occurs from November until June (Perchard 1968) and longer than in Venezuela, where reproduction occurs from November to May (Brownell 1977). In comparison, the reproductive season for queen conch, *S. gigas*, has great variation. It varies from 5 to 12 months, with the shortest season duration in Bermuda and Florida and the longest at Banco Chinchorro (Cruz 1984; Corral & Ogawa 1987; Stoner et al. 1992). A difference in reproductive cycles of *S. gigas* and *S. costatus* as a function of temperature was mentioned by Brownell (1977). He observed that *S. costatus* reproductive season began when the season for *S. gigas* usually ended. Brownell (1977) associated this with a one-centigrade degree decline in mean water temperature. However, in this study *S. costatus* reproduction season was from March to December and coincided with *S. gigas* reproduction period at Banco Chinchorro.

In Banco Chinchorro, the number of *S. costatus* egg masses exceeded that of *S. gigas* (113 vs. 19 egg masses) for the same study period (de Jesús-Navarrete 1999). This could be an effect of fishing activities, because only *S. gigas* is collected not *S. costatus*. Females constitute a high percentage (–65%) of the *S. gigas* catch, (pers. obs.) and that might also explain why there were higher number of *S. costatus* egg masses, juvenile and adults than *S. gigas*, in some areas, like Cayo Centro.

Fishing practices are known to modify the structure of populations by reducing the overall biomass (Alcalá, 1988; Roberts, 1995), decreasing age and size at sexual maturity (Harmelin et al. 1995), and altering sex ratios and genetic structure (Ryman et al. 1995). The displacement of target species due to the effect of fishing pressure and a consequently higher abundance of non-target species was mentioned by Seijo et al. (1997). This may be happening in Banco Chinchorro, as the *S. gigas* population declines there may be an increase in the *S. costatus* density, due to habitat and food resources becoming available.

A greater quantity of *S. costatus* larvae was found in July when mean water temperature was at its maximum. It is possible that this is related to higher egg mass production, and increase in food availability for the larvae (Davis 1998). Local water circulation might also influence number of larvae retained inside of Banco Chinchorro. Larvae were collected from nearly all stages (II, III and IV) indicating a complete larval growth process within the reef lagoon. Although the current circulation pattern of Banco Chinchorro is unknown, it is probably influenced by trade winds, and

TABLE 3.

Results of two way ANOVA of *S. costatus* abundance in Banco Chinchorro Quintana Roo, Mexico.

Source of Variation	Sum of Squares	D.F.	Mean Square	F-ratio	p-level
Sites	20.5434	5	4.1086	4.7170	0.00364
Months	8.24020	5	1.6480	1.8229	0.1310

this circulation would transport larvae toward the interior of the reef lagoon causing local retention. In Florida, Stoner et al. (1997) found that larvae of *S. costatus* were very abundant in early stages and rare in advanced development stages. They noted that the abundance of later larval stages was associated with water flow produced by the wind, which suggests local recruitment from spawning populations that inhabit outer reefs. The same effect could occur in Banco Chinchorro. Evaluating populations outside of the reef lagoon might explain why 68% of the larvae were collected at Cayo Lobos, the southern site of Chinchorro. The high number of larvae may indicate a contribution from deep-water *S. costatus* populations or populations external to Banco Chinchorro.

The density of *S. costatus* larvae found in this study (4.77 ± 3.50 veligers/10 m^3) is higher than the values reported from other sites in the Caribbean. In Florida, densities of 0.04 to 1.40 veligers/10 m^3 have been found with maximum abundance peaks in June (Stoner et al. 1997). In the Bahamas, Stoner and Smith (1998) reported *S. costatus* densities ranging from 0.026 to 0.069 veligers/10 m^3. In Banco Chinchorro, the higher percentage of *S. costatus* larvae in night tows (95p), may be due to lack of intense surges and wind action that were prevalent during the day. Stoner and Davis (1997b) documented vertical movement of *S. gigas* larvae toward deeper zones due to wind and surge effect, and Stoner and Smith (1998) noted that wind and surge also produce horizontal transportation of larvae.

Density of *S. costatus* adults and juveniles found in Banco Chinchorro is higher (0.22 conchs/m^2) than other values reported in the Caribbean. In Bermuda, *S. costatus* density was highest in the basins, (0.00299 conchs/m^2), than on the platform, (1.9×10^{-4} conchs/m^2) (Berg et al. 1989). In Puerto Rico, the density of *S. costatus* varied from 0.18×10^{-4} conchs/m^2 in reef patches to 0.0032 conchs/m^2 in coarse sands to 0.0049 conchs/m^2 in rubble areas (Appeldoorn 1985). Although the densities found in Banco Chinchorro exceed these values, 92% of the population consisted of individuals smaller than 170-mm shell length, which cannot support commercial harvest. In Yucatan State, *S. costatus* shell sizes varied from 65 to 225 mm shell length, and legal fishing size (180 mm) represented over 65% of the relative abundance of conch catches. (Perez 1997). In Banco Chinchorro, the large size was 180-mm shell length and this represented only 8% or an estimated population of 100,000 conch. Therefore commercial catch of this species is not recommended.

Banco Chinchorro was designated as a Biosphere reserve in 1996. The main goals were to conserve biodiversity, protection, and enhance overexploited species, such as queen conch (*S. gigas*) and spiny lobster (*Panulirus argus*). It is now clear that other species should be considered in the management plan, including the milk conch, *S. costatus*.

Many marine reserves like Banco Chinchorro, have small nucleus areas to protect fishing species. At Banco Chinchorro, only 3.2% of the total lagoon area comprises of protected zones. It is likely that these areas do not contain the full habitats needed to protect or enhance species during their entire life cycle. Therefore, the role of these nucleus areas in protecting species and connecting different habitats together cannot be totally ascertained (Appeldoorn & Lindeman, in press). In the establishment of management plans, data on distribution and abundance of adults and larvae, reproductive sites, egg mass numbers, and recruitment dynamics at a regional level are required. For example, the data from this study suggests that critical areas like Cayo Centro with its high distribtuion of milk conch adult, juveniles, egg masses and larvae needs to become a conch protected area within the Biosphere Reserve Banco Chinchorro.

In general, marine reserves help to protect some fishing species, and can be effective in the recovery of commercial exploited species (Alcalá 1988; Roberts & Polunin 1991; Roberts 1995; Allison et al. 1998). However, to assure conservaton of the species it is essential to design reserves with an understanding of the ontogenetic requirements of target and non-target species. Reserves need to be placed in strategic locations to protect larval production sites and settlement sites. This information on source sites and sink sites will support metapopulation dynamics, and help in optimize fishery benefits for many marine invertebrates species like *S. costatus* that have a pelagic larvae. In the Bahamas, a high density of *S. gigas* larvae and adults have been reported in a protected area in Bahamas (Stoner & Ray 1996). It is possible that both *S. gigas* and *S. costatus* populations in Banco Chinchorro can be maintained for conservation and fisheries if reserve areas are expanded and management regulations to be practiced.

VELAR CHARACTERISTICS AND FEEDING CAPACITY OF ENCAPSULATED AND PELAGIC LARVAE OF *CREPIDULA FECUNDA* GALLARDO, 1979 (GASTROPODA, CALYPTRAEIDAE)

O. R. CHAPARRO,[1] A. E. SOTO,[1] AND C. E. BERTRAN[2]

ABSTRACT Veligers of *Crepidula fecunda* develop the capacity for ingesting particulate material during early stages of their development within the egg capsules. The potential feeding rate of encapsulated larvae is low compared with that of hatched larvae and pelagic larvae of other mollusks. Once the veligers emerge from the capsules, they increase the capacity for particle retention. This situation could result from the increase in the velar area, length of the ciliated border, length of the preoral cilia, potential filtering area and the width of the feeding canal, or to some combination of these, compared with encapsulated larvae of the same shell length. Extra-capsular development of the velum is an adaptive feature of the species which promotes efficient feeding and active locomotion during the pelagic phase, in preparation for settlement and metamorphosis on inshore rocky substrates.

KEY WORDS: *Crepidula fecunda*, veliger larvae, velar morphology, particle clearance rate

INTRODUCTION

The presence of a lobed velum is a common characteristic in veliger larvae of the Mollusca (Strathmann & Leise 1979), where in free living species the velar lobes carry out functions of swimming and feeding (Hadfield & Iaea 1989). Veligers have external borders on the velar lobes that include preoral and postoral ciliary bands (Strathmann et al. 1972; Strathmann & Leise 1979). The pre-oral band is formed of long cilia that produce water currents used in locomotion and feeding. The postoral band consists of shorter cilia that beat toward the preoral band. The combined activity of these ciliary bands promotes capture and retention of food particles. Between the two ciliary bands lies the food canal covered with very small cilia that transport food particles to the larval mouth.

In suspension-feeding mollusks the particle clearance rate (CR) may be used to calculate ingestion rate when food concentration is known (Sprung1984). Clearance rate in veliger larvae is partially determined by the length of the velar margin and the length of the preoral cilia (Strathmann et al. 1972). Strathmann and Leise (1979) observed that although longer preoral cilia were related to higher rates of water flow, they were less efficient in capturing particles in the smaller size ranges. The latter may be compensated for by an increase in total filtering area that increases the larval clearance rate. In addition to ciliary size, the length of the velar margin is important in larval feeding. Increase in ciliated area is accompanied by an increase in CR (Strathmann et al. 1972). The rate of clearance is not only influenced by the factors cited, but also by the ability of the organism to transport captured particles away from the primary sites of capture to the mouth. Thus, the rate at which the cilia in the food canal transport particles to the mouth directly affects the overall CR.

Crepidula fecunda, a sedentary filter-feeding gastropod, inhabits intertidal and shallow subtidal zones on the Chilean coast. It is a protandric hermaphrodite whose reproductive mechanism includes the deposition of egg capsules on rocky substrates, followed by parental brooding (Gallardo 1976, 1977, 1979). Most eggs in the capsules develop, and veliger larvae of approximately 500 μm in shell length are released from the capsules (Gallardo 1976, 1977, 1979) to complete their development in the inshore plankton prior to settlement.

Encapsulated larvae have no apparent source of food, and it is not known whether they are capable of suspension-feeding prior to eclosion. Development of the ciliated velum within the capsule (Gallardo 1977, 1979; Chaparro et al., in press) suggests that these larvae are capable of feeding and swimming before hatching, and that these properties would improve upon eclosion, since the pelagic larvae must actively feed and swim in preparation for settlement and metamorphosis (Gallardo 1977, 1979, 1989). We hypothesize that the ability of *C. fecunda* larvae to remove particles from suspension is initiated during the intracapsular phase and further developed during the pelagic phase, including increases in the size of the cilia, filtration area, and capacity for particle transport within the larval food groove.

MATERIALS AND METHODS

Stacks of adult specimens of *C. fecunda* were collected from the intertidal at Yaldad Bay, Chiloé (43°08′S; 73°44′W). In the laboratory, individuals were removed from the substrate in order to expose the egg capsules from which embryos and/or larvae were obtained for experimentation. Before each experiment, the capsules were observed under a stereomicroscope to identify the developmental stage of the embryos.

Developmental stages (egg, morula, blastula, trochophore, and veliger) were identified by their morphology. Fifteen to 20 individuals of each group of larvae were observed microscopically and videotaped as described below. The shell lengths of the larvae were determined from images captured on videotape (see later).

Clearance Rate

Clearance rate (CR) was quantified in several encapsulated stages and in pelagic veligers using the method of Coughlan (1969). Several thousands of embryos (egg, morula, trochophore) and veliger larvae from different spawning masses were manually removed from capsules and placed in individual 1-L glass aquaria containing 500 ml 0.45 μm filtered seawater (salinity 30 ‰, temperature 17°C). Embryos used in each aquarium came from the same egg mass. Laboratory cultured *Isochrysis galbana* was added to each experimental system (final concentration 3×10^4 cells/ml

Aquaria were stirred to ensure adequate mixing. At intervals between one and two h, the concentrations of algae remaining in the aquaria were determined using an ELZONE 180 XY particle counter. Control aquaria were run during each experimental period under the same experimental conditions but without larvae.

At the end of each experiment, five samples of 1.5 ml each were obtained from each experimental system to determine the number of embryos or larvae in each aquarium. For measurement of shell length, larvae from each experiment were fixed in 5% formaldehyde and stored in Eppendorf tubes to await analysis. They were measured as previously described.

Larval cultures were maintained to determine the CR of pelagic larvae of *C. fecunda*. Naturally hatched larvae were collected on a 100 µl nylon screen as they emerged from the capsules and placed in 100-L aquaria containing filtered seawater as described above, with gentle aeration. Each day the larvae were fed *ad libitum* with *I. galbana*. The seawater was replaced every two days. For determination of clearance rate, a known number of larvae were placed in experimental aquaria as described above for the encapsulated larvae, and the same procedures used to determine CR. Groups of larvae from these experiments were also set aside for measurement of shell length.

Velar Morphology

Larvae obtained from capsules as well as pelagic larvae were videotaped by placing them in a plankton decantation chamber with seawater under an inverted microscope fitted with a video camera. Selected images were captured for subsequent processing on a computer equipped with an ATI Corp. "All in Wonder" video card and Scion Image 3.0 PC software. We obtained the velar area (extended velar lobe), length of the ciliated border, length of the preoral cilia, and shell length. The width of the food canal was also determined. The potential feeding area was calculated by multiplying the length of the ciliated border by the length (=height) of the cilia in the preoral band.

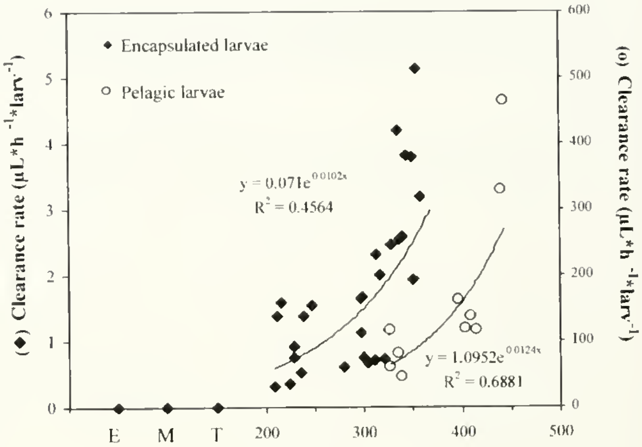

Figure 1. Clearance rate in different embryonic stages, encapsulated (n = 28) and pelagic (n = 10) larvae of *C. fecunda*. E = egg (n = 5), M = morula (n = 5) ,T = trochophore (n = 5).

Velocity of Particle Transport

A suspension of red plastic particles 2–10 µm in diameter was offered to larvae in a plankton settling chamber as previously described by Chaparro et al. (1993). Trajectories of these particles along the food groove were videotaped as described above for observing larvae, and the distances traversed by the particles were calculated using the Scion Image PC program. Simultaneously, the time taken by particles to traverse measured distances was determined (Ward 1996) for calculations of transport velocity. These determinations were carried out on larvae obtained from capsules and on pelagic (cultured) larvae.

RESULTS

Clearance Rate

No uptake of particles was observed in early developmental stages, including the egg, morula, blastula and trochophore (Fig. 1). The clearance rate (CR) of encapsulated veligers of *C. fecunda* increased with the size of the individuals. The initial CR was 0.31 µl h^{-1} larva^{-1} in larvae with shells 208 µm in length, increasing to 5.13 µl h^{-1} larva^{-1} in pre-hatched larvae 353 µm in shell length (CR = 0.071e$^{0.012*\text{larval shell length}}$, r^2 = 0.4564, n = 28) Figure 1.

Recently hatched veliger larvae showed much higher values for CR than those of the same size that remained encapsulated (Table 1). CR values ranged from 45.3µl h^{-1} larva^{-1} in larvae 337 µm in shell length at one day post-eclosion to 464 µl h^{-1} larva^{-1} in larvae 442 µm in shell length at 13 days post eclosion (CR = 1.0952 e$^{0.0124*\text{larval shell length}}$, r^2 = 0.6881, n = 10) Figure 1.

Velar Morphology

Velar Area

The velar area of encapsulated larvae showed linear growth during the developmental period, fluctuating between 0.012 mm^2

TABLE 1.

***Crepidula fecunda*. Comparison of clearance rate (CR), area of a velar lobe (VA), length of ciliated velar border (LCVB), length of preoral cilia (CL), potential filtering area (PFA), and width of food groove (WFG) in encapsulated and pelagic larvae. Values represent individuals of 340 µm in shell length and were obtained from appropriate regression equations. (%) = percent increase in variable when comparing pelagic stage (recently eclosed) with encapsulated larvae having the same shell length.**

Stage	Shell length (µm)	CR (µl · h^{-1} · larv^{-1})	VA (mm^2)	LCVB (mm^2)	CL (µm)	PFA (mm^2)	WFG (µm)
Encapsulate	340	2.28	0.037	688	66	0.034	19
Pelagic	340	74.21	0.049	739	83	0.061	21
%			32.4	7.4	25.8	79.4	10.5

in larvae 188 μm in shell length and 0.056 mm^2 in larvae 372 μm in shell length (velar area = 0.0002 × larval shell length − 0.0312, $r^2 = 0.8755$, $n = 52$) Figure 2.

In recently liberated pelagic larvae of *C. fecunda* the velar area was 32.4 % greater than in encapsulated larvae having the same shell length (Table 1). The velar area was 0.054 mm^2 in recently eclosed larvae 340 μm in shell length, reaching 0.198 mm^2 in larvae ready for metamorphosis at 16 days post-eclosion at 650 μm shell length (velar lobe area = $(6 \times 10^{-7}) \times (\text{larval shell length})^{1.9421}$, $r^2 = 0.9586$, $n = 5$) Figure 2.

Length of Ciliated Velar Border

The length of the ciliated border in encapsulated larvae showed gradual growth with development. The initial length, 287 μm in larvae 205 μm in shell length, increased to 755 μm in larvae 372 μm in shell length (length of ciliated velar border = 858.36 × ln (larval shell length) − 4315.5 , $r^2 = 0.9724$, $n = 19$) Figure 3.

The length of the ciliated velar border in recently liberated pelagic larvae of *C. fecunda* was 7.4% greater than that of encapsulated larvae having the same shell length (Table1). The length of the border varied from 772 μm in larvae of 340 μm shell length, to 1548 μm in larvae of 650 μm shell length (ciliated length of velar border = $1.7826 \times (\text{larval shell length})^{1.0341}$, $r^2 = 0.9307$, $n = 5$) Figure 3.

Length of Preoral Cilia

These cilia showed rapid growth during intracapsular development, reaching lengths of 80 μm in larvae with shell length 400 μm (ciliary length = $-0.0023\,(\text{larval shell length})^2 + (1.7307 \times \text{larval shell length}) - 256.29$, $r^2 = 0.8954$, $n = 29$) Figure 4.

The preoral cilia of recently hatched pelagic larvae were approximately 25.8% longer than the cilia of encapsulated larvae having the same shell length (Table 1). The length of these cilia in recently eclosed larvae was about 82 μm. This increased to 111 μm in those larvae at 15 days post eclosion that were ready to undergo metamorphosis (ciliary length = $61.316e^{0.0009 * \text{larval shell length}}$, $r^2 = 0.9041$, $n = 5$) Figure 4.

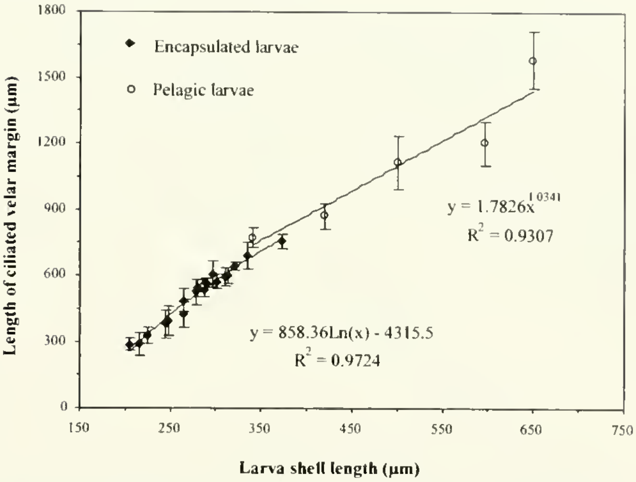

Figure 3. Length of ciliated velar margin (periphery of an extended velar lobe) in relation to larval size in encapsulated ($n = 19$) and pelagic ($n = 5$) larvae of *C. fecunda*. When the SD bar is not shown, it is smaller than the symbol size. Each data point represents the mean for at least 15 individuals for encapsulated larvae and 25 individuals for pelagic larvae.

Potential Filtering Area

The potential filtering area increased during larval development from 0.002 mm^2 in larvae of 205 μm shell length to 0.054 mm^2 in larvae of 372 μm shell length [potential filtering area = $(-5 \times 10^{-7}) \times (\text{larval shell length})^2 + (0.0006 \times \text{larval shell length}) - 0.1121$, $r^2 = 0.9417$, $n = 16$] Figure 5.

In recently eclosed pelagic larvae, the potential filtering area was about 79.4% greater than that of encapsulated larvae of comparable shell size (Table 1). This value was 0.06 mm^2 in one-day-old larvae, increasing to 0.18 mm^2 in larvae at 15 days post eclo-

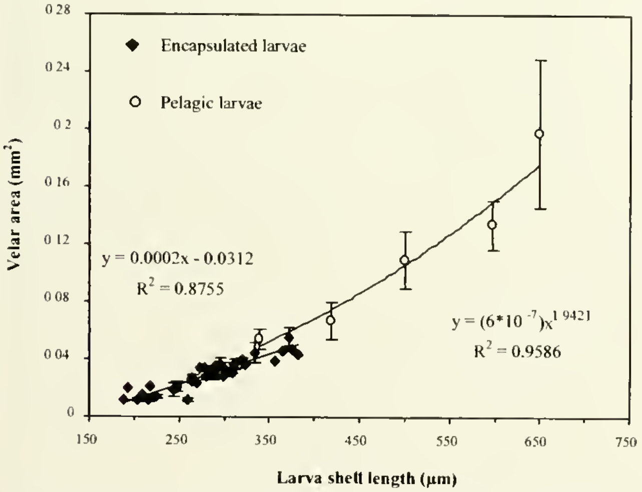

Figure 2. Area of an extended velar lobe in relation to size in encapsulated ($n = 52$) and pelagic ($n = 5$) larvae of *C. fecunda*. When the SD bar is not shown, it is smaller than the symbol size. Each data point represents the mean for at least 10 individuals for encapsulated larvae and 25 individuals for pelagic larvae.

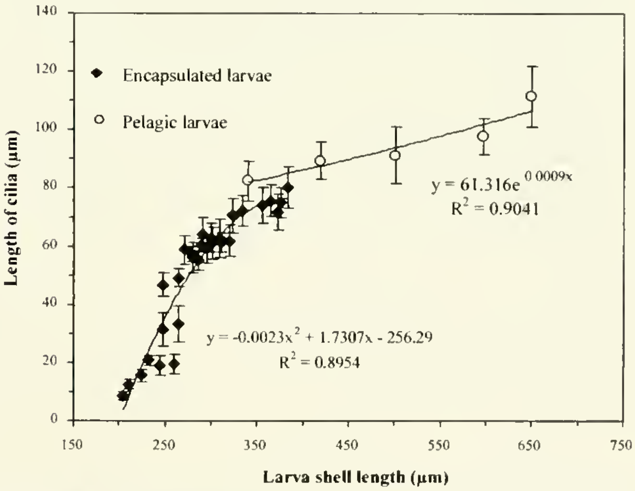

Figure 4. Length of preoral cilia in relation to larval size in encapsulated ($n = 29$) and pelagic ($n = 5$) larvae of *C. fecunda*. When the SD bar is not shown, it is smaller than the symbol size. Each data point represents the mean for at least 15 individuals for encapsulated larvae and 25 individuals for pelagic larvae.

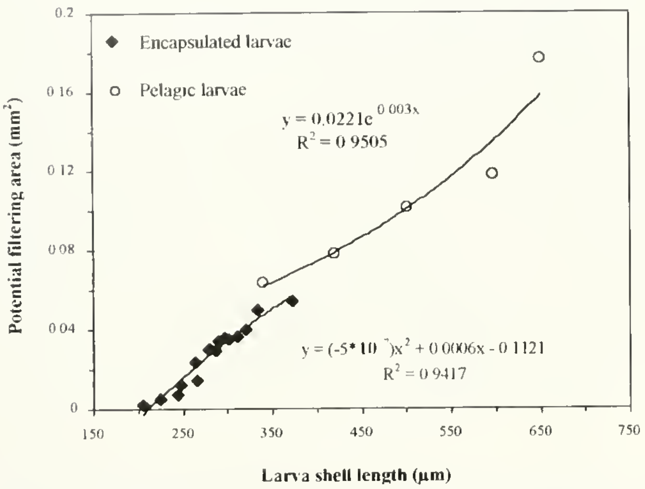

Figure 5. Potential filtering area in relation to larval size in encapsulated ($n = 16$) and pelagic ($n = 5$) larvae of *C. fecunda*. Each data point was calculated by multiplying the mean length of the ciliated velar edge by the mean length of the preoral cilia.

sion (potential filtering area = $0.0221e^{0.003*\text{larval shell length}}$, $r^2 = 0.9505$, $n = 5$) Figure 5.

Width of Food Groove

The width of the larval food groove increased with the size of the individual. The groove of encapsulated larvae 205 µm in shell length was 6.22 µm wide, increasing to 34.98 µm in pelagic larvae of 650 µm shell length (Fig. 6). In recently eclosed larvae, the width of the food groove was 10.5% greater than that of encapsulated larvae of the same shell length (Table 1).

Velocity of Particle Transport in the Food Groove

Particle transport velocity increased throughout the larval encapsulation period, with minimum values of 86 µm s^{-1} in larvae 225 µm in shell length, increasing to 270 µm s^{-1} in larvae 300 µm in shell length (approaching eclosion) [particle velocity = $0.02 \times (\text{shell length})^{1.622}$, $r^2 = 0.3562$, $n = 16$] Figure 7.

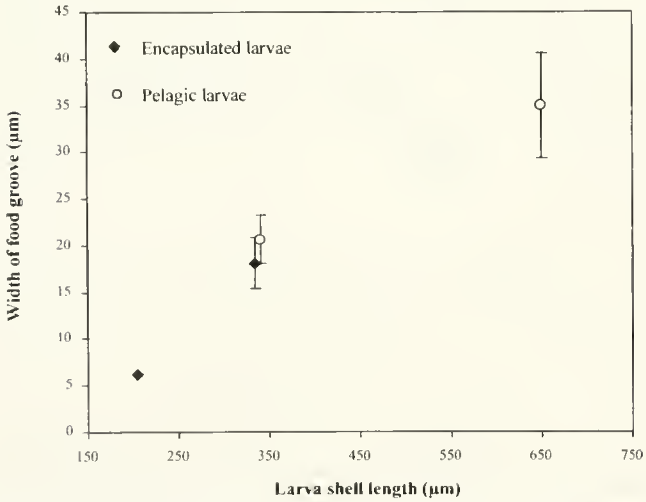

Figure 6. Width of larval feeding groove in relation to individual size in *C. fecunda*. Vertical bar = standard deviation.

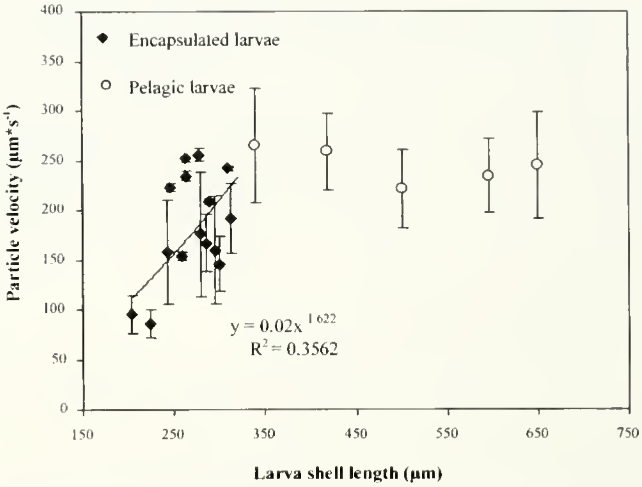

Figure 7. Transport velocity of particles in the larval food groove in relation to individual size in encapsulated ($n = 16$) and pelagic ($n = 5$) larvae of *C. fecunda*. When the SD bar is not shown, it is smaller than the symbol size. Each data point represents the mean for at least 10 individuals for encapsulated larvae and 20 individuals for pelagic larvae.

In pelagic larvae the velocity of the particles remained relatively constant with values near 250 µm s^{-1} (Fig. 7).

DISCUSSION

All encapsulated stages of *C. fecunda* veligers are able to ingest particulate material. This ability is related to the development of the ciliated velum (Gallardo, 1977, 1979), and particularly to the presence of opposed ciliary bands (Chaparro et al., in press). In the pelagic phase of the life cycle, development of the velum is of vital importance to swimming and feeding prior to settlement in this species, thus a large and well developed velum appears to be related to the mixed developmental strategy used by *C. fecunda* (Gallardo, 1979).

Encapsulated larvae of *C. fecunda* develop the ability to ingest particles before their transition to the planktotrophic habit. Chaparro et al. (in press) have observed particle capture and ingestion by pre-eclosed larvae which were fed immediately after artificial excapsulation, suggesting readiness for the planktotrophic phase.

The low CR observed in veligers removed from capsules is probably attributable to the early stage of development, as observed in larvae of other molluscan species (Hawkins et al. 1984; Welborn & Manahan 1990). Values for particle clearance by *C. fecunda* veligers obtained from capsules are lower in all cases than values reported in the literature for pelagic molluscan larvae (MacDonald 1988; Sprung 1984; Bayne 1965), although CR in *C. fecunda* pelagic larvae is well above the rates cited by these authors.

The rapid growth of the velum in encapsulated larvae of *C. fecunda* may be related to the mode of nutrition and the necessity for efficient swimming in the pelagic stage. Once the larva is free from the capsule, it is advantageous to have as large a velum as possible (Fretter & Graham 1962).

The increase in the length of the ciliated border of the velum in *C. fecunda* is a result of enlargement of the bilobed velum, not the formation of new lobes. The length of the preoral cilia in encapsulated and pelagic larvae of this species falls within the size range reported by Strathmann (1987), i.e., 30 to more than 100 µm, and also agrees with the 50 μm value given by Riedel (1992) for larvae of the gastropod *Cabestana spengleri* (200 μm shell length), which also exhibits mixed development.

The potential filtering area of recently eclosed pelagic larvae is nearly 80% larger than that of encapsulated larvae of the same size (370 μm shell length). This is due to the elongation of the ciliated border of the velum and growth of preoral cilia, and provides the larvae with a large surface area for particle capture, as suggested by the CR of pelagic larvae in this study. This is consistent with observations on the planktotrophic character of these larvae (Gallardo, 1977, 1979, 1989). The transport velocity of particles within the food groove of encapsulated larvae of *C. fecunda* increases with developmental stage to values near 250 μm s^{-1}. In pelagic larvae this velocity is more or less constant but the width of the food canal continues to increase during pelagic development, suggesting that pelagic larvae are able to capture and handle several particles at the same time, or increasingly larger particles (or particle aggregates) as they develop. Together with the increase in potential filtering area, this may explain the high values for CR in pelagic larvae of *C. fecunda*.

The greater capacity for particle clearance in pelagic larvae compared with encapsulated larvae in *C. fecunda* may be related to increases in the velar area, cilated length of the border of the velum, length of the preoral cilia, potential filtering area, and the width of the food groove, or to some combination of these variables. These changes are obviously adaptive as the larvae are released into the environment, where they must be able to swim and feed before settling. Some larvae remain in the capsule, yet have a shell size similar to that of newly released larvae, suggesting a differential rate of development between shell and velum, the latter requiring more time to develop before eclosion.

DISTRIBUTION, DENSITY AND LENGTH-WEIGHT RELATIONSHIP OF *CHITON ARTICULATUS* SOWERBY, 1832 (MOLLUSCA-POLYPLACOPHORA) ON ISLA SOCORRO, REVILLAGIGEDO ARCHIPELAGO, MEXICO

OSCAR EFRAÍN HOLGUIN QUIÑONES AND JESÚS EMILIO MICHEL-MORFÍN
Centro Interdisciplinario de Ciencias Marinas Instituto Politécnico, Nacional Apartado Postal 592, La Paz, B.C.S. 23096, México

ABSTRACT *Chiton articulatus* is an abundant mollusk species on the Isla Socorro. In March 1992 *C. articulatus* populations were sampled at four sites on the southwestern and northern coast of the island. Average densities of *C. articulatus* ranged between 3.7 to 8.5 ind/m^2 among sites. The length-weight relationship for all sampled individuals (N = 385) is W(g) = 0.00022 L$^{2.73}$.

KEY WORDS: *Chiton articulatus*, mollusk, distribution, density, Isla Socorro

INTRODUCTION

Chitons are polyplacophoran mollusks that are common grazers of intertidal epilithic and endolithic algae. Since their first appearance in the late Cambrian, chitons have modified hard marine substrates using their strong radula (Glynn 1970; Rasmussen & Frankenberg 1990).

Chiton articulatus is a species that was recently very abundant along the Pacific tropical coast of Mexico, today *C. articulatus* is uncommon because of over exploitation by fishermen. The foot is commercially utilized and sought in subsistence fisheries. In the Revillagigedo Archipelago (Fig. 1) it is a potential resource that has integral usage possibilities, it is still an important member of the malacofauna since it has not been fished commercially (Villalobos 1960; as *C. laevigatus*, Keen 1971; Ferreira 1983; Holguin et al. 1992; Holguin 1994; Bautista-Romero et al. 1994; Mille-Pagaza et al. 1994; Emerson 1995).

Only one study has been conducted for the Mexican Pacific continental shore population of *C. articulatus*, in the Acapulco area (Rojas-Herrera 1988). Little is known about the Revillagigedo Archipelago chiton populations, because of its distance from the Mexican mainland. This article describes the distribution, density and length-weight relationship of *C. articulatus* sampled on Isla Socorro, Revillagigedo in March 1992.

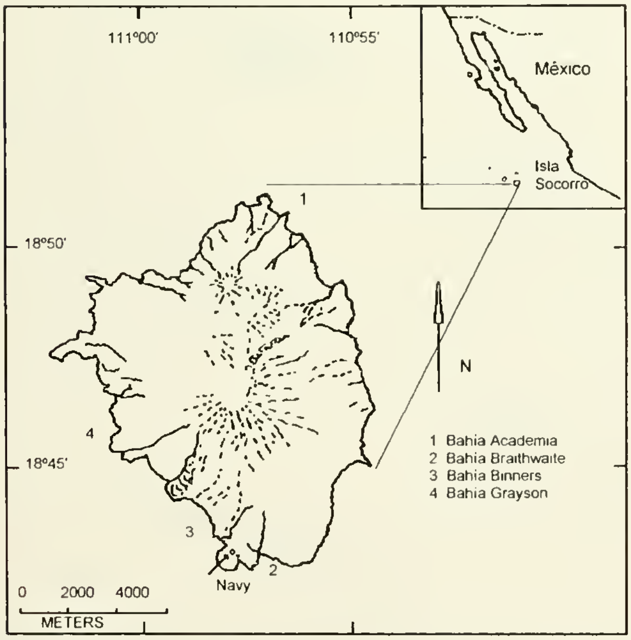

Figure 1. Map of the sampling sites on Isla Socorro, Revillagigedo, March 1992.

MATERIALS AND METHODS

The Revillagigedo Archipelago (Fig. 1) is located approximately 350–650 km, southeast of the Baja California Peninsula and 580 km west of the Colima coast (Llinas-Gutierrez et al. 1993). The Archipelago is comprised of four oceanic islands of volcanic origin, Socorro, Clarion, San Benedicto and Roca Partida.

The surface area of Isla Socorro, the largest island, is 167 km^2 with a maximum diameter of 16 km in a NW-SW direction. Geographically Isla Socorro is located at 18°41′57″N and 110°56′33″W (Troyo-Diéguez & Pedrín 1994). The island is composed primarily of braced igneous rock, with the presence of smooth stones and sandy or stone-sandy beaches (Holguin 1994).

During March 1992, *C articulatus* were sampled in the following rocky areas, from south to north (Fig. 1): Bahía Braithwaite (La Braulia), Bahía Binners, Bahía Grayson (Palmasola), and Bahía Academia (Playa Norte). Some of the areas are more accessible than other areas where there is a greater abundance of organisms. At each one of the four sampling locations, we took samples along a transect of 50 m^2 in the intertidal zone. We laid out transects parallel to the coast line, using 25 m cord which delineated a 2 m wide sampling swath. The entire sampling was accomplished during ebb tides. The density of *C. articulatus* in

Mean densities for *Chiton articulatus* at four sites on Isla Socorro, Revillagigedo, México, March 1992.

Locality	Area (m^2)	No. Total Organism	Relative Density (m^2)	Maximum Number Chitons Grouped
Bahía Binners	50	186	3.72	22
Bahía Braithwaite	50	424	8.48	35
Bahía Grayson	50	193	3.86	33
Bahía Academia	50	249	4.38	[illegible]

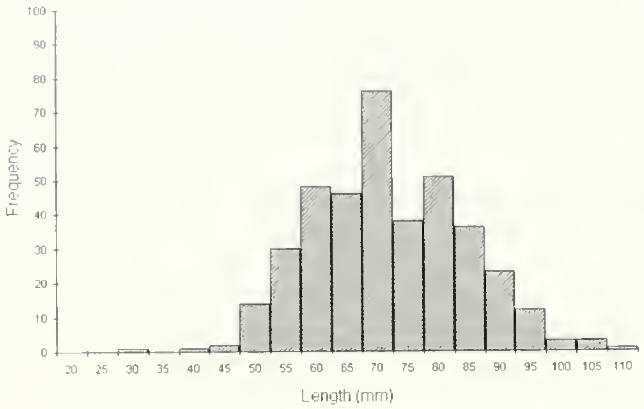

Figure 2. Length frequency distribution of *Chiton articulatus* sampled on Isla Socorro, Revillagigedo, March 1992.

each rocky shore area was determined from the count of all living organisms present in the transect. The maximum number of the chitons grouped was determined.

A sample of 30–40% of chitons (N = 385) was taken from the transects in order to be measured and weighed. The length and weight measurements from selected chitons were recorded. The length was measured using a vernier caliper, taking the major distance between the front and the posterior parts of the body. Weight, including the shell, was obtained with a three-arm scale having an accuracy of ±0.5 g. We liberated all the animals in the rocky intertidal zone after measuring them.

RESULTS AND DISCUSSION

On Isla Socorro all rocky coasts exposed to strong waves are populated by *Chiton articulatus*. The species is discontinuously distributed along the reef line; in some areas adult animals over 4 cm length were found crowded within a narrow belt along the coast, while in adjacent areas animals bigger than 3 cm were not found at all. According to Rojas-Herrera (1988) the size of the mollusk in its first sexual maturity is 40 mm. We observed juvenile *C. articulatus* (<4 cm) in Isla Socorro, mostly in the rock fissures and in the cracks of the intertidal belts occupied by the sea urchin *Echinometra vanbrunti*. We observed that for *C. articulatus* the

Bahía Academia	86	49	90.0	71.9	8.9	8.3	49.0	27.4	9.3
TOTAL	385	29	108.0	69.6	12.5	2.0	86.5	27.9	14.5

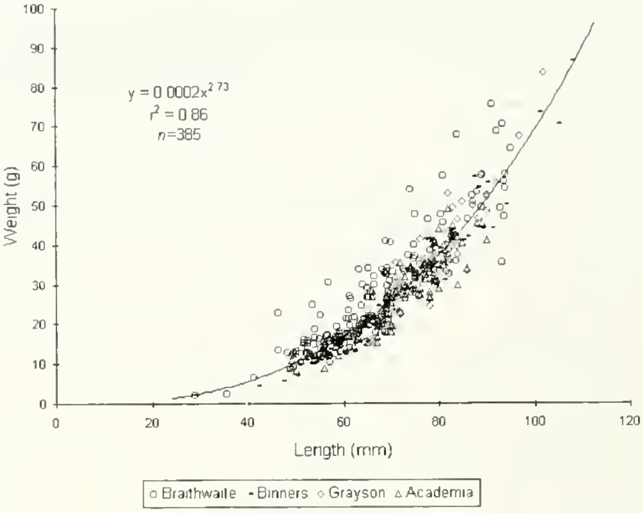

Figure 3. Length-weight relationship of *Chiton articulatus* sampled on Isla Socorro, Revillagigedo, March 1992.

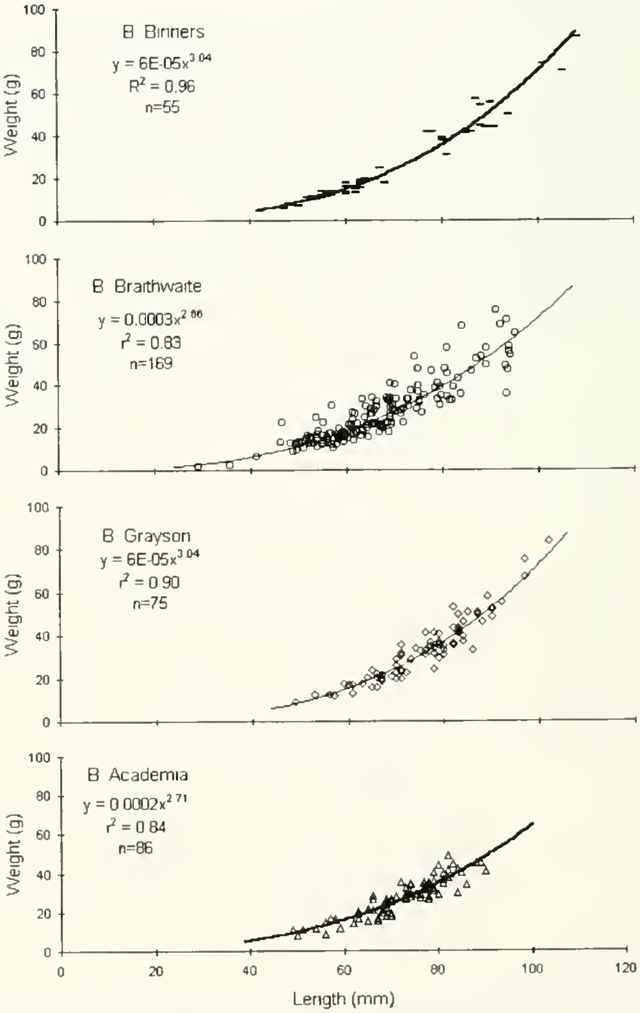

Figure 4. Length-weight relationship of *Chiton articulatus* for each sampling site on Isla Socorro, Revillagigedo, March 1992.

major feeding activity was nocturnal and food was generally composed of crusty filamentous algae and diatoms.

Several other species of invertebrates coexist with *C. articulatus*. Some are chiton predators such as the gastropods *Plicopurpura pansa* and *Thais* spp., as well as the cephalopod *Octopus* sp. Other coexisting species are *Littorina aspera*, *L. modesta* and *L. pullata*, *Nerita funiculata*, *Diodora inaequalis*, *Chama squamuligera*, *Colisella* spp. and *Fissurella spp*. Several crustacean species can also be found in those areas, such as the decapod crab *Grapsus grapsus*, the cirriped *Tetraclita* sp. and the isopod *Ligia exotica*.

We counted a total of 1,052 *C. articulatus* occurring in the sampling transects (Table 1). The highest relative density average (8.5 animals/m^2) was found in Bahía Braithwaite and the lowest in Bahía Binners (3.7 animals/m^2) with an average of 5.3 animals/m^2 for the four sampling sites combined. We observed the maximum densities of up to 41 chitons/m^2 in small sections of the transect (Bahía Academia, Table 1).

The abundance of chitons on Isla Socorro is greater than in Acapulco seaside (4.2 animals/m^2, Rojas-Herrera 1988). The high density of the mollusk, that we observed in Bahía Academia, is probably due to the fact that the bay is far away from any populated center. Bahía Binners which is most accessible to the navy village, shows lower densities because of fishery activity.

The length frequency distribution of the 385 chitons collected on Isla Socorro, ranged between 29 and 108 mm with a mode of 70 mm (Fig. 2). The smallest chiton sampled weighed 2.0 grams, while the longest weighed 86.5 grams (Table 2). The average values are of 69.6 mm and 27.9 g for length and weight respectively (Table 2). The length-weight relationship $W = 0.0022\ L^{2.73}$ where W is total weight (g) and L = total length (mm) was derived from all 385 *C. articulatus* measured in March 1992 on Isla Socorro (Fig. 3 and Fig. 4).

There are no significant differences between length-weight relationship in the sampling areas. The major length weight per unit was found in Bahía Braithwaite and the minor weight was found in Bahía Grayson.

It is important to point out that the predominance of Chiton bigger than 6 cm. in the rocky intertida zone of the Isla Socorro, is due mainly to its geographic location, this part of the island is almost inaccessible by land or sea. The population of this species in general, is unaltered and its partial exploitation under strict protection measures is possible.

CELLULAR IMMUNOLOGICAL PARAMETERS OF THE OCTOPUS, *OCTOPUS VULGARIS*

BEATRIZ NOVOA, CAROLINA TAFALLA, ANGEL GUERRA, AND ANTONIO FIGUERAS
Instituto de Investigaciones Marinas, CSIC, Eduardo Cabello, 6. 36208 Vigo, Spain

ABSTRACT The white body is the main hematopoietic organ of cephalopods. In this study, we have investigated the capacity of the octopus (*Octopus vulgaris*) white body cells to perform common cellular defense parameters known to be done by hemocytes of other mollusks such as phagocytosis of zymosan particles, respiratory burst activity and nitric oxide (NO) production. White body cells were capable of respiratory burst and NO production, however, they exhibited a low phagocytic response. Similar capabilities were observed in hemocytes withdrawn from the hemolymph. We have studied the effects of in vitro incubation with bacterial lipopolysacharide (LPS) or zymosan for 24 hours on these two functions. Incubation of the white body cells with zymosan, but not with LPS, resulted in a significantly increased respiratory burst activity and NO production.

We have also investigated the capacity of circulating hemocytes and white body cells to increase their thymidine uptake (indicative of DNA synthesis) in response to LPS and phytohemaglutinin (PHA). In some animals, both mitogens induced a significant increase in thymidine uptake. If this thymidine uptake correlates with cell proliferation, this will be the first report of any proliferation of hemocytes in mollusks.

In the hemolymph, we observed two different morphologies under the electron microscope, however, we cannot conclude that they correspond to two distinct cell types. Among white body cells different morphologies that may correspond to intermediate stages were observed. All these findings represent a baseline for future studies to elucidate mechanisms of host defense in this mollusk.

KEY WORDS: *Octopus vulgaris*, hemocytes, white body, respiratory burst, thymidine uptake, nitric oxide (NO), phagocytosis

INTRODUCTION

Due to the decrease in Spanish cephalopod fisheries, the interest in the commercial culture of cepahalopod species has gained increasing attention. Diseases are one of the major obstacles in achieving this goal. Several pathogens have been identified in wild and aquarium-kept octopuses, including viruses, bacteria and fungi. Farley (1978) described the presence of viruses in the muscle of the octopus, *Octopus vulgaris*. Bacteria have been reported to cause several disease outbreaks in laboratory reared octopuses (Hanlon & Forsythe 1990; Hanlon et al. 1984). Parasites have been blamed for several pathogenic problems. Hochberg (1990) described a flagellated parasite in cultured octopuses. Fungi have been also described as causing problems in cephalopods maintained in captivity (Polglase 1980; Polglase et al. 1984). Despite the threat these pathogens may cause to octopus populations, elucidation of defense mechanisms in these species have received little attention.

Humoral defense factors have been identified and are reviewed by Ford (1992). Rogener et al. (1985) and Fisher and Dinuzzo (1991) described hemaglutinating activity and aglutinnins in cell free hemolymph of several molluskan species, including the octopus, *Octopus vulgaris*. In this species, an antiprotease of the α-macroglobulin family was also detected in the hemolymph (Thogersen et al. 1992). Malham et al. (1998) reported lysozyme and antiprotease activity in hemocytes and hemolymph of the lesser octopus *Eledone cirhhosa*. Like in other mollusks, cephalopod hemocytes are believed to play a role in host defense mechanisms, however, the function of the hemocytes has been poorly studied. Cowden and Curtis (1981) estimated that the phagocytic capacity of octopus hemocytes was low while high phagocytosis of carbon particles has been described in *Eledone cirrhosa* (Stuart 1968). Bayne (1983) reported a clearance of *Serratia marcescens* by hemocytes of the octopus, *Octopus dofleini*.

The generation of hemocytes of cephalopods is believed to take place in an organ situated around the optic nerve called the white body, gland of Hensen or gland of Faussek (Stuart 1968; Cowden 1983; Bolognari et al. 1980). Hence, the aim of this study was to determine whether white body cells from *Octopus vulgaris* are capable of performing certain functions believed to be of relevance to defense mechanisms like phagocytosis of zymosan, respiratory burst and nitric oxide (NO) production and to compare their functionality to that of circulating hemocytes. We have also examined the ability of two mitogens, bacterial lipopolysacharide (LPS) and phytohemaglutinin (PHA), to stimulate thymidine uptake, an indicative of DNA synthesis. In the case of the respiratory burst and NO production, we have also determined the effect of in vitro activation with bacterial lipopolysacharide (LPS) and zymosan.

MATERIALS AND METHODS

Sampling

Adult octopuses (*Octopus vulgaris*) of both sexes, weighing 2–3 kg were caught from a raft in the Ría de Vigo (Spain) and after a day of adaptation under laboratory conditions, were anesthetized with excess MS-222. When animals were fully anesthetized (identified by muscle relaxation and absence of movement), the visceral cavity was dissected. Once the heart and its associated vessels were reached, around 1 ml of hemolymph was drawn using a 27 gauge needle from the artery and subsequently from the heart, placed in an eppendorf and kept on ice until used. The white body was removed and kept on ice until used.

In order to obtain single cell suspensions, individual white bodies were passed through a 100 μm nylon mesh using Leibovitz medium (L-15, Gibco) supplemented with penicillin (100 IU/mL), streptomycin (100 μg/mL) and 2% fetal calf serum (FCS). The resulting cell suspension was centrifuged (500 × g for 15 min at 4°C) and the cells were resuspended in L-15 supplemented with penicillin, streptomycin and 2% (FCS). Cell viability was determined by Trypan blue exclusion. Cells were resuspended in L-15 supplemented with penicillin, streptomycin and 0.1% FCS a [illegible] density of 1×10^6 cells/mL.

Hemocytes were obtained by centrifuging octopus hemolymph (500 × g for 15 min at 4°C) and hemocytes were resuspended in L-15 supplemented with penicillin, streptomycin and 2% FCS. The cell viability was determined by Trypan blue exclusion test. Cells were resuspended in L-15 supplemented with penicillin, streptomycin and 0.1% FCS at a concentration of 1 × 10^6 cells/mL.

Electron Microscopy

Pelleted cells (from white body and hemolymph) were fixed for one hour in 1% osmium tetroxide in cacodilate buffer 0.1 M (pH 7.3). In some cases, a previous step of fixation with 1% glutaraldehyde in cacodilate buffer 0.1 M (pH 7.3) for 15 minutes was performed. Following three washes in 0.1 M cacodilate, the cells were dehydrated with increasing percentages of ethanol and embedded in Araldite/Poly Bed (Polyscience). Ultrathin sections (50–70 nm) were stained with uranyl acetate and lead citrate and examined using a Phillips electron microscope CM100.

Phagocytosis Assay

To measure the phagocytic ability of octopus cells, 200 μL of cell suspensions (derived from white body or hemolymph of six animals) were incubated in chamber slides (Nunc) for 2 h at 18°C in moist incubation chambers to allow the cells to adhere. Medium was removed and the adherent cell layer was washed twice with L-15. Zymosan A (Sigma) resuspended in sterile phosphate buffered saline, PBS, at a concentration of 1 mg/mL, was heated at 100°C for 30 min, washed twice, and resuspended in the same PBS volume. Zymosan was added to the cells at a final concentration of 250 μg/mL, and the same volume of L-15 was added to the controls. Slides were incubated in a moist chamber for one hour at room temperature or 18°C to allow phagocytosis. Some slides were kept up to three hours. Slides were then washed twice in PBS, fixed in absolute ethanol, stained with Hemacolor, and mounted with DePex. Two replicas were made for each octopus and at least 150 cells were observed in each replica.

Respiratory Burst Activity

Respiratory burst activity of octopus cells was assayed by the reduction of ferricytochrome C (Cit C, Sigma) by released superoxide anion (O_2–), following stimulation of the cells with phorbol myristate acetate (PMA, Sigma) (Secombes 1990) in 4 octopuses. White body adherent cells and circulating hemocytes were obtained as described above, resuspended in L-15 supplemented with penicillin, streptomycin and 0.1% FCS and dispensed into 96-well tissue culture plates (Iwaki) at a concentration of 1 × 10^6 cells/mL (100 μL per well).

In a preliminary experiment, we determined the specificity of the respiratory burst by assaying the response of the cells to PMA. After 24 hours of incubation at 18°C, octopus cell monolayers were washed twice in phenol red-free Hank's balanced salt solution (HBSS, Gibco). One hundred μL of HBSS containing Cit C (2 mg/mL) and PMA (1 μg/mL) were added to each well. As a control for specificity, 300 IU/mL superoxide dismutase (SOD, Sigma) was added to some wells. The optical density (O.D.) was measured at 550 nm after 30 min in a multiscan spectrophotometer (Labsystems). Triplicate wells were used in all the experiments for each octopus and the mean ± SD was calculated.

Once the responsiveness of octopus cells to PMA had been determined, the effects of stimulation with zymosan or *Escherichia coli* serotype 0111: B4 lipopolysacharide (LPS) on the respiratory burst of octopus cells triggered by PMA was also studied. After three hours incubation of the cell monolayers at 18°C, LPS and zymosan were added to a final concentration of 50 and 250 μg/mL respectively. After an additional 24 hours of incubation at 18°C with these substances, the respiratory burst activity was measured by adding 100 μL of HBSS containing Cit C (2 mg/mL) and PMA (1 μg/mL) were added to each well. The O.D. at 550 nm was then determined as described above.

NO Production

The ability of octopus cells to produce NO in response to LPS and zymosan was also determined in 4 animals. Cells resuspended in L-15 with 0.1% FCS were disposed into 96-well plates at a concentration of 1 × 10^6 cells/mL. After 3 h of incubation at 18°C, LPS and zymosan were added at a final concentration 50 and 250 μg/mL respectively. After additional 24 h of incubation at 18°C, the NO concentration present in the cell supernatants was assayed through the Griess reaction (Green et al. 1982) that quantifies the nitrite content of the cell supernatants, since NO is an unstable molecule and degrades to nitrite and nitrate. Fifty μL of hemocyte supernatants were removed from individual wells and placed in a separate 96-well plate. One hundred microliters of 1% sulfanilamide (Sigma) in 2.5% phosphoric acid were added to each well, followed by the addition of 100 μL of 0.1% N-naphthylethylenediamine (Sigma) in 2.5% phosphoric acid. Optical density at 540 nm was determined using a multiscan spectrophotometer. The molar concentration of nitrite in the sample was determined from standard curves generated using known concentrations of sodium nitrite (100, 10, 5, 2.5, 1, 0.5, 0.25, and 0.1 μM).

Effect of Mitogens on (^{3}H)-Thymidine Uptake by Octopus Cells

The thymidine uptake by octopus cells was assayed following a modification of the method described by Marsden et al. (1994) in six octopuses. Briefly, hemocytes derived from the hemolymph or the white body were adjusted to a density of 5 × 10^6 cells/mL in RPMI 1640 medium (Gibco) supplemented with penicillin (100 IU/mL), streptomycin (100 μg/mL), 25 mM $NaHCO_3$ and 1 × 10^{-5} M 2-β-mercaptoethanol. Aliquots of 100 μL of cell suspensions were added to wells of 96-well plates containing 100 μL of LPS or PHA dilutions (Sigma) to make final concentrations of 50, 25 and 12.5 μg/mL or 5, 2.5, and 1.25 μg/mL, respectively. Controls without mitogens were also included. After 3 h of incubation at 18°C, FCS was added to the wells to give a final concentration of 10%. Following 48 h of incubation, the cells were pulsed with 0.5 μCi of (^{3}H)-thymidine (Amersham). After additional 24 h incubation at 18°C, DNA was harvested onto glass filter mats. One mL Xylofluor scintillant (Packard) was added to dried filter circles in vials and counts per minute (cpm) were recorded using a Packard liquid scintillation counter. Triplicate cultures were used in all cases.

Statistics

The data were compared using a Student's *t* test. Results are expressed as the mean ± standard deviation and differences were considered statistically significant at $P < 0.05$.

RESULTS

Cell Morphology

After two hours of incubation of the cell suspensions at 18°C, the white body adherent cells were adhered to the bottom of the wells, flatten and spread over the surface by extending pseudopodia. Circulating hemocytes presented the same aspect.

When visualized under the electron microscope (Fig. 1), what seems as two different morphologies, that were distinct under the inverted microscope, were observed among circulating hemocytes. No differences were found in the quality of fixation when the previous glutaraldehyde step was omitted and therefore the cells were always directly fixed in osmium tetroxide. We identified in the first cell type a kidney-shaped nucleus that occupied about 2/3 of the cell volume with a well-defined nucleolus and abundant heterochromatin in peripheral positions. Their cytoplasm was rich in vacuoles and electron-dense granules of various sizes. The second cell type had a nucleus with faint chromatin, a round nucleus that occupied about 1/3 of the cell volume. The cytoplasm was rich in vacuoles, but had only scarce granules. However, these results are not conclusive and we cannot assure that what looks as two different morphologies corresponds to two distinct cell types.

In the case of white body cells, we were able of identifying cells showing other morphologies that may correspond to intermediate stages between the two cell types found in the hemolymph.

Phagocytosis Activity of White Body Adherent Cells and Circulating Hemocytes

The phagocytic activity detected after incubation of octopus hemocytes and white body cells with zymosan was low. The percentage of phagocytosis observed in circulating hemocytes was 19.3% (SD = 14), while only 9.3% (SD = 8) of white body cells contained zymosan particles in their cytoplasm. In all cases, variations among individuals were high, since in some samples no phagocytosis was observed (0% of phagocytosis). The same results were obtained with the two incubation temperatures (18°C or room temperature) in both circulating and white body cells. No differences were observed when the hemocytes were incubated in their own hemolymph (data not shown).

Respiratory Burst Activity

Octopus white body cells showed a significant increase in the release of superoxide anion after stimulation with PMA compared with controls, as depicted in Figure 2A. The specificity of the reaction was demonstrated since SOD completely inhibited the respiratory burst response of octopus cells in all cases. This response was also observed with circulating hemocytes. The respiratory burst activity of hemocytes incubated directly in their own hemolymph was also assayed. In these conditions, some octopuses did not respond to PMA and did not elicit a respiratory burst response.

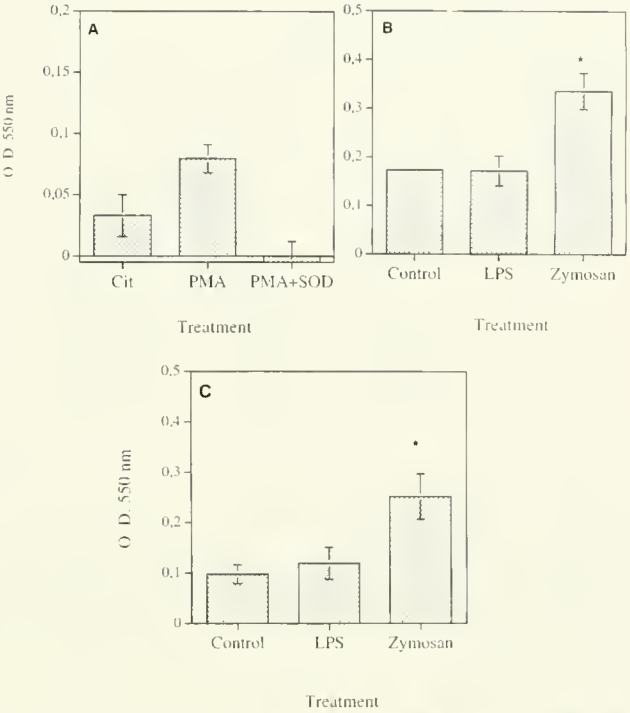

Figure 2. Respiratory burst activity of octopus white body cells. First, the capacity of PMA to stimulate the respiratory burst activity and the specificity of the reaction was assayed (A) (N = 2). Once, this was determined, the effects of LPS and zymosan on the respiratory burst activity of white body hemocytes (B) (N = 4) and circulating hemocytes (C) were studied through the reduction of Cit C, stimulating the cells with PMA. Data are shown as the mean O.D. at 550 nm. *Respiratory burst significantly higher than the respiratory burst obtained in controls. $P < 0.05$.

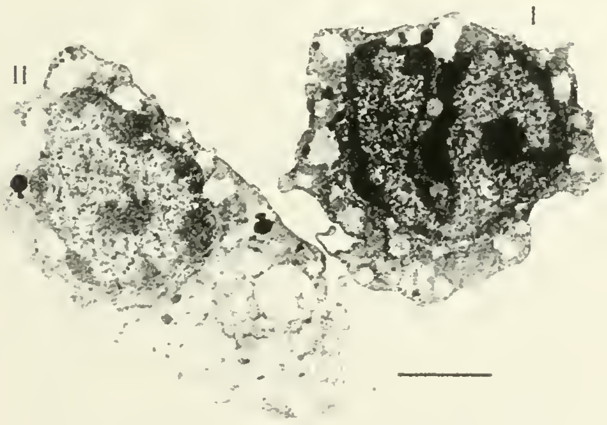

Figure 1. Under the electron microscope, two distinct morphologies were identified among circulating hemocytes. The first cell type (I) is characterized by its kidney-shaped nucleus and the high number of electron-dense granules. The second cell type (II) possessed a round nucleus with a few electron dense granules. Bar = 5 μm.

Figure 2B shows the effect of incubation for 24 hours with LPS or zymosan on the respiratory burst triggered by PMA of white body cells, compared to the respiratory burst observed in cells that had been incubated with L-15 only. The pre-incubation of the cells with zymosan, but not LPS, significantly increased the respiratory burst of white body cells in response to PMA. The same response was observed in cells obtained from hemolymph, showing a higher respiratory burst after zymosan treatment than controls (Fig. 2C).

NO Production

The NO production of white body cells in response to LPS and zymosan is shown in Figure 3. Zymosan significantly stimulated the cells for NO production in all individuals, however, as in the case of the respiratory burst activity, LPS failed to stimulate the cells.

In the case of hemolymph cells, a similar response was observed. The NO production in the cultures treated with zymosan (8.4; SD = 0.8) was higher than the response observed in controls (6.7; SD = 0.3).

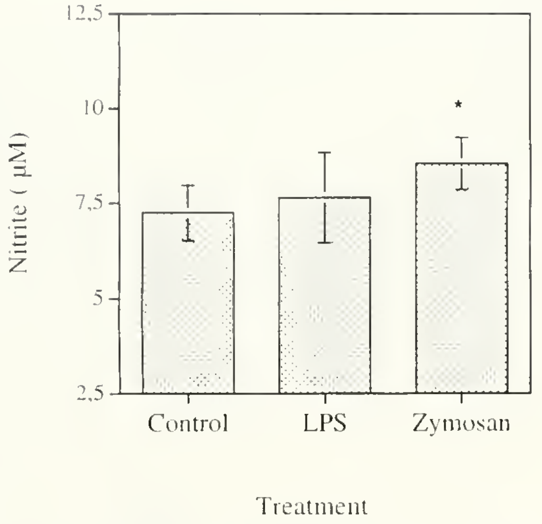

Figure 3. NO production of cells from the white body after incubation with LPS or zymosan. Data are presented as the mean nitrite concentration obtained with 4 octopus. *Nitrite concentration significantly higher than the one observed in controls only treated with L-15. $P < 0.05$.

(^{3}H)-Thymidine Uptake

Not all animals studied showed a significant response. Only two out of six individuals assayed responded with a significant increase of the thymidine uptake in response to mitogens. The individual responses observed in these two animals are shown in Table 1. When means were compared, concerning white body cells, a maximum thymidine uptake was observed with the higher LPS dose (687.3; SD = 6.7). In this case, the PHA dose that significantly stimulated the thymidine uptake was 2.5 µg/ml (495; SD = 20) in comparison to controls (378.5; SD = 2.5).

In these two responsive animals, hemocyte thymidine uptake was also significantly affected by the mitogens. All concentrations of LPS significantly increased (^{3}H)-thymidine uptake compared to non-stimulated controls, although the higher response was observed with the highest LPS dose. However, hemocyte thymidine uptake was only significantly increased with the higher dose of PHA.

TABLE 1.

Thymidine uptake by circulating hemocytes and white body cells in two responsive animals. Data are presented as the mean cpm obtained in the replicas (N = 3) ± SD.

	Octopus 1		Octopus 2	
Mitogens	Circulating Hemocytes	White Body Cells	Circulating Hemocytes	White Body Cells
LPS 50 µg/ml	630.6 ± 242	694 ± 351	515.3 ± 37	680.6 ± 104
LPS 25 µg/ml	340 ± 118	366 ± 144	457 ± 217	370 ± 70
LPS 12.5 µg/ml	458 ± 98	761 ± 418	427 ± 41	524 ± 142
PHA 5 µg/ml	340 ± 92	241 ± 171	615 ± 128	253 ± 58
PHA 2.5 µg/ml	238 ± 12	475 ± 147	141 ± 32	515 ± 154
PHA 1.125 µg/ml	178 ± 52	313 ± 79	222 ± 42	290 ± 55
Control	204 ± 64	381 ± 105	294 ± 94	376 ± 12

DISCUSSION

The findings in this study suggest that both octopus white body cells and circulating hemocytes are capable of performing functions associated with host defense mechanisms. This is particularly important to determine since scanty data is available on the immune response of this octopus species. This is the first work in which reagents and techniques usually used in vertebrate immunology have been successfully applied to study cellular responses of cephalopods.

Under the electron microscope, two distinct morphologies among circulating hemocytes were identified, although it had been described as only one cell type of the hemolymph of *Octopus vulgaris* (Bidder et al. 1989). Our results are not conclusive and more work should be done to determine whether these two morphologies correspond to different states of activation or they constitute two different cell types. Previous studies in bivalve mollusks have identified two main hemocyte types in the hemolymph (Fisher 1986; Lopez et al. 1997) that have been subdivided (Auffret 1988; Nakayama et al. 1997). In the white body, it is well known that there are cells, referred to as hemocytoblasts, with a large cytoplasmic volume and abundant rough endoplasmic reticulum and nucleoli (Ford 1992). Hemocytoblasts transform to leukoblasts by reducing its cytoplasmic volume and decreasing its nuclear size, whereas secondary leukoblasts (mature hemocytes) are cells with a larger size and a folded nucleus. Both under the light and electron microscope, we were able to identify different morphologies that may correspond to these intermediate stages among white body cells. As well, the two different morphologies that we describe in this work among circulating hemocytes seem to correspond to these two cell types (hemocytoblasts and leukoblasts). It may be possible that in these individuals maturation ends in the hemolymph or as will be discussed later, that these two cell types are functionally different.

The first cell type may correspond to what has been called granulocyes in bivalves (Auffret 1988). These cells possess a kidney-shaped nucleus that resembles those of vertebrate granulocytes. The second cell type had a round nucleus and a cytoplasm that was also rich in vacuoles, but had only scarce granules. This cell type may correspond to what in bivalves has been called hyalinocytes (agranular hemocytes) (Auffret 1988).

Results concerning in vitro phagocytosis by octopus hemocytes are in accordance with those previously reported (Crowden & Curtis 1981) where it was suggested that gill tissue or phagocytes from gill tissue could be responsible for clearing foreign substances and that circulating hemocytes had low activity (Crowden & Curtis 1981; Bayne 1983). However, studies in other cephalopod species, like *Eledone cirrhosa* reported bacterial phagocytic rates of even 40% (Malham et al. 1997). The low phagocytic activity that is observed in the octopus, *Octopus vulgaris*, circulating hemocytes also contrasts with the high phagocytic rate detected in bivalves (Mortensen & Glette 1996; Ordas et al. 1999), animals in which phagocytosis is a critical defense mechanism. Many factors can affect phagocytic rates in mollusks such as temperature (Carballal et al. 1997), time and pH (Abdul-Salam & Michelson 1980), size and nature of the particle presented for phagocytosis (Bayne 1983). In some cephalopod species, phagocytosis is not possible in the absence of hemolymph (Stuart 1968). It may be possible that on the contrary to what happens with the respiratory burst (that is inhibited by the presence of hemolymph), phagocytosis in this species needs humoral factors present in the hemolymph.

Octopus hemocytes, however, were able to respond to PMA and release significant amounts of superoxide anion. Respiratory burst activity is an interesting non-specific defense mechanism that vertebrate macrophages use to avoid bacterial and parasitic infections due to the potent microbiocidal effects of oxygen radicals. The reason why the respiratory burst activity was not detected in some of the octopuses while incubated in their own hemolymph is unknown. The immune system is regulated by multiple signals that can up or down modulate the animal responses. Maybe regulating factors, affecting this immune response, are present in the hemolymph of these animals, in the same way that other humoral factors such as lysozyme or antiproteases have been detected in cephalopod hemolymph (Malham et al. 1998).

We have also demonstrated that octopus cells derived from hemolymph and white body produced NO. In vertebrates, NO mediates many functions including neurotransmission, vasodilatation, as well as several immune functions. It is known that this molecule when secreted by macrophages is microbicidal against viruses, parasites and bacteria (Nathan & Hibbs 1991; Tafalla et al. 1999). In the octopus, NO production was significantly increased when the cells were incubated with zymosan for 24 hours. However, incubation with LPS did not have an effect on the NO secretion. This is the first report on NO production by cells of any cephalopod. NO production in other mollusks has been shown, in which NO production was demonstrated by indirect methods (Martinez 1995; Otaviani & Franchini 1995).

Octopus hemocytes were also able to increase their thymidine uptake after stimulation with LPS and PHA, although this response was not found in all individuals, maybe because this immune function is more related to a specific response not known to be present in cephalopods. Thymidine uptake implies DNA synthesis, so this increase may mean that the hemocytes are proliferating. If so, this will be the first report of any proliferation in mollusks, outside the hematopoietic organ. More work must be done to determine if this thymidine uptake detected correlates with cell proliferation. In higher vertebrates, these two mitogens correlate to B and T lymphocyte mitogens, respectively. Since we observed ultrastructurally two morphologies among hemocytes in responsive animals, it may be possible that LPS and PHA-induced proliferation are being supported by different hemocyte populations, and therefore imply a certain grade of heterogeneity, as in vertebrate immune cells.

In conclusion, we have effectively applied immunological techniques designed for vertebrates to evaluate cephalopod hemocyte functions. Among mollusks, cephalopods are highly evolved animals with a body design, nervous system and sense organs that often reach vertebrate standards (Budelmann et al. 1997). It seems possible that immune system may also be more developed than other mollusks in which modulation of immune responses by pathological agents or other factors has been reported (Ordas et al. 1999). We have set up different in vitro techniques, such us determination of respiratory burst activity, NO production and cell proliferation, which will let us further evaluate the octopus immune response against infections or the influence of environmental conditions. This latter aspect is especially relevant because of increasing interest that cephalopod aquaculture has had in the past years (Osako & Murata 1983; Guerra & Rocha 1994; Guerra et al. 1994). More work must be done to clarify the regulation of these immune functions in cephalopods and determine their role in the defense against pathogens.

ABSTRACT A new method was developed to estimate the gonado-somatic index in bivalves, taking into account that in most bivalves gonad and non reproductive tissues are fused. As examples, four tropical bivalve species (*Donax dentifer, Cardita affinis, Pinctada imbricata* and *Pteria colymbus*) from the Colombian Pacific and Caribbean were used. The fused gonad regions were replaced by geometric bodies, thus the gonad volumes were estimated with geometric equations (corresponding to geometric bodies) and linear measures obtained directly on frozen soft-body samples. The very good correlation between the gonado-somatic index and the gametogenetic cycle of the stage "ripe", leads to the conclusion that this method is a suitable tool to estimate gonad indices of bivalves with fused gonads.

KEY WORDS: method, gonado-somatic index, bivalves, *Donax dentifer, Cardita affinis, Pinctada imbricata, Pteria colymbus*

INTRODUCTION

A standard procedure in marine biological reproductive studies is to determine gametogenetic stages (Guillou et al. 1990) or to estimate indices (Moore 1934; Giese 1967; Pearse 1965). Among many existing indices the so called gonado-somatic indices, calculated from the relationship between a variable depending directly on reproductive processes and a variable independent from reproductive processes, are most frequent used. Examples for the variables used in gonado-somatic indices are the gonad volume and the total volume. Such a gonado-somatic index, followed periodically over a year, is a valuable tool because it is related directly to reproductive activities, such as spawning events. Among marine species, the estimation of gonado-somatic indices in bivalves often presents a problem because most species of this group have fused gonads, such that reproductive and non-reproductive tissues cannot—or are difficult to be separated.

Based on four tropical bivalve species, the objective of this article is to present and explain a new method, that permits the estimation of gonado-somatic indices in bivalves with fused gonads. In order to evaluate the new method, the gonado-somatic index is compared with gametogenetic stages obtained from smear samples.

MATERIALS & METHODS

Investigations were carried out in three areas: the *Tayrona National Nature Park*, close to the city of Santa Marta, Caribbean of Colombia (11°20′N, 74°10′W, Fig. 1a), the "*Cabo de la Vela*", a Peninsula located in the Guajira province, Caribbean of Colombia (12°10′N, 72°20′W, Fig. 1b) and the "*Bahía Málaga*", a bay close to the harbor town of Buenaventura, Pacific Coast of Colombia (3°56′N, 77°19′W, Fig. 1c). In *Tayrona Park* the pearl oyster *Pteria colymbus*, which lives attached to octocorals is a dominant species, while in *Cabo de la Vela* a characteristic *Thalassia testudinum* community gives a suitable substrate for a variety of bivalve species, especially a dense *Pinctada imbricata* popula-

tion. Finally, at *Bahía Málaga* the infaunal *Donax dentifer* found in the intertidal of sandy beaches and the borer clam *Cardita affinis* from rocky shores were studied.

Sampling for *Donax dentifer* was carried out in 1997/98 as well as in 1999/00, while for the latter three species the study period lasted one year, but at different dates (*Pteria colymbus*: 1994/95, *Pinctada imbricata*: 1997/98, *Cardita affinis*: 2000/01). At monthly intervals, samples were taken and the shell length (anterior-posterior axis) of all specimens was recorded with vernier callipers. Two subsamples of 30 specimens per species each were taken. One subsample was used for length-weight relationships: soft parts were removed and dried at 70°C to constant weight to determine shell free dry weight (SFDW). Monthly length weight relationships were used to estimate a shell free dry weight (= condition) cycle of a standard individual (= 66% of maximum length) based on Equation (1):

$$SL = a \cdot SFDW^{b} \qquad (1)$$

where SL is the shell length [mm] and SFDW is the shell free dry weight [g]. The second subsample was deep frozen and used to obtain linear measures of gonad regions with a vernier callipers in order to estimate the gonado-somatic index (details are given under "Results" later). Finally, after taking the linear measures, gametogenetic stages of smear samples were determined according to a microscopic scale (Urban 2000): "developing 1 (= early developing)", "developing 2 (= late developing)", "ripe" and "spent".

RESULTS

Using frozen samples, six transversal sections (thick slices) were taken at different locations of the body; these were used to identify the gonad region geometrically. As an example only the morphological sections of two of the four species are presented. Figure 2a shows the soft parts (mantle, siphons and gills removed) on the left shell of *D. dentifer* and *C. affinis* demonstrating the fused character of somatic and gonad tissues. Figure 2b shows the six transversal sections. In *D. dentifer* the visceral mass is located in the middle-dorsal body part, partially enclosed by the gonad region. The pedal muscle occupies the major part of the total body volume extending in anterior-posterior direction and enclosing the gonad region. Contrary, in *C. affinis* the visceral mass is located in the posterior-dorsal part, decreasing towards the anterior end. The gonad region is located in the posterior-ventral zone, increasing its volume towards the middle part (section 3) and then extending

Figure 3. Geometric bodies defined according to the morphological examinations of the transversal sections (Fig. 2b). The linear measures necessary to calculate the volume as well as the formulas are given (see text). a) Ellipsoid of *Donax dentifer*. b) Two fused triangle prisms of *Cardita affinis*. c, d, and e) Fused cylinder and pyramid of *Pinctada imbricata* and *Pteria colymbus*. Simple small letter correspond to linear measures of somatic and reproductive tissues, while gonadal tissues are given as small letters with "′" (e.g. a′).

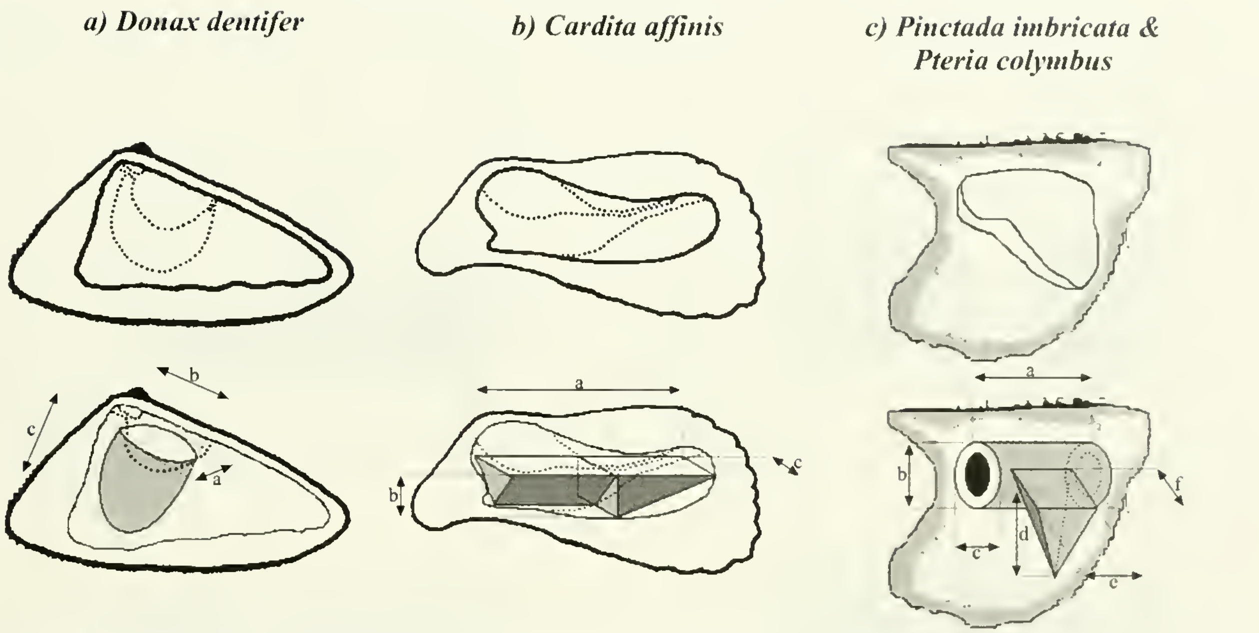

Figure 4. Body tissues (upper row) and geometric bodies replacing gonad region and or body tissues (lower row). a) ***Donax dentifer*****, b)** ***Cardita affinis*** **and c)** ***Pinctada imbricata*** **and** ***Pteria colymbus***

towards the anterior-dorsal part where its volume decreases gradually. The pedal muscle is reduced, corresponding to a small extension of the posterior-ventral end. The volume of the abductor muscle increases from the middle ventral zone, extending towards the anterior end.

Based on the morphological examination of the gonad region (Fig. 2) for all species three-dimensional bodies of the gonad region were defined. In other words, the gonad region was replaced with geometric bodies. The volumes of these bodies and thus the gonad volume, can be estimated using the following geometric equations and linear measures [mm] taken directly on the bivalves from frozen samples. Based on macroscopic criteria such as texture, color, etc., gonad tissue could be easily distinguished from somatic tissue. Thus, for each species during the study period the gonad volumes [ml] of approximately 30 specimens were obtained at monthly intervals.

Donax dentifer

The gonad morphology corresponds to an ellipsoid half (Figs. 3a & 4a), located between the foot and the visceral mass. The equation below Figure 3a corresponds to the volume of an ellipsoid half. It is clear, however, that a small visceral region is located in the dorsal part of the "gonadal ellipsoid" (Fig. 2a). On average, this visceral tissue occupied 10% (max: 19%, min: 6%) of the total ellipsoid volume. Thus, in order to yield the gonad volume, the formula was corrected multiplying with 0.9 (Eq. 2):

$$V_{gon.Donax} = \left[\left(\frac{4}{3}\cdot\pi\cdot\frac{a}{2}\cdot\frac{b}{2}\cdot c\right)/2\right]\cdot 0.9 \qquad (2)$$

Measures are indicated in Figures 3a & 4a; "a" is the gonad breadth (lateral to the body axis), "b" is the gonad length (anterior-posterior body axis) and "c" is the gonad height (dorsal-ventral body axis at transversal section number 3.

Cardita affinis

The geometry of the gonad region suggests the form of two fused triangle prisms (Fig. 3b & Fig. 4b). Thus, the formula of a single triangle prism has to be multiplied by 2 (Eq. 3):

$$V = [A_{base}\cdot h_{prism}]\cdot 2 = \left[\left(\frac{a\cdot h_a}{2}\right)\cdot h_{prism}\right]\cdot 2 \qquad (3)$$

Where A_{base} is the area of the base, which corresponds to a triangle with "a" being one side and "h_a" the height of the triangle corresponding to "a", finally "h_{prism}" is the height of the prism. The gonad volume was calculated as the sum of these two prisms (Eq. 4):

$$V_{gon.Cardita} = \left[\frac{a\cdot b\cdot c}{2}\right]+\left[\frac{a\cdot b\cdot c}{4}\right] \qquad (4)$$

Where "a" is the gonad length (anterior-posterior body axis), "b" is the gonad height (transversal to gonad length corresponding to transversal section number 3, Fig. 2) and "c" is the gonad breadth at the fusion point of both prisms. (Note: "a" corresponds to the length of both fused prisms, therefore for the two bodies "1/2 a" has to be used yielding Eq. 4.)

Pinctada imbricata *and* Pteria colymbus

These two species of the family Pteridae are different from the latter two because the gonad tissue covers the somatic tissues. In *D. dentifer* and *C. affinis* the total body volume was estimated with the water displacement method and gonad volume corresponds directly to the geometric abstractions, while in *P. imbricata* and *P. colymbus* first the total body volume (visceral mass and foot including gonads) and then in a second step the "covering" gonad volume was estimated. The total body volume can be defined by a cylinder (Fig. 3c & Fig. 4c, Eq. 5a) fused with a pyramid (Fig. 3d & Fig. 4c, Eq. 5b). The cylinder corresponds to the visceral mass

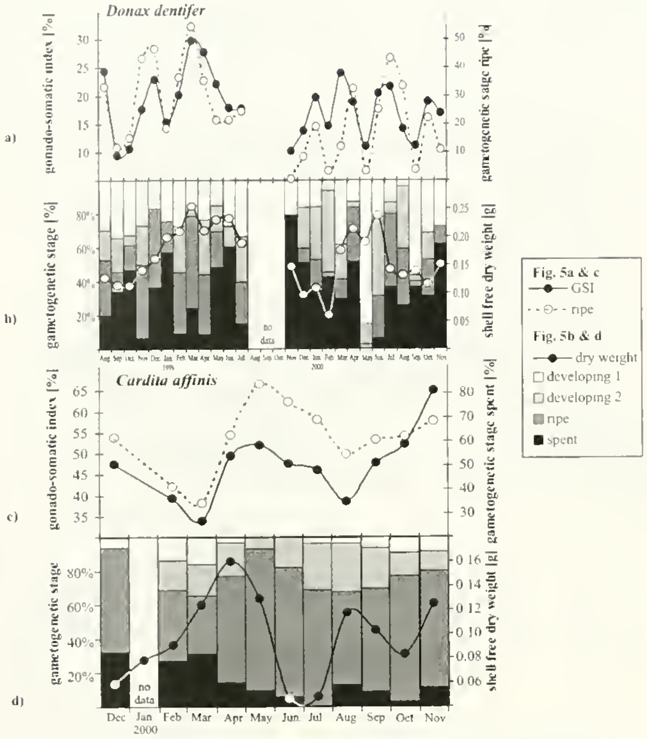

Figure 5. a) Overlay of gonado-somatic index and gametogenetic stage "ripe" cycle. b) Overlay of shell free dry weight cycle and distribution of gametogenetic stages of *Donax dentifer* from Bahía Málaga, Colombian Pacific. c & d) *Cardita affinis* from Bahía Málaga, Colombian Pacific.

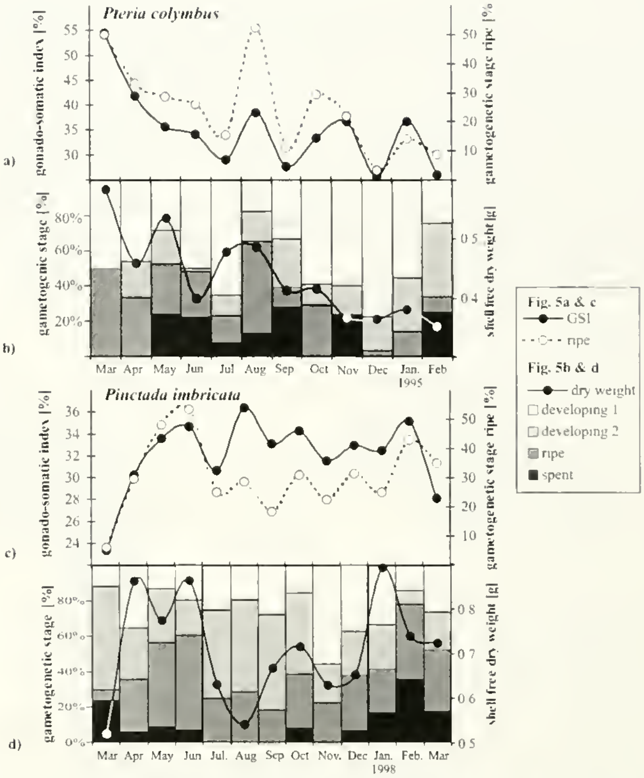

Figure 6. a) Overlay of gonado-somatic index and gametogenetic stage "ripe" cycle. b) Overlay of shell free dry weight cycle and distribution of gametogenetic stages of *Pteria colymbus* from Tayrona Park, Colombian Caribbean. c & d) *Pinctada imbricata* from Cabo de la Vela, Colombian Caribbean.

and the pyramid to the basal region of the foot. These two bodies have the general formula:

$$a)\ V_{cyl} = \pi \cdot r^2 \cdot h_{cyl},\ b)\ V_{pyr} = \frac{1}{3} A_{base} \cdot h_{pyr} \quad (5)$$

Where "r" is the radius, h_{cyl} is the height of the cylinder (Fig. 3c), "A_{base}" is the area of the base of the pyramid and "h_{pyr}" is the height of the pyramid (Fig. 3d). So the total body volume of these two species corresponds to the sum of the volume of a cylinder and a pyramid (Fig. 3e, Eq. 6 & 7):

$$\begin{aligned} V_{body\ tot_{Pteridae}} &= V_{cyl} + V_{pyr} \\ &= \left[\pi \cdot \left(\frac{b+c}{4}\right)^2 \cdot a\right] + \left[\frac{1}{3} \cdot \left(\frac{e \cdot f}{2}\right) \cdot d\right] \end{aligned} \quad (6)$$

Where "a" is the length, "b" is the height and "c" is the breadth of the visceral mass (including gonad region) and "d" is the length, "e" is the height and "f" is the breadth of the foot (including gonad region). In the second step the somatic volume was estimated using the same equation (Eq. 6), but with linear measures where gonad regions were excluded. Gonad volume was estimated subtracting the somatic volume from the total volume (Eq. 7):

$$\begin{aligned} V_{gon\ Pteridae} &= V_{body\text{-}tot} - V_{body\text{-}somat} \\ &= \left\{\left[\pi \cdot \left(\frac{b+c}{4}\right)^2 \cdot a\right] + \left[\frac{1}{3} \cdot \left(\frac{e \cdot f}{2}\right) \cdot d\right]\right\} \\ &\quad - \left\{\left[\pi \cdot \left(\frac{b'+c'}{4}\right)^2 \cdot a'\right] + \left[\frac{1}{3} \cdot \left(\frac{e' \cdot f'}{2}\right) \cdot d'\right]\right\} \end{aligned} \quad (7)$$

Where "$V_{body\ tot}$" is the total body volume and "$V_{body\text{-}somat}$" is the volume of the somatic tissues [ml], "a", "b", "c", "d", "e", and "f" are identical to the measures of Eq. (6), while a', b', c', d', e', and f' are linear measures parallel to "a", "b", "c", "d", "e", and "f" corresponding only to somatic tissues (Fig. 3e).

Figure 4 shows in the upper row for all four species the soft body parts on the right shell and below the geometric abstractions defined to estimate the gonad volume. Note that in *D. dentifer* and *C. affinis* only the gonad region corresponds to the (gray) geometric abstractions, while in *P. imbricata* and *P. colymbus* all soft parts were replaced with the geometric abstraction, and the gonad volume is covering non-reproductive tissues (in black).

TABLE 1.

Spearman correlation matrix of gonado-somatic index and gametogenetic stage "ripe" as well as shell free dry weight cycle

	P. colymbus	*P. imbricata*	*D. dentifer*	*C. affinis*
	Gonado-Somatic Index (GSI)			
Ripe	0.811	0.501	0.669	0.627
SFDW	0.594	0.170	0.488	0.264

Based on the total body and the gonad volume a gonado-somatic index (GSI, Eq. 8) was estimated.

$$GSI = \frac{V_{gon}}{V_{body}} \cdot 100 \quad (8)$$

Table 1 gives the Spearman correlation matrix of the gonado-somatic index (GSI) and the gametogenetic stage "ripe" as well as the condition (= shell free dry weight, SFDW) cycle. For all species a high correlation between GSI and the amount of ripe gonads is indicated ($p > 0.5$). For the correlation between GSI and SFDW only for *Pteria colymbus* and *Donax dentifer* high values can be observed.

This result is confirmed in Figure 5a & c and Figure 6a & c where GSI and ripe cycles are plotted in overlay graphs. In all species the pattern of GSI and ripe cycle is very similar. Figure 5b & d and Figure 6 b & d show the SFDW cycles together with the distribution of gametogenetic stages.

DISCUSSION

In order to evaluate a new method it is most convenient to compare the results with alternative information obtained completely independent. This can easily be accomplished for the GSI. It can be assumed that the GSI is positively correlated with the gametogenetic stage "ripe". GSI gives the mean gonad volume/total volume relationship per month. In other words if a large part of the population has voluminous gonads, the GSI is high. On the other hand the gametogenic stage "ripe" gives the percentage of specimens with ripe gonads (shortly before spawning). In this development stage, egg and sperm size is large, resulting in voluminous gonads. The results clearly confirm this assumption and thus prove the applicability of the GSI method. Graphically (Fig. 5a and c and Fig. 6a and c) as well as statistically (Table 1) a high correlation between the GSI and the gametogenic stage "ripe" exists. It should also be noted that GSI and stage "ripe" are completely independent measures: The GSI is a quantitative index based on linear measures, whereas the "ripe" cycle is a semi-quantitative measure obtained from microscopic observations of smear sample.

Together with the GSI and the "ripe" cycle, the shell free dry weight (SFDW = condition) cycle as well as the distribution of all gametogenetic stages is presented (Fig. 5b and d and Fig. 6b and d). Here, the typical pattern of tropical species with a very long or permanent spawning season and continuous reproduction strategy is demonstrated. All four species studied have ripe ovaries through out the year with no resting or inactive gonads found. This characteristic pattern is in contrast to cold temperate species. As an example, Urban and Campos (1994) studied the gonad cycles of the infaunal clam *Gari solida* from Chile at 37°S. In this species during 9 months of the year, developing 1 and/or spent stages dominate (85%). Only during the latter 3 months did ripe and/or developing 2 stages dominate indicating a short spawning period.

Contrasting to the "ripe" cycle only for *Pteria colymbus* and *Donax dentifer*, a high correlation between GSI and SFDW was observed. However, a high correlation between these two variables cannot be expected generally in a tropical environment with little annual variability of biotic and abiotic factors such as temperature, nutrients or phytoplankton. Thus, under rather continuous feeding conditions a condition cycle might be independent from the gonad activities, contrasting to cold temperate latitudes with typical spring/summer phytoplankton blooms.

ACKNOWLEDGMENTS

Data were obtained in the context of two larger projects: "Bivalve Culture in the Colombian Caribbean, 01/94–04/99" and "Effects of El Niño on Biological Resources of Latin America 1999–2001". The first author thanks the following students for their collaboration in the field, as well as working on the samples: Ángela Maria Pérez, Maria Cristina Murillo, Juan Pablo Assmus and F. Marcos Ablanque.

COMPARATIVE FECUNDITY OF THREE *PROCAMBARUS* SPECIES

ARNOLD G. EVERSOLE* AND YAVUZ MAZLUM
Department of Aquaculture, Fisheries and Wildlife, Clemson University, Clemson, South Carolina 29634-0362

ABSTRACT Adult female *Procambarus acutus acutus*, *P. zonangulus*, and *P. clarkii* (n = 64) were held in simulated burrows for 160 days. Mean percentage hepatopancreas moisture for a subsample (n = 12) of *P. zonangulus* was significantly less than that for the other two species. *Procambarus clarkii* oviposited eggs 30 days earlier than the other two species; however, a significantly lower proportion of the *P. clarkii* (33.3%) oviposited eggs than did *P. a. acutus* (95.3%) and *P. zonangulus* (71.9%). The number of extruded eggs increased with crayfish total length (TL). Similar-sized *P. clarkii* oviposited significantly more eggs than *P. zonangulus* and the eggs/female for *P. a. acutus* were significantly less than for the other two species. The dry weight, protein, and lipid content per egg for *P. a. acutus* and *P. zonangulus* were similar and significantly greater than those for *P. clarkii* eggs. The smaller eggs of *P. clarkii* yielded shorter instars than *P. a. acutus* and *P. zonangulus* instar TL. A standard-sized *P. a. acutus* (104.6 mm TL) allocated 10.2%, 13.6%, and 22.2% of total-body dry weight, protein, and lipid to extruded eggs, respectively.

KEY WORDS: crayfish, fecundity, *Procambarus clarkii*, *Procambarus zonangulus*, *Procambarus acutus acutus*

INTRODUCTION

Red swamp crayfish, *Procambarus clarkii* (Girard), dominates crayfish aquaculture and wild harvests in the southeastern United States (Eversole & McClain 2000). Frequently, these harvests contain the white river crayfish, originally classified as *Procambarus acutus acutus* (Girard) until Hobbs and Hobbs (1990) revised the taxonomy. Upon revision, the white river crayfish, which overlapped *P. clarkii*'s range in Louisiana and in other states along the Gulf of Mexico, was named *Procambarus zonangulus* Hobbs and Hobbs. *P. a. acutus*, whose range extends from Maine to Georgia, occurs sympatrically with *P. clarkii* only in locations where the latter has been introduced.

Comparative studies of *P. clarkii* and *P. zonangulus* indicate significant differences in life history traits between the two species. For example, *P. zonangulus* produces fewer large eggs, whereas *P. clarkii* produces a greater number of small eggs (Noblitt et al. 1995; Noblitt & Payne 1995). Noblitt et al. (1995) suggested that *P. zonangulus* followed a prudent reproductive strategy that was characteristic of species adapted to an environment where nutrients are low or pulsed at an unpredictable rate. In contrast, *P. clarkii*'s reproductive strategy is consistent with existence in a nutrient-abundant, predictable environment. *P. zonangulus* also appears to be more conservative in mobilizing nutrients during starvation than is *P. clarkii* (Powell 2001). Other comparisons include length–weight relationships, production characteristics, and population studies in aquaculture systems (Romaire & Lutz 1989; Deng et al. 1995; Huner 1994).

P. clarkii was introduced into South Carolina for aquaculture in 1978 (Pomeroy & Kahl 1987). Although *P. clarkii* is the mainstay of the South Carolina aquaculture industry (Whetstone, pers. comm.), there are concerns about its and other crayfish introductions (Taylor et al. 1996). Comparative research on *P. clarkii* and *P. a. acutus* has been limited to investigations of the two species in experimental culture ponds. Denson and Eversole (1996) reported a dramatic shift in species composition from *P. clarkii*- to *P. a. acutus*-dominated culture ponds over a relatively short period. Follow-up 2 years of supplemental stockings (59–114 kg/ha) of *P. clarkii* failed to increase its long-term production in these *P. a. acutus*-dominated ponds (Eversole et al. 1999). Although reflooding of drained culture ponds in September increased *P. clarkii* percentage in the harvest in comparison to October and November reflooding dates, it did not improve production (Mazlum & Eversole 2000).

A series of investigations have been designed to gain a better understanding of *P. clarkii* and *P. a. acutus* interactions. The focus of this study was to provide comparative reproductive data for *P. a. acutus*, *P. zonangulus*, and *P. clarkii*. Specific objectives were to determine the number of extruded eggs, egg size and composition, egg development time, and instar size for the three species.

MATERIALS AND METHODS

Experimental Animals

Adult female *P. a. acutus* and *P. clarkii* were collected from harvests at two locations in South Carolina: Clemson University Aquaculture Research Facility at Clemson and a commercial farm in Fountain Inn on May 24 and June 1, 1999, respectively. Female *P. zonangulus* were collected from Ben Hur Farm, Louisiana State University, Baton Rouge, Louisiana, air shipped, and arrived at Clemson on May 19, 1999. Individuals (n = 76) of each species with a complete set of appendages were either placed in simulated burrows (n = 64) or sacrificed for hepatopancreas moisture determinations (n = 12).

Hepatopancreas Moisture

The total length (TL) of 12 individuals of each species was measured to the nearest millimeter. The hepatopancreas was excised, weighed to the nearest 0.01 g after blotting (H_{ww}) and dried in a convection oven (80°C) to a constant weight (H_{dw}). Moisture content of the hepatopancreas (HM) was calculated using the following formula:

$$\mathrm{HM} = \frac{\mathrm{H}_{\mathrm{ww}} - \mathrm{H}_{\mathrm{dw}}}{\mathrm{H}_{\mathrm{ww}}} \times 100$$

Reproductive Success

Individual crayfish (n = 64) were measured (TL) and placed in 1-L plastic containers (simulated burrows). Although these con-

Technical Contribution No. 4728 of the South Carolina Agricultural Experiment Station, Clemson University, Clemson, South Carolina.

tainers were not intended to duplicate conditions in earthen burrows, they do represent a technique to compare fecundities across species under more uniform test conditions. The simulated burrows were suspended in restaurant glass racks held in four raceways receiving dechlorinated aerated water. Each raceway contained a rack of 16 individuals of each species. Holes drilled in the bottom and along the side of the container allowed water exchange and maintained 5-cm water depth. Crayfish were held at ambient water temperatures and not fed over the 160-day experimental period. Crayfish were checked 5 days/wk and every fifth day the water was exchanged in the raceway. Water temperature and dissolved oxygen were checked by meter (Model 55, YSI). Survival and the presence of extruded eggs were noted by date. A proportion of the ovigerous females were removed from burrows, usually within 24 h of oviposition, and the extruded eggs removed with forceps, counted, and fixed in 10% neutral formalin. Eggs on the other ovigerous females were allowed to develop and hatch. Development time was recorded and the TL of third instars measured.

Egg Characteristics

Egg subsamples ($n = 4$–5) from 12 individuals of each species dried at 80°C were weighed to the nearest 0.001 mg to estimate mean egg dry weight. Following drying, the nitrogen content of egg samples was determined by the Dumas method using a Carlo-Erba NA 1800 (Series 2) nitrogen analyzer. Nitrogen content (percent) in an egg sample was multiplied by 6.16 to estimate the percentage protein per egg on a dry weight basis (Noblitt & Payne 1995). Lipid content was determined on duplicate subsamples of 10 eggs each from six ovigerous females per species. Egg lipid content (percent) was determined as described by Mann and Gallager (1985). Egg lipid content (percent) was calculated on a dry weight basis as a mean of the duplicate subsamples.

Statistical Analysis

Data were analyzed with the analysis of variance (ANOVA), analysis of covariance (ANCOVA), and linear regression using Micro-SAS Statistical Software System Version 8 (SAS 1999). A split-block design with trays representing blocks was used to analyze the effects of raceways on the reproductive performance of the three species. The general linear model for ANOVA was used to compare species differences in initial TL, instar TL, hepatopancreas moisture content, time to ovipositing, hatching time, and egg size (dry weight, lipid, and protein content). The differences between ovipositing and nonovipositing female crayfish within species were compared by ANOVA. Linear regression was used to determine the relationship between crayfish TL and number of extruded eggs per ovipositing female. The ANCOVA procedure was used to compare slopes and intercepts of the regressions and eggs/female. Differences in means were detected with least-significant difference (LSD) test (Ott 1993). Level of significance was set at $P \leq 0.05$.

RESULTS

Experimental Animals

The TL of the species stocked in simulated burrows were significantly different; *P. a. acutus* was the longest, *P. zonangulus* the shortest, whereas *P. clarkii* was intermediate in TL (Table 1). *P. zonangulus* hepatopancreas contained the least amount of moisture and was assumed to be in better conditions than the other two species (Huner et al. 1985; Huner et al. 1990). Mortality in the simulated burrows was low; only two individuals each of *P. zonangulus* and *P. clarkii* died over the 160-day experimental period. Mean (±SD) water temperature and dissolved oxygen was 24.5 ± 2.21°C and 4.0 ± 1.38 mg/L, respectively, over the period.

TABLE 1.

Mean (±SD) and range of total length (TL) of the females used in the experiment, ovipositing and nonovipositing crayfish, hepatopancreas moisture, time from the start of experiment to ovipositing, and number of extruded eggs per female.

Variable*	*P. a. acutus*	*P. zonangulus*	*P. clarkii*
Initial female TL (mm)	109.1 ± 6.89^{a} (90–127) $n = 64$	95.7 ± 7.95^{b} (80–120) $n = 64$	100.5 ± 9.44^{c} (83–125) $n = 64$
Hepatopancreas moisture (%)	55.1 ± 8.31^{a} (41–69) $n = 12$	39.1 ± 6.17^{b} (29–50) $n = 12$	55.3 ± 5.93^{a} (48–64) $n = 12$
Ovipositing female TL (mm)	109.3 ± 6.99^{A} (90–127) $n = 61$	97.4 ± 7.22^{A} (85–120) $n = 46$	103.0 ± 7.50^{A} (88–115) $n = 24$
Nonovipositing TL (mm)	104.7 ± 1.15^{A} (104–106) $n = 3$	91.1 ± 8.38^{B} (80–112) $n = 16$	99.1 ± 10.51^{A} (83–125) $n = 38$
Time to ovipositing (days)	108.4 ± 6.87^{a} (89–122) $n = 61$	114.0 ± 8.00^{a} (92–146) $n = 46$	99.0 ± 19.72^{b} (58–131) $n = 24$
Eggs/female	304.9 ± 50.34^{a} (234–555) $n = 40$	367.2 ± 36.48^{b} (189–420) $n = 24$	586.5 ± 58.89^{c} (282–764) $n = 12$

* Those means sharing lower case superscripts within rows or uppercase superscripts within columns are not significantly different ($P > 0.05$).

Percentage of crayfish ovipositing was similar among the four raceways. Because of the lack of difference among the raceways, blocks (raceways) were pooled in subsequent statistical analysis of reproductive performance measures among species.

Reproductive Success

A significantly higher proportion of *P. a. acutus* (95.3%) oviposited eggs than *P. zonangulus* (74.2%), and the proportion of ovipositing *P. clarkii* (38.7%) was significantly less than the other two species. In contrast, *P. clarkii* was the first species to oviposit eggs, more than 30 days earlier than the other two species (Table 1). No crayfish were observed ovipositing eggs within the last 4 weeks of the experiment; however, glair gland development was not assessed in these crayfish.

Individuals of *P. a. acutus* entire size range (90–127 mm TL) oviposited eggs, whereas some smaller individuals of the other two species did not oviposit (Table 1). Although the ovipositing individuals of each species were larger than the nonovipositing individuals, the only significant difference in TL was observed with *P. zonangulus*.

Number of extruded eggs ranged from 189 on a 85-mm TL *P. zonangulus* to 764 on a 114-mm TL *P. clarkii* (Table 1). Extruded eggs per female varied significantly with increased TL in the three species (Fig. 1). These linear relationships explained 80%–90% of the variation among individuals of the species. Using TL as a covariant, ANCOVA indicated significant differences in extruded egg counts among the three species, with *P. clarkii* being most fecund (Table 1). The slopes and intercepts of the regressions were also significantly different among species.

Egg Characteristics

Eggs of *P. a. acutus* and *P. zonangulus* were similar in weight and significantly heavier than *P. clarkii* eggs (Table 2). The eggs of these two species also contained a significantly greater proportion of lipid and protein than did those of *P. clarkii*. The smaller eggs of *P. clarkii* hatched approximately 3 days earlier than those of the other two species; however, the TL of the third instars were significantly shorter than the instars of *P. a. acutus* and *P. zonangulus* (Table 2).

DISCUSSION

P. a. acutus and *P. zonangulus* share many morphological, ecological, and reproductive characteristics. Both species belong to the subgenus Ortmannicus, diagnosed by the terminal element of the first pleopod (Hobbs 1972; Hobbs & Hobbs 1990). Although this characteristic clearly distinguishes *P. zonangulus* as a species and distinct from *P. a. acutus*, these two species have similarly shaped chelipeds, carapace, and overall body proportions (Hobbs 1981; Hobbs & Hobbs 1990, pers. observations). Crayfish with similar body forms frequently occur in similar habitats (Hobbs 1975; Holdich & Reeve 1988). *P. a. acutus* and *P. zonangulus* occur in sluggish streams with aquatic vegetation and lentic habitats, including those with fluctuating water levels such as borrow pits, roadside ditches, sloughs, and farm ponds (Hobbs 1981; Hobbs & Hobbs 1990; Deng et al. 1993). Adults of both species retreat to burrows in drying habitats and also to oviposit eggs, which is characteristic of tertiary burrowers (Hobbs 1981).

P. a. acutus and *P. zonangulus* shared several of this study's measured reproductive characteristics with the exception of hepatopancreas moisture content and the number of extruded eggs per female (Table 1). Crayfish store large amounts of energy (lipid) in the hepatopancreas for oocyte development and survival while in the burrow (Huner 1989). For this reason, relative moisture content of the hepatopancreas has been suggested as an indicator of crayfish condition (Huner et al. 1985; Huner et al. 1990). It was expected, based on hepatopancreas moisture content, that *P. zonangulus* fecundity would be greater than a similar-sized *P. a. acutus*, which was the case. The "better conditioned" *P. zonangulus* oviposited more lipid as eggs (349.9 mg on a dry weight basis) than a comparable-sized *P. a. acutus* (271.6 mg lipid).

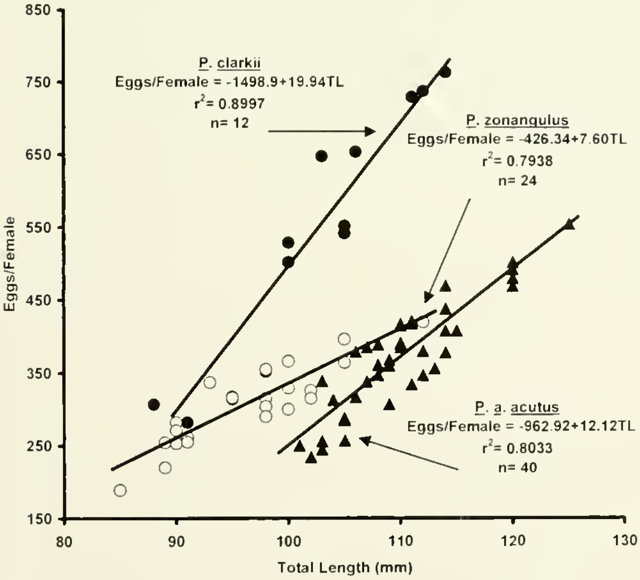

Figure 1. Relationships between total length (TL, mm) and number of extruded eggs per female for *Procambarus clarkii*, (closed circles), *P. a. acutus* (triangles), and *P. zonangulus* (open circles).

TABLE 2.

Mean (±SD) and range of egg dry weight, lipid, protein, hatching time from ovipositing date to the appearance of instars and the total length (TL) of instars.

Variable*	No.	*P. a. acutus*	*P. zonangulus*	*P. clarkii*
Dry weight (mg/egg)	12	3.49 ± 0.379^a (2.83–4.20)	3.44 ± 0.443^a (2.64–4.29)	1.94 ± 0.245^b (1.46–2.27)
Egg lipid (%)	6	26.0 ± 1.16^a (23.6–28.2)	26.6 ± 2.06^a (22.0–28.6)	17.6 ± 1.75^b (19.2–20.7)
Egg protein (%)	12	58.9 ± 3.67^a (47.4–60.1)	57.6 ± 4.37^a (43.4–58.8)	45.4 ± 3.21^b (40.5–50.9)
Hatching time (days)	9	21.1 ± 0.60^a (20–22)	21.6 ± 0.88^a (20–23)	18.6 ± 0.73^b (18–20)
Instar TL (mm)	200	9.5 ± 0.55^a (9–11)	9.6 ± 0.58^a (9–11)	7.6 ± 0.51^b (6–8)

* Those means within rows sharing lowercase superscripts are not significantly different ($P > 0.05$).

The reproductive characteristics of *P. a. acutus* and *P. zonangulus* contrasted that of *P. clarkii* (Tables 1 and 2). For example, *P. clarkii* fecundity was higher and the extruded egg size was smaller than that observed for *P. a. acutus* and *P. zonangulus*. Also, the hatching time and TL of hatchlings (instars) was shorter for *P. clarkii* than for the other two species. Our observations are consistent with the hypotheses of Noblitt et al. (1995) in that the reproductive characteristics of *P. zonangulus* and *P. a. acutus* follow a prudent strategy where more resources (energy) are invested in each egg, improving the survival or fitness of offspring in less predictable environments. Instar fitness is more dependent on size in this reproductive strategy scenario, and those species with bigger eggs yield larger instars. The larger instar *P. a. acutus* (10 mm TL) in allopatric and sympatric competition experiments survived at a higher rate than the smaller *P. clarkii* instars (8 mm TL) (Mazlum & Eversole, unpubl.).

The fraction of dry weight, protein, and lipid extruded in eggs were computed from linear regressions for whole-body female *P. a. acutus* dry weight, protein and lipid levels (calculated from data of Turker 1997) and for our fecundity estimates in terms of each of these parameters. A standard-sized *P. a. acutus* (104.6 mm TL) with an average fecundity of 249.4 eggs oviposited 1,065 mg dry weight, 573.7 mg protein, and 271.6 mg lipid. The fraction of the whole-body dry weight, protein, and lipid used for extruded eggs was 10.2%, 13.6%, and 22.2%, respectively. The average reproductive lipid output (extruded eggs) of 22.3% total-body lipid computed for 31 ovipositing *P. a. acutus* (Eversole et al. 2000) was almost identical to the estimate derived in this study. Similarities in the proportion of lipid devoted to reproduction are explicable in terms of fecundity, egg size, and the total-body content. Because of the differences in systematics and reproductive strategies among the species, it might be expected that the allocation of energy (lipid) to reproduction differs as well. Unfortunately, this comparison will have to wait until compatible data are available for the species or reproductive strategies.

ACKNOWLEDGMENTS

Funding was provided by the S.C. Aquaculture Research Initiative, S.C. Agricultural Experiment Station, and the Turkish Ministry of Education. Dr. L. W. Grimes provided statistical advice. Dr. Robert Romaire provided the *P. zonangulus*, and Ms. J. Richardson suffered through multiple drafts of this manuscript. We also thank Shane M. Welch and Danny R. Jones for reviewing the manuscript.

[2]*Department of Biotechnology and Aquaculture, Institute of Oceanography, Nhatrang, Vietnam*

ABSTRACT Adult and juvenile mud crabs (genus *Scylla*) were collected from two sites in the Mekong Delta, Vietnam. The specimens were examined morphologically and analyzed by starch gel electrophoresis to confirm the species present based on a recently published revision of the genus *Scylla* that recognizes four species from adult morphological characters and electrophoresis. The Mekong Delta samples contained two species, S. *olivacea* ("red crab") and *S. paramamosain* ("green crab"). Ratios derived from measurements of the carapace width and the frontal spines, which are species diagnostic in adult mud crabs, did not separate juvenile *S. paramamosain* and *S. olivacea* reliably. However, in combination, differences in the shape of the frontal spines, the spination on the cheliped, and cheliped shape and color, make it possible to distinguish juveniles of these two species down to a size of about 1.5 mm carapace width. This is the modal body size of new recruits entering the mangroves of the Lower Mekong Delta. The diagnostic morphological features of adult and juvenile *S. olivacea* and *S. paramamosain* from the Mekong Delta are based on the architecture of the frontal lobe spines and the number of dorso anterior propodal spines and ventral carpal spines. These are described, together with features relating to their coloration and habitat preferences. The recognition of two named species of *Scylla* within the mangrove populations of mud crab in the delta is important to fisheries management and aquaculture development, as both adult and juvenile mud crabs are fished heavily for marketing and for stocking in aquaculture systems, respectively.

KEY WORDS: *Scylla*, mud crab, species identification, mangrove, Mekong Delta

INTRODUCTION

Mud crabs of the genus *Scylla* are the only swimming crabs (Family *Portunidae*) that are found habitually in tropical and subtropical mangrove forest ecosystems; their habitat extends to mangrove estuaries, embayments and surrounding coastal waters (Macnae 1968). As well as providing shelter from predation and desiccation, especially during moulting, mangroves also provide mud crabs with a plentiful supply of food in the form of other crustaceans and molluscs (Arriola 1940; Hill 1979).

Mud crabs have significant economic importance to artisanal fisheries throughout the Indo West Pacific region. They are also contributing increasingly to aquaculture production in several countries, most notably Vietnam and the Philippines (Johnston & Keenan 1999; Fortes 1999). Their rapid growth and high market value, coupled with easy post-harvest handling, make them an attractive alternative to farming shrimp within coastal areas (Overton & Macintosh 1997). The growing importance of mud crab farming is also supported by a rapidly expanding demand for crab products, both regionally and internationally.

The mangrove forests of Vietnam originally covered an area of up to 400,000 ha (Maraund 1943), of which about 250,000 ha flourished in the Mekong Delta. The greatest concentration of mangrove (150,000 ha) was in the Minh Hai Peninsula, which is now divided into Ca Mau and Bac Lieu provinces (Fig. 1). Despite heavy exploitation in recent decades, mangroves are still the dominant habitat in the extensive saltwater-influenced regions of the delta.

Within the coastal provinces of the Lower Mekong Delta (LMD), rural communities are heavily dependent on mangrove-based fisheries and aquaculture to support their livelihoods. These include crab fishing and crab culture as a secondary activity to shrimp farming within the mangrove forest ecosystem. Average mud crab production in the LMD ranges from 504 to 839 kg/ha/y (World Bank/Danida 2000). Nearly all the available brackishwater areas of the delta have been converted to extensive aquaculture ponds for shrimp and/or crab production integrated to varying degrees with the mangrove forest (these farming systems are described by Binh et al. 1997; and Johnson et al. 1999). To date, there are no commercial hatcheries in Vietnam to support mud crab culture and, consequently, the natural recruitment of juvenile mud crabs into the mangrove ecosystem provides the only source of seed available to crab farmers.

A previous study using morphometric analysis confirmed the existence of two common morphs of *Scylla* within the South China Sea region (Overton et al. 1997; Overton 2000), while Keenan et al. (1998) have proposed a total of four species of mud crab based on genetic data from a wider geographical range. They also describe morphological characters to distinguish the four species. Although Keenan et al. (1998) attribute two species to Vietnam, only one species is mentioned from the Mekong Delta, called *Scylla paramamosain* Estampador. Moreover, the study is based entirely on large adult specimens (carapace width greater than 95 mm), because the distinguishing characteristics of each species are more clearly defined in the adult stages. Until now, no species identifications have been reported for the juvenile stages. The people who catch or rear juvenile mud crabs in the Mekong Delta recognize two morphs of *Scylla* on the basis of color, using the local names "cua xanh" (green crab, due to its greenish carapace) and "cua lua" (red crab, due to dark red coloration on the lower chelae). These color differences are not distinct in the smaller juveniles, however, especially after capture.

In the present study, adult and juvenile mud crabs were collected from the Lower Mekong Delta. They were then examined morphologically and analyzed using electrophoresis to determine which species are recruiting into the mangrove crab fishery. The main objective was to produce scientific descriptions of both juveniles and adults of the species identified, which confirm [illegible]

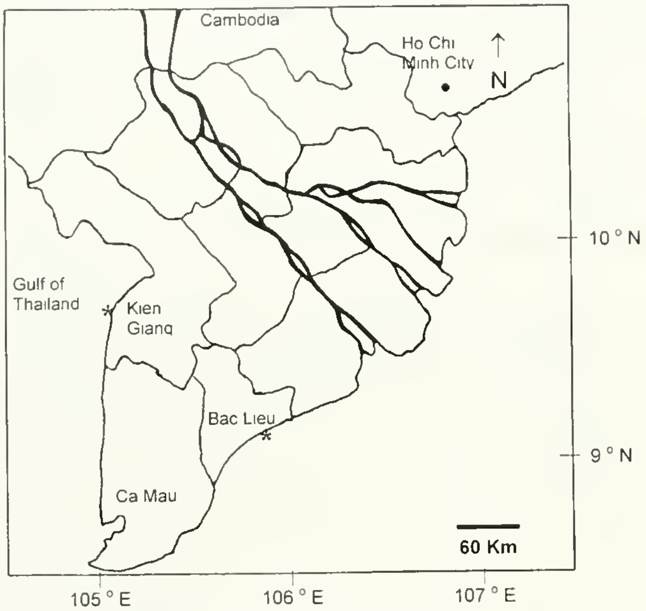

Figure 1. The Mekong Delta, Vietnam showing the location of the sampling sites in Bac Lieu and Kien Giang provinces.

local identities based on color and behavior. This knowledge is vital for mud-crab stock assessment and for the future development of mud crab culture using selected, known species of *Scylla*. Recruitment and growth studies on juvenile mud crabs are particularly needed in this regard.

MATERIALS AND METHODS

Crab Collection

Study sites were chosen within two of the most southerly coastal provinces of the Mekong Delta: Bac Lieu (9°00'N; 105°14'E) and Kien Giang (9°22'N; 104°26'E) (see Fig. 1). The crabs were collected from mud crab fishers or traders. They were interviewed to confirm that the crabs obtained were all fished from the selected locality.

In the first investigation, 23 adult crabs, 84 to 125 mm carapace width (CW), including both common morphs of *Scylla*, were sampled from the commercial mud crab fishery in Bac Lieu Province. Their species identities were confirmed by comparing their morphology and allozyme mobility with those published by Keenan et al. (1998). In the second investigation, juvenile mud crabs (CW 45–62 mm) from Bac Lieu and Kien Giang provinces (62 and 58 individuals, respectively) were studied. The majority of specimens from Kien Giang were the "red" morph, whereas all those collected from Bac Lieu in the second sample were typical of the "green" morph. In addition, a larger number of smaller juveniles (CW 10–45 mm) were available for examination from the commercial crab seed fishery in Ca Mau.

Crab Measurement

Three physical measurements were made on each sampled mud crab using digital calipers, namely Frontal Lobe Width (FLW), Internal Carapace Width (ICW) and Frontal Median Spine Height (FMSH) (Fig. 2). Measurements were recorded to the nearest 0.1 mm. From these measurements, two ratios described by Keenan et al. (1998) as discriminating between the four known species of *Scylla* were used to compare the red and green morphs of *Scylla* from the LMD. These ratios were FLW/ICW and FMSH/FLW.

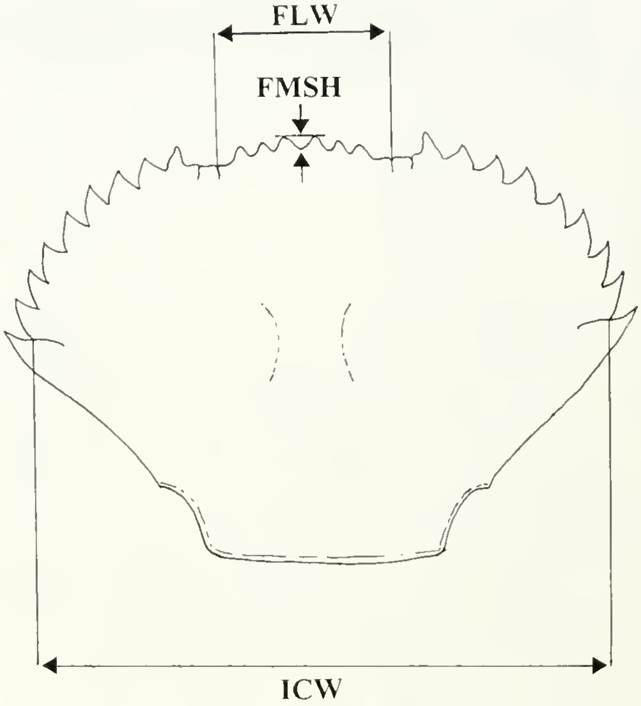

Figure 2. Illustration of the three measurements forming the ratios used to discriminate between the two *Scylla* species. FLW: Frontal Lobe Width; FMSH: Frontal Median Spine Height; ICW: Internal Carapace Width.

Allozyme Electrophoresis

Use of genetic markers, including allozyme electrophoresis, are the most reliable in identifying *Scylla* species (Keenan et al. 1998; Overton 2000). Other mud crab specimens representing the four *Scylla* species proposed by Keenan et al. (1998), which had been identified earlier (Overton 2000), were used as reference material to help interpret the results from electrophoresis using the mud crabs obtained from the Mekong Delta.

Muscle tissue was extracted from each crab specimen and stored at −80°C. The allozymes extracted from the muscle tissue were separated using starch gel electrophoresis. The electrophoretic techniques used followed those described by Harris and Hopkinson (1976), Shaklee and Keenan (1986) and Pasteur et al. (1988). Four allozymes, using two buffer systems that distinguish the four species of *Scylla* identified by Keenan et al. (1998), were used to identify the two common species collected from the LMD. These enzymes were alanine aminotransferase (ALAT), argenine kinase (ARGK), mannose phosphate isomerase (MPI) and phosphoglucomutase (PGM). They were visualized using standard staining procedures (Shaw & Prasad 1970; Harris & Hopkinson 1976; Shaklee & Keenan 1986; Pasteur et al. 1988).

RESULTS

The results of the allozyme electrophoresis confirmed that the two common species of *Scylla* in the Mekong Delta are *S. olivacea* Herbst (red morph) and *S. paramamosain* Estampador (green morph), as described by Keenan et al. (1998). Figure 3 and Table 1 illustrates the fixed mobility observed between the LMD specimens and the typed samples of the four species (also based on Keenan et al.).

The frontal spine morphology represented by the ratios FLW/ICW and FMSH/FLW did not prove to be conclusive in distinguishing the two species identified from the allozyme data. Both adults and juveniles of the green morph (*S. paramamosain*) have narrower frontal lobe widths (compared to their internal carapace width) and taller frontal lobe spines, than crabs of the red morph (*S. olivacea*). This conforms with the spinal architecture of sharp frontal spines on the green morph and smooth, obtuse frontal lobe spines on the red morph (Fig. 4). However, the ranges obtained for each of the ratios show that there is a large overlap between the two species and that it is not possible to identify an individual crab solely from either of these ratios.

Although both juveniles and adults of the two mud crab species from the Mekong Delta could be distinguished from each other using the above ratios, it is less clear which species they represent when they are compared to the equivalent ratios for the four *Scylla* species proposed by Keenan et al. (1998) (Table 2). Mean values of FLW/ICW for the juvenile red and green morphs of *Scylla* lie out with the ratios reported by these authors. The mean values for the adult specimens from Bac Lieu are within the published ranges for the four *Scylla* species recognized by Keenan et al. 1998, but they lie between the values of 0.037/0.038 for *S. serrata*/*S. paramamosain* and 0.412/0.415 for *S. tranquebarica* /*S. olivacea* (Table 2).

Mean values for the ratio FMSH/FLW for adults and juveniles of both Vietnamese morphs also fall within the ranges set by Keenan et al. 1998 for the four *Scylla* species they recognize (Table 2). FMSH/FLW ratios positively identified the adult green morph from Bac Lieu as *S. paramamosain* and the juvenile red morph as *S. olivacea*, but the other two sample groups cannot be classified reliably on the basis of this ratio. This is not surprising as there is also considerable overlap in the ranges of the FMSH/FLW values for each species as reported by Keenan et al. 1998.

DISCUSSION

The results from allozyme electrophoresis were conclusive in identifying the two common species of *Scylla* in the coastal mangrove ecosystem of the Mekong Delta. Based on the recent review of the genus *Scylla* by Keenan et al. (1998), the morphs recognized by fishers and crab farmers as "red crab" and "green crab" are *S. olivacea* and *S. paramamosain*, respectively. These confirmed identifications help to overcome the long-standing confusion about the identity of mud crab species when their fisheries biology, or use in aquaculture is described. As noted by Fortes (1999), several authors have assumed a single species, *Scylla serrata*, in aquaculture, despite evidence that this mud crab is actually rare in the Southeast Asian region compared to the other three species of *Scylla* now recognized (Keenan et al. 1998; Overton 2000).

It is not surprising that the morphometric ratios based on carapace measurements (FLW/ICW and FMSH/FLW) were inconclusive for the identification of juvenile mud crabs, or that the values obtained do not lie within the equivalent ranges for adult specimens. Developmental changes in exoskeletal dimensions between juvenile, sub-adult and adult crabs are well documented (Hartnoll 1982). Indeed the relative allometic changes in the dimensions of the body are often used to define the molt of maturity in crustacean species (e.g., Somerton 1980; Paul & Paul 1995). However, the same ratios obtained from the adult mud crabs sampled also did not conform to the equivalent values reported by Keenan et al. (1998). This apparent discrepancy may be explained by (a) operator differences when taking carapace measurements with calipers; or (b) natural variation in the morphology of these closely related species. It is notable that there is a high degree of overlap between the ratios recorded by Keenan et al. (1998), and clearly morphometrics alone cannot be used to identify individual mud crabs reliably.

The morphological characters used to identify the species in adult samples can also be extended to juvenile crabs down to a size of 1.5 cm carapace width, the modal size of new recruits into the Mekong Delta. In particular, the architecture of the frontal lobe spines and the number of spines on the carpus are reliable characters which can be used to distinguish juveniles of *S. olivacea* and *S. paramamosain*, even in the field.

The presence of two species in the Mekong Delta mud crab fisheries is important from a fisheries management and aquaculture development perspective, as natural recruitment of juvenile mud crabs into the mangrove ecosystem is the only source of seed available to crab farmers in the delta. It will now be possible to investigate and compare ecological differences between these two species, especially their potential in aquaculture.

The yield of mud crab in Ca Mau Province was 5000 tonnes in 1999, of which 1000 tonnes came from aquaculture production (Xuan 2001). In the ten-year fisheries development plan for Ca Mau Province (2000 to 2010), the production of cultured mud crab is expected to increase to 3,500 tonnes per annum. This increased emphasis on aquaculture has important implications regarding the sustainable level of exploitation of the mud crab seed recruiting into the coastal mangroves. From observations of the crab seed fishery in Ca Mau, it is clear that there are significant seasonal fluctuations in the supply and species composition of juvenile mud crabs caught by local fishers. It also appears that the recruitment dynamics of *S. paramamosain* and *S. olivacea* vary from province to province in the delta (Macintosh: personal observation). By being able to identify these two common species of *Scylla* down to the early juvenile stages entering the mangroves, a more accurate assessment of this important fisheries resource can now be attempted.

Scylla paramamosain and *S. olivacea* are farmed throughout the brackish water regions of the Mekong Delta, usually in earthen ponds constructed within the mangrove forests. The farmers generally stock juveniles of both species purchased from fishermen or crab dealers. Their general opinion is that *S. olivacea* is the more aggressive species. It also likes to burrow, which weakens the pond structure and making harvesting very difficult. In contrast, *Scylla paramamosain* is regarded as more suited to pond culture as it seldom burrows. However, female *S. olivacea* are very popular as "egg crab" (crabs with mature ovaries) because they develop large ovaries at a comparatively small body size. Differences in size at maturity and gonosomatic index have also been recorded in sympatric populations of *S. olivacea* and *S. paramamosain* in the Gulf of Thailand (Overton 2000). By confirming their species identity at the juvenile stage, it will now be possible to research the

biological basis for the farmers' observations about red crab (*S. olivacea*) and green crab (*S. paramamosain*) in aquaculture. Studies of their comparative tolerance to different combinations of salinity and temperature, their comparative growth rates and maturation under different pond conditions, and the possible affect of interspecific interaction between *S. olivacea* and *S. paramamosain* in mixed culture, could yield valuable information to improve mud crab farming in the Mekong Delta.

Diagnoses of the Two Common Species of Scylla in the Mekong Delta

Scylla olivacea Herbst

Dorsal carapace brown to dark green. Dorsal chelae and pereiopods range from dark brown to green, no reticulation present. Ventral propodus orange/red. Carapace rounded with blunt, obtuse frontal lobe teeth all equal in size, with shallow interspaces. Short,

obtuse anterolateral spines uniform in size and shape. None to two vestigial spines present on dorsal propodus of the chelae. Pronounced nodule present on inner lateral propodus. Spination on ventral carpus of chelae ranges from two vestigial, nodule-like spines to a total absence of spines. Abdominal flap of mature females dark brown to purple with a pale lateral stripe on each abdominal segment.

Coloration of juveniles similar to that of the adults. Chelae are elongate, with a distinctive dark red flash on the outer propodus and fixed dactyl. Chelae bear blunt, obtuse frontal lobe teeth that are equal in size, with shallow interspaces. Two sharp spines on dorsal propodus, and one pronounced nodule on inner lateral propodus. Single spine present on ventral carpus.

Scylla paramamosain Estampador

Adult carapace pale olive green. Dorsal chelae and pereiopods pale green with prominent dark green/brown reticulation. Reticulation breaks up and forms brown dots on outer upper half of propodus. Lower half of outer lateral propodus pale yellow to cream with orange to red flashes on tips of propodus and dactylus. A black patch is present on ventral surface of carpus.

Carapace flattened dorso-ventrally, with short, triangular frontal lobal teeth with angular interspaces. Central pair of frontal lobe teeth slightly protruded in some individuals. All anterolateral spines uniform in morphology, and compressed with small spaces between spines. Two sharp spines on dorsal propodus with ridges following posteriorly behind spines. One small spine present on inner lateral propodus. Two sharp spines on ventral carpus, on some individuals the anterior spine is vestigial, or missing.

Juveniles have similar body coloration to adult form. Carapace bears short frontal lobal teeth, sharp and triangular with angular interspaces. Two pronounced spines on the dorsal propodus. No nodule on inner lateral propodus. Ventral carpus usually bears two spines, but 6% of crabs examined have only one spine.

Habitat

Scylla olivacea is associated with mangrove forests, in particular estuarine and lower salinity areas associated with the river systems well within the mangrove zone or deltas where there is a high amount of freshwater runoff. *S. olivacea* prefers to burrow in the soft embankments during low tide. *S. olivacea* has an extensive distribution, populations of this species having been identified from the coastlines fringing the western Indian Ocean to northern and western Australia and islands of the Pacific Ocean (Keenan et al. 1998). Another species, *Scylla tranquebarica*, is often associated with *S. olivacea*. These two mud crabs occupy similar niches in the mangroves of East Malaysia and the Philippines (Macintosh, personal observation).

Scylla paramamosain inhabits a more subtidal environment than *Scylla olivacea*. This species is found in the mouth of estuarine areas and shallow subtidal mudflats and along the coastal fringes of mangrove areas. Keenan et al. 1998 also remarks that the habitat of this species extends to coral reefs areas, as in Singapore. *Scylla paramamosain* is widely distributed along the coastlines of the South China Sea particularly along the coast of Vietnam and the eastern seaboard of the Thai-Malay peninsula (Overton 2000).

ACKNOWLEDGMENTS

The authors thank the staff of the Aquaculture and Fisheries Sciences Institute of Can Tho University, Vietnam for providing facilities and manpower support for this study. Financial assistance was provided by Danida through the Can Tho University – Aarhus University Link in Environmental Sciences (CAULES) project, and in the form of a Danida scholarship awarded to Mr H.V.T. Thu.

PHYSICO-CHEMICAL CHANGES IN ACID SULFATE SOIL DURING SEMI INTENSIVE CULTURE OF *PENAEUS MONODON* FABRICIUS, IN CLEARED MANGROVE AREAS OF THE CHAKARIA SUNDARBANS, BANGLADESH

BIPLOB DAS,[1] YUSUF SHARIF AHMED KHAN,[1] KHAN TOWHID OSMAN,[2] PRANAB DAS,[1] AND MD. NURUL AMIN[1]

ABSTRACT The present study analyzed physico-chemical properties of pond soil during *Penaeus monodon* culture in a semi-intensive shrimp farm in Cox's Bazar district, Bangladesh during winter 1996 to 1997. Soils were acidic with high concentrations of SO_4-S, extractable Fe and Al. Soluble salt concentration were in order Na>Mg>Ca>K. The physico-chemical properties changed with flooding both under simple inundation and inundation with shrimp culture. The most noticeable change was soil P^H, SO_4-S and extractable Al. Extractable Al decreased a minimum value at 145 days after preparation of the culture ponds. Extractable Na and K were increased gradually while, Ca and Mg remained fairly constant throughout the entire period. The extent of change was different for the culture and the inundated ponds. Results of the present study indicated a positive effect on the improvement of acid sulphate soil in the cleared mangrove forest area because of shrimp culture.

KEY WORDS: *Penaeus monodon,* shrimp pond, culture

INTRODUCTION

Pond soil plays an important role in the balance of an aquacultural system and consequently on the growth and survival of aquatic organisms. Sediment/soil can function as a buffer. It provides water nutrients and serves as a biological filter through the adsorption of organic residues (Ray & Chien 1992). Soil thus playing a vital role in aquaculture practices is considered the "Chemical Laboratory" of the pond (Felix 1988). In ponds there is an intense interchange of organic and mineral compounds between the soil and the water (Wrobel 1983). Accumulation and decomposition of organic matter take place on the pond floor. As a result macro elements are eliminated from the pond water while the decomposition of organic matter releases inorganic substances and acids, and dissolutes minerals. These go into solution with water and influence aquatic biota.

A number of conditions are conducive to the formation of acid sulfate soils (Pons & Van Breemen 1982). Vast tracts of acid sulfate soils abound in Asia and Africa (Singh 1980; Brinkman & Singh 1982). In Bangladesh about 0.23 M ha of land constitute acid sulfate soils (FAO 1988). However, these are considered problem soils everywhere resulting in severe limitations for agricultural use (Nhung & Ponnamperuma 1982; Van Breemen & Pons 1978; Ponnamperuma & Solivas 1982; Hechanova 1983; Simpson et al. 1983).

Severe acidification of pond water in acid sulfate areas has been reported by many workers (Webber & Webber 1978; Lin 1986; Boyd 1989). The low P^H exerts its effects through the influence on most aspects of pond water chemistry. The main problems arising after construction or deeper excavation of fish ponds in acid sulfate soils comprise insufficient growth of algae, poor condition and consequent slow growth of phosphate fertilizers (Camacho 1977; Baylon 1981; Brinkman & Singh 1982; Poernomo & Singh 1982). Low P^H of the acid sulfate soils causes damage to gill tissues of fish (Ferguson 1988) and influences the impact of toxins (Alabaster & Lloyd 1980; Colt & Armstrong 1981) and heavy metals (Boyd 1989). In acid waters crustaceans and fish may experience impaired ionic regulation. P^H <4.8 is lethal for the Penaeids (Tsai 1990). Additionally, a high organic matter content in the bottom soil depletes O_2 of water (Wrobel 1983).

Characteristics of acid sulfate soils in some areas of Cox's Bazar have been reported by Rahman (1990), Rahman et al. (1993), and Mahmood and Saikat (1995). But no study has so far been done on the changes of pond bottom acid sulfate soil that take place by the amendments done for shrimp culture. Keeping these views in mind, this work was undertaken in a semi-intensive shrimp farm at Cox's Bazar. Ponds constructed on acid sulfate soils revealed physico-chemical changes in soils of shrimp (*Penaeus monodon*) culture ponds as well as inundated ponds.

MATERIALS AND METHODS

Location of the Farm

The semi-intensive shrimp farm namely "Chakaria Chingri Khamar" is situated on the western bank of the Matamuhuri River, about 5 km upstream from the estuary and about 65 km south of the Chittagong City.

Sampling

P. monodon was cultured in 14 ponds during winter of 1996 to 1997. Among those, three ponds (P-1, P-2 and P-3) were selected randomly on the basis of the previous years production data and soil P^H values to accommodate the maximum variability for the present study. From the rest of the fallow ponds (termed as inundated ponds), three others (P-4, P-5 and P-6) were selected where pond preparation was done similarly to the culture ponds but stocking was not.

Soil samples from 0–15 cm and 15–30 cm depths of pond bottom were taken from three spots diagonally of each pond (cultured and inundated), so that one spot was in the center and two were in the corners. Samples were drawn underwater with a specially designed sampler. Soil sampling was done 30 days before (DBP) and 7, 50, 95 days after completion of pond preparation (DAP). Soil samples were also taken at 145 DAP from the culture ponds.

Analysis of Soil Somples

Soil texture was determined according to Bouyouco's Hydrometer method (Piper 1950), P^H from 1:2 soil water suspensions and

organic matter from loss of ignition. Total nitrogen was determined by micro-Kjeldhal digestion and distillation procedures. Available phosphorus was extracted with Bray and Kurtz No. 2 extractant (0.03 N NH_4F in 0.10 N HCl) followed by Spectrophotometric determination according to $SnCl_2$ reduced molybdophosphoric blue color method (Jackson 1958). Extractable Ca, Mg, Na, K and Mn were determined by 1 N NH_4OAC, P^H 7.0 ± 0.1 saturation and FE by 1 N NH_4OAC, P^H 4.6 saturation followed by Atomic Absorption Spectrophotometry (Allen et al. 1986).

RESULTS AND DISCUSSION

Physico-chemical parameters of the culture ponds and inundated ponds are tabulated in Table 2 and Table 3 respectively. The textural classes of the soil samples are shown in the Table 1.

Soil samples of the present study were sandy clay to clay loam in texture. The texture has been inherited from the deposition of the sediments. Such compositions of acid sulfate soils are also met with the saline soils of Chakaria Sundarbans (Rahman et al. 1990). The textural variation could have been created by the sedimentation processes during past mangrove swamp systems.

The soils were found rather poor in total nitrogen in comparison to the organic matter content resulting in high C/N ratio, that may inhibit the decomposition of organic matter. This feature shows the characteristics of peat layers. A high organic matter poor in nitrogen is also conducive to reduction processes. Similar total nitrogen values were reported earlier from other acid sulfate soils of the area in association with low organic matter (Rahman et al. 1993).

Values of soil P^H remained neutral. After submergence, the P^H of acid sulfate soils gradually increases due to reduction and inactivation of SO_4-S through microbial activities (Singh 1982). This reduction rate depends on the presence of sulfur reducing bacteria, P^H of the system, energy source (organic matter), etc. (Van Breemen 1976; Pons et al. 1982). In the present investigation, the P^H of soils was found to be reduced by air-drying with the average values ranging from 3.68 to 6.2. Further reduction could have been achieved by slow oxidation with prolonged drying. Additionally, there were significant differences in P^H values of the soils of the same pond at different spots. It might be due to the fact that the sulfidic horizon had not been uniformly parallel to the land surface and during excavation residual sulfidic materials were left. Evidence indicates that the pond soils had acid sulfate characters. In

the Chakaria Sundarbans zone, dry P^H of surface soil was found as low as 3.15, which increased gradually with depth (Mahmood & Saikat 1995). The wet soil P^H in the surface soil of the present study was less than the sub-soil. Excavating a depth greater than 1 m for pond construction might have exposed the less acid sub-soil. Aeration of water might have caused some oxidation. The higher reduction in P^H of the sub-soil due to drying might, on the other hand, be responsible for downward leaching of sulfate. Air dry soil P^H was found to range from 2.6 to 4.3 in some acid sulfate soils of Cox's Bazar and Chakaria (Rahman et al. 1993). Liming during the past cropping might have also caused an increase in P^H value. Electrical Conductivity (EC) values of the presently studied pond soils are quite high. ECe values greater than 80 ds/m were reported from Senegambia (Vieillefon 1977). Some of the present values (ECe = EC 1:2 × 4 approximately) appear to be still higher and soil salinity may be responsible for the salinity of inundated water because of the similar trend of variation with ponds.

In the present findings, available P concentration was found frequently above 24 ppm. In acid sulfate soils, low available P is a result of solubility in acid reaction, insolubilization of fixation by Fe, Al and Mn, and low release from organic matter (Banerjea & Ghosh 1970; Andriesse et al. 1973; Subosa & Bautista 1991). Addition of phosphate fertilizer to acid sulfate soil is ineffective because of fixation of added P in the form of irreversible iron and aluminum phosphates. In alkaline conditions, colloidal materials in mud and organic matter may be inactive P (Tisdale & Nelson 1975; Singh 1982; Poernomo & Singh 1982). Available P in pond soil might have increased due to application of 25 kg TSP/ha.

The problems of extreme acidity of soils in agriculture and aquaculture arise from toxicities of H_2S, SO_4, Fe, Al, and Mn (IFP 1974; Singh 1982). In the present study SO_4-S values ranged from 0.26 to 2.93 ppt, oxidizable S from 1.04 to 15.41 ppt, extractable Fe from 88.2 to 326.0 ppm, extractable Al from 0 to 602.03 ppm and extractable Mn from 37.2 to 127.93 ppm. Extractable Ca was found to be low and the concentration followed the sequence Na>Mg>Ca>K. Another study of Rahman (1990) on acid sulfate soils of Cox's Bazar and Chakaria, the ranges of soluble Fe, Al and Mn were found to be from 52 to 75 ppm, from 3 to 260 ppm and from 2 to 22 ppm respectively (Rahman 1990). There was, however, a basic difference between the nature of the two studies and soil type. Concentrations of iron and aluminum in the present study were found lesser than the acid sulfate soils of many other countries (Baylon 1981; Hechanova 1983; Andriesse et al. 1973). The extractable Mn values in the present study were found corresponding to the active Mn concentrations reported from the Chakaria Sundarbans (Rahman 1990). In acid sulfate soils of Thailand, Vietnam, and Philippines active Mn ranges from 5 to 400 ppm (Ponnamperuma 1972). Actual acid sulfate soils have smaller amounts of active Mn (Tanaka & Yoshida 1970; Van Breemen 1976). Concentration of Mn in the present study were found higher than the flooded acid sulfate soil (Rahman 1990; Attanandana 1971).

From the present study it was observed that during shrimp culture or keeping the ponds inundated without stocking, soil P^H increased gradually while SO_4-S and extractable Al decreased rapidly. Such phenomena are characteristic of acid sulfate soils under flooding and may be exploited in their reclamation and utilization. Extractable Al was found negatively correlated (Table 4 and 5) with the soil P^H, which was also observed by some other workers (Van Breemen 1973, 1976; Baylon 1981; Rahman 1990). On the other hand, oxidizable S and extractable Fe were positively correlated with the organic matter. It appears that transformation of aluminum was P^H dependent and transformation of S and Fe in submerged systems were organic matter dependent. Both S and Fe transformations are microbial processes, the agents of which may utilize organic matter as energy source. So, submergence of many acid sulfate soils may eliminate two most important problems, low P^H and high Al, but the removal of S seems to be inadequate if the soil/sediment contains high organic matter. Therefore, flooding these soils is a temporary relief. Together with liming, this might keep the soils more tolerable. To remove pyrite, drying of pond bottom with subsequent repeated flushing has been advised (Felix 1988) but prolonged drying, or intense pyrite oxidation may render the soils more acidic.

CONCLUSION

The extents of increase in P^H and decrease in extractable Al and SO_4-S were higher in the culture ponds than those under simple inundation. This suggests that shrimp culture had a positive effect on the improvement of acid sulfate soils under submergence. This could be due to fish fed, mechanical aeration of water, frequent water exchange, shrimp excretion, mixing of surface soil by burrowing, leaving Ca rich in shells during molting, etc. In the light of the above discussion, it seems that clearance of mangrove forests would lead to destruction of environmental balance. In cleared areas, however, cultivation of shrimp under careful management should be preferred to other forms of land use because of the better scope of soil improvement. Research on integrated soil-water and crop management is necessary to address these problems.

ABSTRACT Previous workers performing classical agricultural field experiments and aquaculture pond trials have emphasized that in order for results from experiments to be analyzed and evaluated, it is important to either demonstrate that the experimental units are homogeneous or quantify any variation between plots, ponds or blocks of these experimental units. Moreover to ensure that results of aquaculture experiments are applicable to industry, research ponds must have similar characteristics to those of industry. Physical, chemical and biological characteristics of 24 research ponds were recorded at the Avondale Research Station, Western Australia. This demonstrated that: (a) The ponds behaved in a manner similar to farm dams typical of the Western Australian wheat belt; (b) The water chemistry and turbidity profiles of the ponds were within the range recorded for wheat belt farm dams; (c) The average % organic matter of the sediments was 3.49%, which was within the range recorded for farm dams in Western Australia (d). The coefficient of variation for growth of yabbies (*Cherax albidus*) among the ponds at the Avondale Research Station was 9.26%. The comparatively low level of variation among the ponds was attributed to a number of factors including the age and design of the facility, and the homogeneous water supply for all ponds. Power analysis has been applied to determine the number of replicates required for experiments in these research ponds.

KEY WORDS: variation, ponds, crayfish, *Cherax albidus*, power analyses

INTRODUCTION

Agricultural plot experiments on field research stations provide a bridge between glass house experiments and industry paddocks (Fisher 1958; Fisher 1960). Similarly, aquaculture research pond experiments provide both a bridge between aquarium studies and commercial ponds, and a more realistic estimate of production than laboratory aquarium or tank studies that tend to underestimate yields (Shell 1983).

For the results of aquaculture experiments to be applicable to industry it is essential to be able to measure production characteristics both accurately and in a system that mimics the natural environment in ponds as closely as possible. Aquarium studies provide an opportunity to measure single characters accurately in a tightly controlled environment. However, they do not simulate production in ponds well because they do not provide the same natural biota, or algal and clay turbidity. Consequently, long-term growth performance and nutritional health of freshwater crayfish, such as yabbies (*Cherax albidus* Clark 1936), is usually so poor in clean aquaria that experimental comparisons are compromised (Morrissy 1984a). Generally, aquaria studies tend to underestimate yields (Shell 1983). Furthermore, laboratory tank experimentation is impractical at industry densities of 1–5 yabbies/m^2. Since density and growth of freshwater crayfish are related inversely (Morrissy 1992; Mills & McCloud 1983; Brown et al. 1995; McClain 1995a; Morrissy et al. 1995), tank experiments in small containers at high densities are unrealistic and give poor growth and survival (Ackefors et al. 1989; Verhoef & Austin 1999a; Verhoef & Austin 1999b).

Another alternative is to estimate production characteristics of yabbies (*C. albidus*) directly from commercial ponds. In contrast to the smaller Eastern Australian yabby (*C. destructor*) industry that relies on wild caught and pond reared animals, the much larger farmed Western Australian yabby (*C. albidus*) industry is based on large "commercial ponds" that are argillotrophic, clay-based, paddock catchment dams filled by rainfall runoff to provide drinking water for sheep (Lawrence 1998; Lawrence & Jones 2001). However, it is difficult to obtain useful information from the large ponds and farm dams used for rearing yabbies (*C. albidus*) because of the variability in physical and biological characteristics (Morrissy 1974; Lawrence, et al. 1998). In addition there are other limitations of farm dams for efficient research. Management practices differ between dams, they are difficult to drain and hence measure the total population, and they generally contain so many yabbies (*C. albidus*) that the labor required to measure production traits like growth and population size is excessive.

Research station experiments include most of the advantages of true ecological studies, where the population of animals is influenced by many uncontrolled natural factors, as is experienced in commercial ponds, and classical experimentation, usually single factor, under highly controlled conditions in the laboratory.

To carry out yabby (*C. albidus*) experiments a research facility, consisting of 25 ponds supplied by a homogeneous water supply from a header dam, was built near Beverley Western Australia (32°7′S, 116°55′E). This was capable of supporting replicated, randomized and reproducible experiments, with controls, in an environment that simulated farm dams.

Large variability among ponds in aquaculture experiments often leads to imprecise estimates of treatment effects. Previous workers in classical agricultural field experiments such as at Rothamsted (Fisher 1958; Fisher 1960) and aquaculture pond trials at Auburn (Shell 1983) emphasized that in order for results from experiments to be analyzed and evaluated, it is important first to: (a) demonstrate that the experimental units are relatively homogeneous; or (b) to quantify any variation between plots, ponds or blocks of these experimental units.

Cross-over (Change-over) designs, which make comparisons

Corresponding author. Craig S. Lawrence, Department of Fisheries, WA Marine Research Laboratories, PO Box 20, North Beach, WA 6020, Australia. E-mail: clawrence@fish.wa.gov.au

directly within the same pond instead of between ponds, have been proposed for use in aquaculture experiments to eliminate the variation between ponds (Smart et al. 1997). The construction of an appropriate cross-over design is challenging (Cheng 1996; Cheng & Street 1997) as: (a) due to environmental factors most species in aquaculture respond significantly differently according to seasonal variations over a year; and (b) the interaction between seasonal and other treatment effects are unknown. It is likely that seasonal variation and the effect of the interaction between seasons and other treatments in each pond within a year may be greater than the variation among ponds within the same time frame. Consequently cross-over designs require a longer experimental period and the analysis may involve a more complex statistical model. To increase the degree of precision for estimation of treatment effects, the most efficient way to account for between pond variation is to minimize the variability between ponds and quantify that level of variation.

By measuring the level of variation between ponds prior to commencing a field trial program it was possible to (a) take variation between experimental units into account when planning the randomization and replication of treatments in future experiments, and (b) determine whether results recorded from future experiments will be due to the application of treatments or merely a result of naturally occurring variability between ponds.

This study aimed at testing the homogeneity of experimental units, quantifying the variation between these units, determining the number of replicates required when planning experiments and confirming that the ponds had similar characteristics to wheat belt farm dams.

MATERIALS AND METHODS

The site for ponds was selected according to clay profiles from the region and to ensure that all ponds were placed as close as practicable to each other. All 25 ponds were constructed within the same soil type with the same dimensions (10 m × 10 m water surface area, 1.5 m deep and 3:1 side, or batter slopes). The 25 ponds all received water from the same supply dam.

The twenty-five 0.01 ha ponds were filled from the water storage dam four weeks prior to stocking. Two weeks prior to stocking each pond with yabbies (*C. albidus*) for the first experiment, the ponds received the addition of 50 L of sheep manure to condition pond sediment and increase organic matter to the level commonly found in farm dams.

Twenty-four of the 25 ponds were divided into 6 blocks according to possible sources of variation (clay type, location—north, south, east, west, upper row, lower row); a randomized block design was used, each block contained 4 ponds which received the same four treatments (yabbies 4.5/m^2 unfed, yabbies 4.5/m^2 fed lupins at the rate of 2.5 g/m^2/week, yabbies 1/m^2 unfed, yabbies 1/m^2 fed lupins at the rate of 2.5 g/m^2/week). The remaining pond received yabbies 4.5/m^2 fed lupins at the rate of 2.5 g/m^2/week. Prior to stocking each yabby (*C. albidus*) was weighed, sexed and 10% of animals were tagged by tail punching (Morrissy 1980; Getchell 1987). The ponds were stocked with 7,050 yabbies (*C. albidus*) (mean weight 19.41 g ± 0.22 SE) at a sex ratio of 1 male:1 female on the 29th November 1994 and the trial was harvested between the 8th to the 15th of March 1995.

At the commencement and conclusion of the experiment samples were collected for water chemistry analyses. Samples were submitted to the Chemistry Centre of WA for analyses of Ca, N-NO$_2$, N-NO$_3$, Cl, Cu, Fe (dissolved), Fe-total (unfiltered sample), HCO$_3$, K, Mn (dissolved), Mn-total (unfiltered sample), Na, P-SR (Phosphorous, soluble reactive), SO$_4$-S (Sulphate, expressed as sulphur), Zn-total (unfiltered sample), CO$_3$, pH, Electrical conductivity (25°C) (Econd.), Alkalinity and Hardness. Max-Min thermometers were used to record water temperature in the ponds.

At fortnightly intervals subsurface water samples (10-cm depth) and benthos core samples were collected from each pond. The benthos corer removed a 2-cm diameter core of sediment and clay to a depth of 15 cm. The percentage organic matter of water samples and sediment was determined by drying samples in pre-dried and weighed crucibles and then ashing out. As the loss in weight is due to combustion of organics, percentage organic matter was calculated according to the formula:

$$\text{Organic Matter} = [\text{weight of organic matter/dry weight}] \times 100\%$$

At fortnightly intervals Secchi disk depth was measured in each pond as an index of turbidity.

All data in the randomized block design were analyzed using analysis of variance (ANOVA) to determine significant differences among treatment means. Data were considered significantly different at the 0.05 level of significance. The coefficient of variation (C.V.) is a measure of variation and was calculated according to the formula:

$$\text{C.V.} = \text{standard deviation/mean (Shell 1983).}$$

Power analyses was applied using the methods described by Searcy-Bernal (1994) to determine the number of replicates required for a given number of treatments to measure a difference of 5, 10, and 20% in the growth of yabbies (*C. albidus*) from the research ponds.

RESULTS

Water Chemistry

Water chemistry parameters at the commencement and conclusion of the experiment are presented below (Table 1). Using the nonparametric Wilcoxon-Mann-Whitney test (Wilcoxon 1945; Mann & Whitney 1947) to examine paired observations, there was no significant difference between the initial chemical parameters and final chemical parameters ($P = 0.73$). During the experiment water temperature ranged from 13 – 35°C (mean 22°C ± 0.6 SE). There was no significant difference in minimum ($P = 0.51$) (C.V. = 9.63%) or maximum ($P = 0.21$) (C.V. = 12.38%) water temperature among blocks of ponds.

Turbidity

There was no significant difference in turbidity among blocks of ponds at either the commencement ($P = 0.67$) (C.V. = 4.74%) or conclusion of the experiment ($P = 0.73$) (C.V. = 11.75%). However, there was a significant decrease in turbidity over the course of the experiment across all ponds ($P < 0.0001$) by two tailed *t*-test with paired observations (Fig. 1). As there was no variation in salinity (measured as electrical conductivity Table 1), it is probable that the decrease in turbidity was due to a reduction in suspended organic matter (see Fig. 3).

TABLE I.

Water chemistry parameters of Avondale research ponds at commencement and conclusion of experiment ($n = 25$).

		Commencement				Conclusion			
Parameter	**Units**	**Mean**	**SE**	**Min**	**Max**	**Mean**	**SE**	**Min**	**Max**

pH		8.4	0.1	7.5	8.8	8.4	0.3	7.5	8.8

Organic Matter

The organic matter of the pond sediment (Fig. 2) was not significantly different among blocks of ponds at the commencement ($P = 0.16$) (C.V. = 19.88%), conclusion ($P = 0.07$) (C.V. = 31.03%) or during the experiment ($P = 0.09$) by two tailed *t*-test. All ponds ranged between 1.6% and 5.3% sediment organic matter content.

There was no significant difference in the suspended organic matter in water among blocks of ponds at either the commencement ($P = 0.10$) (C.V. = 24.87%) or conclusion ($P = 0.13$) (C.V. = 21.13%) of the experiment (Fig. 3). However, there was a significant decrease in suspended organic matter over the course of the experiment across all ponds ($P < 0.0001$) by two tailed *t*-test with paired observations (Fig. 3). The low levels of variation in organic matter during this trial may be largely attributed to the low industry based feeding rates (0–2.5 g/m^2/week) in this experiment.

Yabby (C. albidus) *Survival, Growth and Biomass*

There was no significant block effect on yabby (*C. albidus*) production determined as either survival (65% ± 2 SE) ($P = 0.24$), change in biomass of adult yabbies (*C. albidus*) stocked ($P = 0.26$), total change in biomass of all yabbies (*C. albidus*) harvested (including juveniles) ($P = 0.50$) or final mean weight of yabbies (*C. albidus*) ($P = 0.47$) (Fig. 4). The coefficient of variation for yabby (*C. albidus*) growth (expressed as final mean weight-initial mean weight) between the blocks of research ponds was 9.26% ($n = 6$).

These results indicate that there was no trend across the ponds

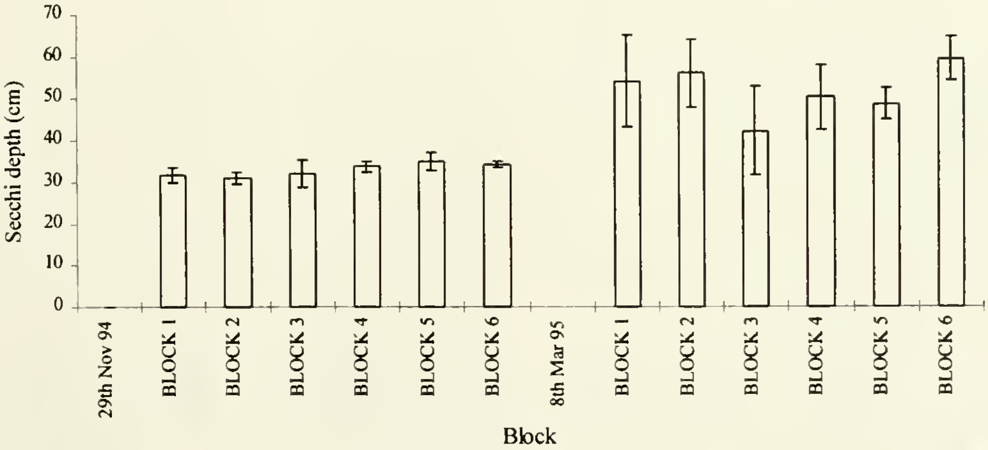

Figure 1. Turbidity of research ponds (cm ± SE) at the commencement and conclusion of experiment - the higher the Secchi disk depth, the lower the turbidity of the water.

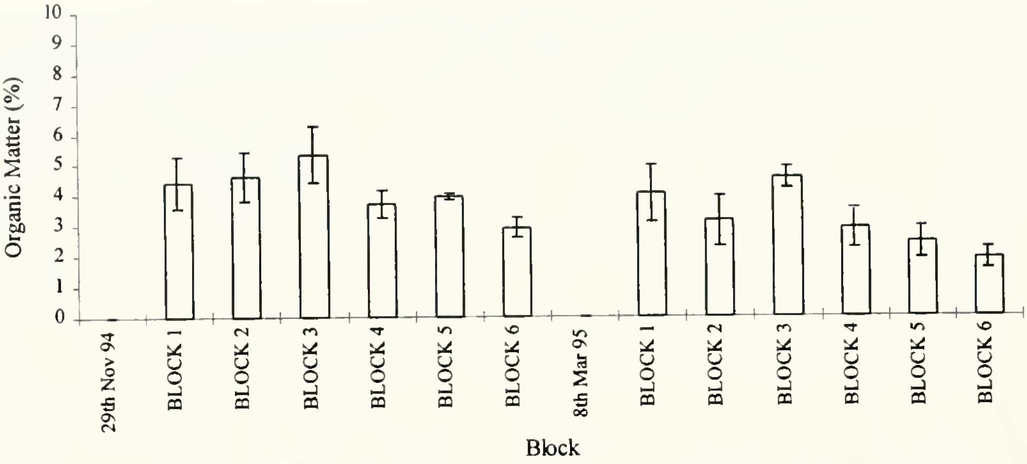

Figure 2. Organic matter (% ± SE) of pond sediment at the commencement and conclusion of experiment.

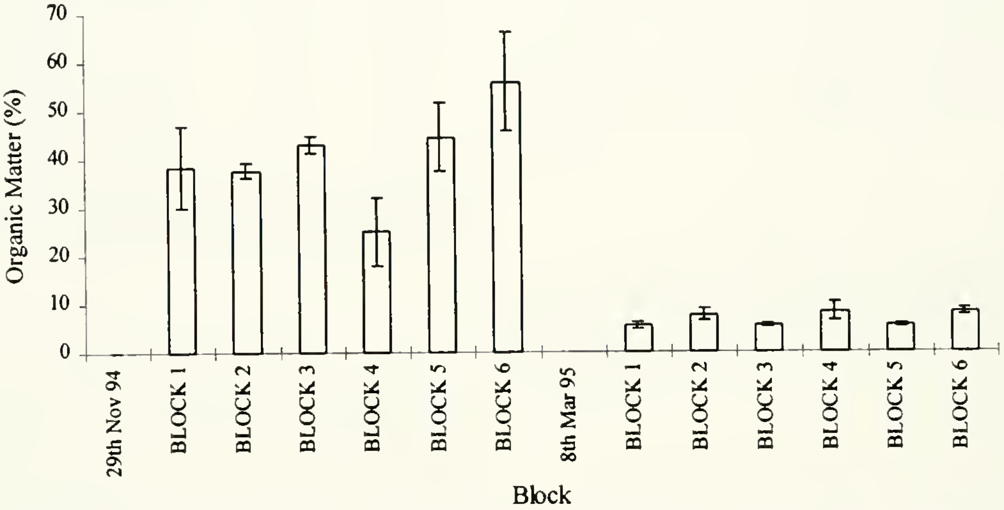

Figure 3. Suspended organic matter (% ± SE) of pond water at the commencement and conclusion of experiment.

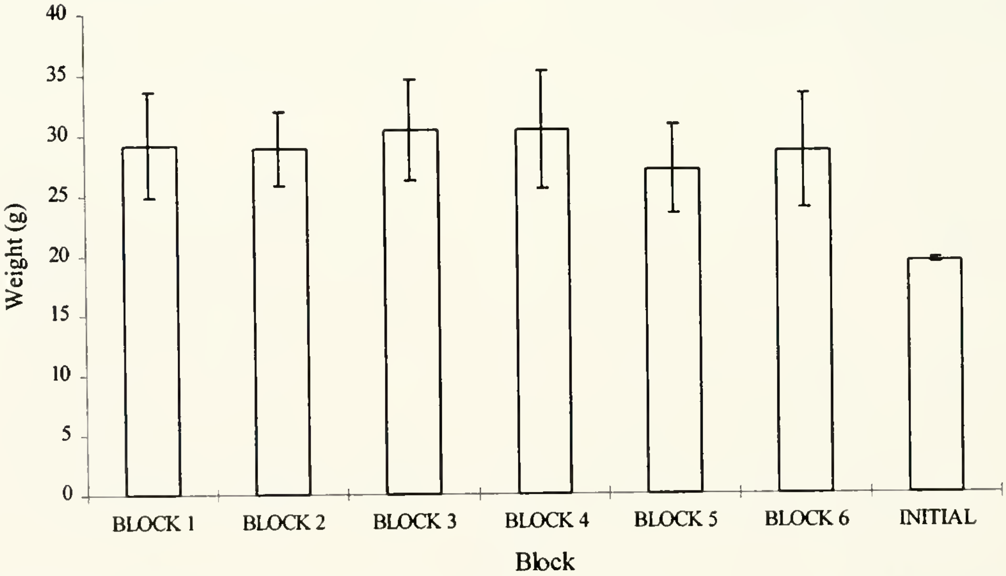

Figure 4. Mean yabby (*C. albidus*) weight (g ± SE) at commencement of experiment (Initial) and variation in final yabby (*C. albidus*) weights (g ± SE) among pond blocks at conclusion of experiment (Block 1–6).

for change in yabby (*C. albidus*) growth due to inherent pond factors at the site. The low variation in yabby (*C. albidus*) growth (C.V. = 9.26%) between individual ponds treated identically showed a highly acceptable homogeneity in the pond site for future experiments.

DISCUSSION

To ensure that results of aquaculture experiments are applicable to industry, research ponds must have similar characteristics to those of commercial ponds. In addition the variation (C.V.) in yabby (*C. albidus*) growth among ponds due to inherent site factors needs to be as small as possible to minimize the replication needed for future experiments to be effective in showing effects due to different treatments. If differences between treatments are smaller than the coefficient of variation then the observed differences are likely to be due to chance variation rather than a treatment effect.

The coefficient of variation for yabbie growth among the ponds at the Avondale Research Station was 9.26%.

Experiments within earthen ponds at the Auburn University aquaculture research station in Alabama have produced coefficients of variation for fish production ranging from 4.2–34.6%, with an average of 20% (Shell 1983). Previous research using adjacent ponds for marron (*Cherax tenuimanus*) experiments attributed 11% of variation in growth to differences between ponds. (Morrissy 1992; Morrissy et al. 1995).

The comparatively low level of variation between the ponds at the Avondale Research Station may be attributed to a number of factors including: (1) the age of the facility; (2) the planning and design of the facility to ensure a homogeneous environment; and (3) the homogeneous water supply for all ponds.

Comparative trials between ponds, cages and lined tanks have shown that the primary causes of variation are differences in environmental conditions (including water quality, productivity, soil types, and water source) (Shell 1983). This experiment has shown that the pond site was homogeneous and although environmental parameters (i.e., turbidity and % suspended organic matter which showed an inverse relationship due to the initial algal bloom from pond fertilization declining) change over time, all ponds followed similar patterns of change. The ponds were therefore suitable for testing treatments (such as density, diet, monosex culture etc.) because any observed difference in yabbie growth greater than 9.26% (C.V.) was likely to be due to the effect of the experimental treatment.

For a given number of treatments, power analysis can be used to determine the number of replicates required. Power analyses are therefore considered to be a basic tool in experimental and sampling design (Searcy-Bernal 1994). In general, aquaculture experiments can only detect relatively large effect sizes with a reasonable power. This is particularly true with pond experiments that are often characterized by high within-treatment variability and low numbers of replicates (Searcy-Bernal 1994; Shell 1983). A power value of 0.80 has been proposed as the minimum desirable to avoid committing a Type II error (i.e., accepting a false null hypothesis) (Searcy-Bernal 1994). Applying the methods described by Searcy-Bernal (1994) a power table (Table 2) using the data from this experiment shows the minimum number of replicates (n) required for treatments (k) to measure a difference of 5, 10, and 20% in the growth of yabbies (*C. albidus*) from the research ponds, using the $\alpha = 0.05$ level of significance, with a power of 0.8. As would be expected from the C.V. of 9.26% an unrealistically high number of replicates (>20) would be required to measure a difference in yabby (*C. albidus*) growth of 5% between 2 or more treatments (Table 2). In contrast, to record a difference in growth of 10% requires considerably less replicates (i.e., 3–5 replicates depending on number of treatments under investigation).

TABLE 2.

Number of replicates (n) required to identify a difference in growth of 5, 10, and 20% with mean 60g and standard deviation 4.5g for $\alpha = 0.05$ level of significance with a power of 0.8 for (k) treatments.

Difference in Growth	No. Treatments (k)	No. Replicates (n)
5%	2	20
	3	30
	4	60
	5	70
10%	2	3
	3	3
	4	4
	5	5
20%	2	2
	3	2
	4	2
	5	2

The condition of the ponds was similar in manner to typical farm dams of the Western Australian wheat belt. The water chemistry of the ponds was within the range recorded for farm dams in the Western Australian wheat belt (Morrissy 1980; Lawrence et al. 1998; Cheng et al. 2001), which is dominated by sea salt ions, (Na and Cl), rather than by salts from catchment erosion, (Ca, Mg, SO_4), as found in other world freshwaters (Francesconi et al. 1995b). The high salinity recorded 346 mS/m (1885 mg/l), is typical of cleared catchments in the Western Australian wheat belt (Lawrence et al. 1998; Cheng et al. 2001). The values of a number of parameters (i.e., Cl, Na, SO_4-S and hardness) were higher than those recorded from most wheat belt farm dams but within the range suitable for yabbies (Morrissy 1980; Lawrence et al. 1998; Cheng et al. 2001) (Table 1). This may be attributed to initial disturbance of the catchment due to dam construction and subsequent flushing of the catchment.

The turbidity of the ponds was within the range recorded for farm dams in the Western Australian wheatbelt (Lawrence et al. 1998). Similarly, the percentage of organic matter in the sediments of the experimental ponds, mean 3.49%, was also within the range recorded for farm dams in the Western Australian wheat belt, which range from 0.27–12.13% organic matter (Lawrence et al. 1998).

The research ponds were therefore suitable for conducting experiments on yabbie farming and the results were likely to be directly applicable to the farm dam environment.

ACKNOWLEDGMENTS

This work was supported by funding from FRDC Project No. 94/75. We thank R. Allison and M. Stuckey technical officers, Fisheries WA for assistance in maintaining the experiments. We also thank Dr. G. Maguire, Dr. N. Hall, and Dr. N. Caputi for their comments.

ABSTRACT The dynamics of a population of adult spiny lobsters, *Panulirus guttatus*, was studied in a group of coral reef patches in Puerto Morelos, Quintana Roo (Caribbean coast of Mexico), from October 1986 to November 1987. Lobsters were extracted by divers from traps deployed in the perimeter of reef patches for 10–13 days every month. In total, 778 *P. guttatus* were caught. Males (size range: 42.4–87.5 mm carapace length (CL), were significantly larger than females (45.5–73.5 mm CL). The highly biased sex ratio (2.6 males: 1 female) was partly due to a differential catchability in traps of males and females. We tagged 227 males and 90 females with spaghetti-type tags and recaptured 62 males and 12 females, some on multiple occasions, yielding 119 recaptures of males and 26 of females. The monthly population size in the patch complex, as separately estimated for each sex with the Fisher-Ford multiple-recapture model, was higher from June to November 1987, when both the percentage of ovigerous females and the mean size of individuals was smaller, indicating a possible recruitment of young adults into the trappable population during the summer and early autumn. The average density of lobsters was 126 lobsters ha^{-1}. Growth data were scarce, but suggest that growth rates decrease as size increases, and that males can molt at least 2–3 times per year. The egg-incubation period of recaptured females was 2–3 weeks. Females >50 mm CL may produce 3–4 broods per year. In addition to *P. guttatus*, 120 individuals of *P. argus*, mostly sub-adults (<80 mm CL) were also caught. Size of male and female *P. argus* was similar, but the size of *P. argus* was significantly larger than that of *P. guttatus*. Time at large of recaptured individuals suggests that the reef patches are a temporary habitat for *P. argus*, but a more permanent residence site for *P. guttatus*.

KEY WORDS: *Panulirus guttatus*, *Panulirus argus*, population dynamics, spiny lobster, abundance, growth, reproduction, Mexico

INTRODUCTION

Spiny lobsters are among the most valuable fishing resources in the world. Population studies provide information on the abundance, movements, growth rates, reproductive dynamics, and survival of these species, and are therefore useful to improve their fishery management (Morgan 1980). However, such studies are also important to increase the knowledge on the ecology of the species, whether they support major fisheries or not. In the Caribbean Sea and adjacent Western Atlantic coasts, two sympatric species of spiny lobsters occur, *Panulirus argus* (Latreille) and *P. guttatus* (Latreille). *Panulirus argus* is a migratory, large-sized species that undergoes several ontogenetic changes in habitat. The postlarvae (pueruli) of *P. argus* settle in shallow, vegetated areas, where they remain throughout the so-called "algal juvenile" phase (6–15 mm carapace length (CL)). The "postalgal juveniles" (15–45 mm CL) move to crevice-type shelters, also in shallow areas, whereas the "subadults" (45–80 mm CL) move to coral reef habitats. Further on, the adults (>80 mm CL) migrate to deeper, more diverse habitats (Butler & Herrnkind 1997). In contrast, *P. guttatus* is a small, rather sedentary species. The pueruli of *P. guttatus* are believed to settle directly on the coral reef habitat, and remain in this habitat throughout their entire benthic life (Briones-Fourzán & McWilliam 1997; Sharp et al. 1997).

Panulirus argus supports major fisheries throughout its geographic range, but *P. guttatus* is mostly a by-catch or secondary catch in most areas, with specific fisheries only in Bermuda and the French West Indies (Evans & Lockwood 1994). Consequently, numerous and extensive population studies of *P. argus* have been conducted in locations such as Florida (e.g., Lyons et al. 1981; Forcucci et al. 1994), Cuba (review in Baisre 2000), Jamaica (Munro 1974), and Mexico (review in Briones-Fourzán & Lozano-Álvarez 2000). In contrast, most population studies on *P. guttatus* have been conducted in Martinique (Farrugio 1975, 1976; Farrugio & Saint-Felix 1975; Marfin 1978), and Bermuda (Sutcliffe 1953; Evans & Lockwood 1994; Evans & Evans 1995, 1996; Evans et al. 1995, 1996), but also in Florida (Caillouet et al. 1971; Chitty 1973; Sharp et al. 1997) and in Mexico.

In the Caribbean coast of Mexico (coast of the state of Quintana Roo), *P. guttatus* amounts to ~6% of the lobster catch (Padilla-Ramos & Briones-Fourzán 1997), and has been the subject of specific studies on size distribution (Briones-Fourzán 1991), movement patterns (Carrasco-Zanini 1985; Lozano-Álvarez et al. unpubl. data), reproductive dynamics (Briones-Fourzán & Contreras-Ortiz 1999), and the description of its puerulus (Briones-Fourzán & McWilliam 1997). Also, comparative studies have been conducted on biological, ecological and fisheries aspects of *P. guttatus* and *P. argus* (Colinas-Sánchez & Briones-Fourzán 1990; Briones-Fourzán 1995; Padilla-Ramos & Briones-Fourzán 1997; Briones et al. 1997), and on the den choice and occupation patterns of shelters by these two sympatric species (Lozano-Álvarez & Briones-Fourzán 2001).

The present paper provides information on a field investigation into the population dynamics of adult *P. guttatus* in a coral reef of northern Quintana Roo. Monthly changes in the population size of adult *P. guttatus* were explored, by means of capture-recapture techniques, in a group of coral reef patches separated, but not entirely isolated, from adjacent coral patches. Because *P. guttatus* is a sedentary species, we hypothesized that population additions would be due mostly to recruitment of young adults, and population losses to predation-induced mortality. We also aimed to determine the growth rates of *P. guttatus* and to compare them to those reported for *P. argus*, as well as to obtain direct evidence for repetitive breeding of females throughout the year. Although our study was focused on *P. guttatus*, our samplings also yielded individuals of *P. argus*, providing an opportunity to compare the size ranges and time at large of individuals of both lobster species in this reef patch habitat.

MATERIALS AND METHODS

Study Area

The study was conducted in the coral reef at Puerto Morelos, in northern Quintana Roo (Fig. 1). Puerto Morelos is located in the northern portion of a barrier-fringing reef tract that extends from Belize to the Yucatan Strait. Rather than a continuous barrier, the coral reef in Puerto Morelos consists of a series of reef patches, separated from the coast by a reef lagoon 300–1000 m in width. The reef lagoon (<5 m in depth) is covered by seagrass meadows, a habitat where juveniles of *P. argus* dwell, but where *P. guttatus* does not occur (Briones-Fourzán 1995). Along the reef tract, the sloping fore-reef has relatively few high-relief features, but hard coral cover is dense at the reef crest and in the back-reef zone (Ruiz-Rentería et al. 1998), providing an intricate habitat with numerous crevices and caves where both *P. guttatus* and *P. argus* occur (Briones-Fourzán 1995; Lozano-Álvarez & Briones-Fourzán 2001).

Lobster Sampling and Tagging

The main study site (site 1) consisted of a group of several reef patches, close to each other (maximum distance between adjacent patches: 50 m), but relatively separated (~200 m) from the rest of the reef tract. In addition to their relative isolation, we chose these reef patches because they are not fished for lobsters, owing to their proximity to the navigational channel to the port. The area of the patch complex was 2.5 ha, excluding the areas between patches, which consisted mostly of sand and sparse sea grasses. Average depth around the reef patches was 4 to 5 m. From October 1986 to November 1987, 20 lobster traps (mesh size: 5 × 2.5 cm) were deployed by divers in the underside of ledges or coral formations around these patches. The distance between adjacent traps ranged from ~20 to 100 m. The traps remained fixed for 10–13 days every month, during the dark portion of the lunar cycle, after which the traps were recovered and relocated the following month. The divers carefully extracted the lobsters from within the traps every morning during each sampling period, unless impeded by bad weather. Lobsters were tagged with modified Australian spaghetti-type tags (Lozano-Álvarez et al. 1991; Lozano-Álvarez 1992) that were manually assembled in the laboratory as described by Chittleborough (1974). These tags consist of an individually numbered vinyl "spaghetti" and a small plastic toggle, joined by a thin nylon thread. The toggle is inserted in the dorsolateral muscle of the lobster, between the cephalothorax and abdomen, with a stainless steel applicator. The original toggles measured 11 × 3 × 0.5 mm, but we shortened them to 9 mm in length with a grinding machine before assembling the tags, in order to reduce their possible deleterious effects on the relatively small-sized *P. guttatus*.

All lobsters were measured (carapace length, CL, in mm, from between the rostral horns to the posterior margin of the cephalothorax) with digital calipers (±0.1 mm), and injuries (i.e. number and type of missing appendages) were recorded. The reproductive stage of females was determined according to the following scale (Briones-Fourzán & Contreras-Ortiz 1999): (1) clean carapace, no extruded eggs or traces of spermatophore; (2) new and intact spermatophore on sternum; (3) newly extruded eggs (bright orange); (4) dark orange eggs, with eyespots visible; (5) brown eggs, embryo and eyes clearly visible; (6) remnants of empty egg capsules and/or eroded spermatophore. After tagging, the lobsters were returned immediately to natural crevices in the coral patches. To reduce tag loss, individuals that were about to molt or recently molted ("soft-shelled") were not tagged. All lobsters were carefully examined to ascertain whether they had lost a tag, as evidenced by a distinctive scar in the site of tag application.

Additional information on size composition and sex-ratios was obtained from a large, elongated patch (site 2) located 4 km north of site 1, where 13 traps were used in a similar fashion as in site 1. Lobsters from site 2 were not tagged because they were sacrificed to study their diet (Colinas-Sánchez & Briones-Fourzán 1990) and the fecundity of females (Briones-Fourzán & Contreras-Ortiz 1999).

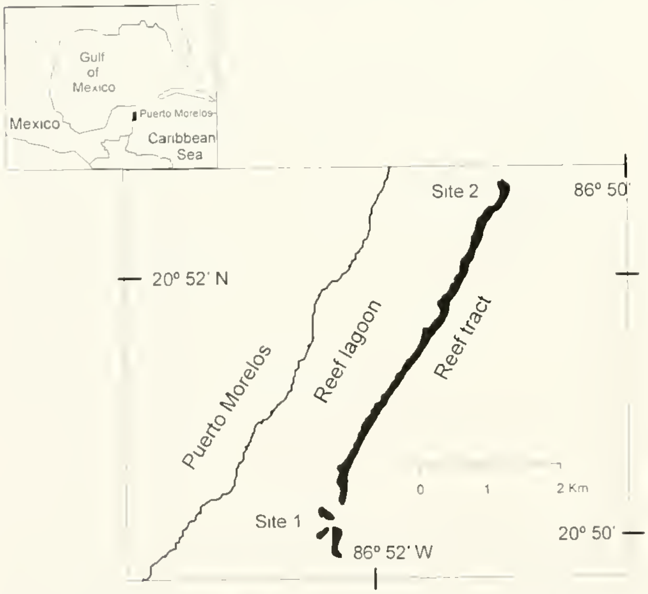

Figure 1. Location of study sites on the coral reef tract at Puerto Morelos, México.

Size Distribution

We compared the overall size distribution of *P. argus* and *P. guttatus*; of *P. guttatus* between sites 1 and 2, and of males and females of each species, with Student's *t*-tests for unequal sample sizes (Zar 1984). When necessary, data were log-transformed to homogenize variances. To explore temporal changes in the size distribution of *P. guttatus* in site 1, monthly data were grouped in 2-mm size classes and analyzed with a one-way repeated measures ANOVA, with time as the repeated factor, followed by a Tukey's test for unequal sample sizes (Winer 1971).

Population Size and Survival

The population size of *P. guttatus* was monthly estimated by means of the Fisher-Ford model (Fisher & Ford 1947), which relies on several tagging occasions and several recaptures. We chose this model because the capture-recapture data were relatively scarce and the survival rate was fairly constant (see Results). In these circumstances, the Fisher-Ford model tends to yield more reliable results than other models based on multiple-recapture data (Bishop & Sheppard 1973; Begon 1979; Lozano et al. 1982), while still providing estimates of population losses (death + emigration), and population additions (recruitment + immigration). The Fisher-Ford model assumes a constant survival rate (ϕ), but this assumption can be analyzed by means of two goodness-of-fit tests (Begon

1979): a test of the period-to-period differences in ϕ (observed vs. expected periods survived) (test 1), and a test of the independence of ϕ from the age of tags (observed vs. expected recaptures of various ages) (test 2). To avoid bias due to a possible "trap addiction" of lobsters, individuals that were recaptured more than once within a sampling period were only considered to have been captured once (Bishop & Hartley 1976). Owing to differences in catchability between sexes (see Results), we applied the Fisher-Ford model separately to males and females, and then summed the monthly estimates of both sexes to obtain the monthly and average population sizes and sex ratios. Estimates of population size were further standardized as lobster density (number of adult lobsters ha^{-1}).

Growth

Because of possible measurement errors, only lobsters whose CL increased over 1 mm between recaptures were considered as having grown (Forcucci et al. 1994). Growth rate (mm CL $week^{-1}$) was calculated by dividing the increase in CL of recaptured individuals by the number of weeks between recaptures. To calculate molt increments (increment in CL per molt), we followed the technique proposed by Forcucci et al. (1994), in which each observation in change in CL is plotted against time at large (in weeks). In these plots, the data points cluster in groups representing single and multiple molting events. Since growth may vary as a function of sex, size, and injury condition (Hunt & Lyons 1986), we produced different plots for uninjured and injured males and females, and analyzed the data for each sex by size class (<60 mm CL, 60–70 mm, and >70 mm CL). Only single-molt observations were used to estimate molt increments. The intermolt period (in weeks) was then calculated by dividing the average molt increment (mm CL) by the average growth rate. The results were then summarized in a table.

Reproductive Aspects

The monthly percentage of ovigerous females was obtained from the total sample to determine the main reproductive season. Data from females of *P. guttatus* that were recaptured in different reproductive stages allowed for a preliminary estimate of the egg-incubation period, and of the duration of a complete breeding cycle.

RESULTS

In total, 920 lobsters (including recaptures) were obtained, 778 (85%) *P. guttatus* and 142 (15%) *P. argus*. Results on the issues explored are given for each species separately.

Panulirus guttatus

Size Distribution

In all, 551 *P. guttatus* were caught in site 1 (410 males and 141 females), and 227 in site 2 (160 males and 67 females). Mean size of *P. guttatus* was similar between sites (t = 0.782, df = 777, P = 0.495). Overall, male *P. guttatus* ranged in size from 42.4 to 87.5 mm CL (mean ± SD: 64.5 ± 7.6 mm CL), significantly larger than females (range: 44.5 to 73.5 mm CL; mean ± SD: 59.3 ± 5.2 mm CL) (log-transformed data, t = 8.748, df = 774, $P < 0.0001$) (Fig. 2A).

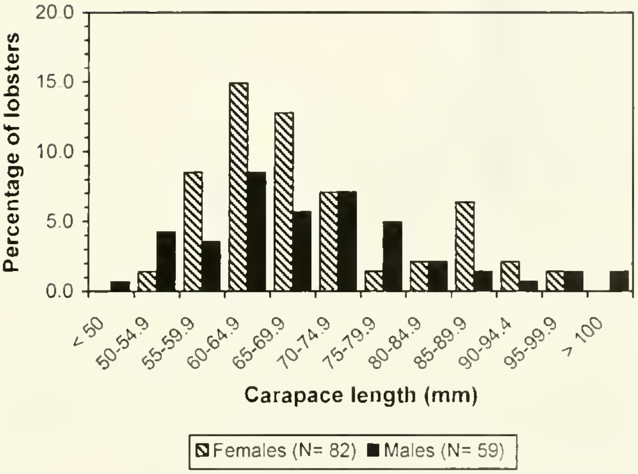

Figure 2. Size distribution of the total sample (including recaptures) of (a) *Panulirus guttatus* and (b) *Panulirus argus* caught in traps in coral reef patches at Puerto Morelos, México.

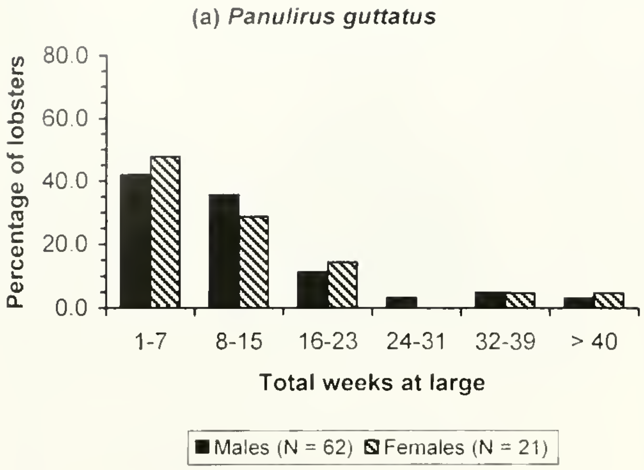
Tagged and Recaptured Individuals

Individuals of *P. guttatus* (excluding recaptures) in site 1 were 331 males and 127 females (sex ratio 2.6:1). Of these, we tagged 227 males and 90 females, and recaptured 62 males (27.3%) and 12 females (13.3%). Individual males remained at large for 1–50 weeks, and females for 1–43 weeks (Fig. 3a). No significant differences were found in time at large of males and females (χ^2 = 1.22, df = 5, $P > 0.95$). Some individuals were recaptured on multiple occasions (from two to seven), yielding a total of 119 recaptures of males and 26 recaptures of females. Fifteen lobsters (10.3% of recaptures) lost their tags, but were taken into account when estimating the population size by calculating the "average age" of their tags, based on the average age of the tags of the individuals concurrently recaptured (Lozano et al. 1982). Of the recaptured individuals, 53% were recaptured within a distance of 20 m from their site of release, 45% at distances from 20 to 50 m, and 2% at distances from 50 to 100 m. Predation-induced mortality within the traps was high (28%), accounting for 94 males (69 untagged and 25 tagged) and 33 females (28 untagged and five



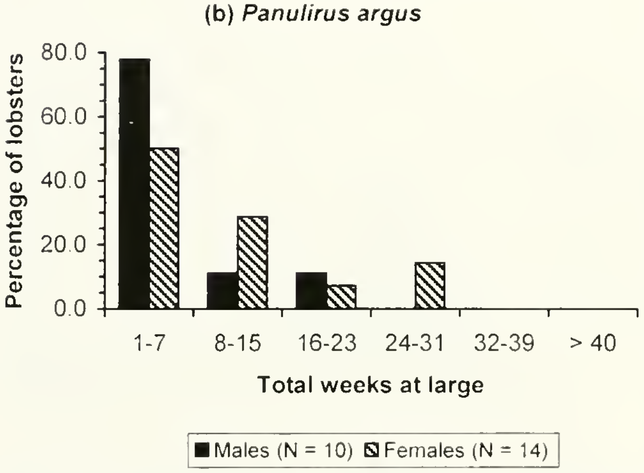


Figure 3. Percentage of individual lobsters recaptured in different periods at large (in weeks). (a) *Panulirus guttatus*, (b) *Panulirus argus*.

tagged). Predators found in traps included groupers (*Epinephelus* spp.), triggerfish (*Balistes vetula*), snappers (*Lutjanus* spp.), and moray eels (*Gymnothorax* spp.).

Population Size and Survival

A lower catchability of female *P. guttatus* in traps was reported by Evans and Lockwood (1994) in Bermuda. A differential catchability of males and females in our traps would contradict one of the principal assumptions of the Fisher-Ford model, namely that all individuals are equally catchable. Therefore, before applying the Fisher-Ford model, we explored whether the biased sex ratio of *P. guttatus* was (a) the actual sex ratio over the size range of trappable lobsters, caused by a lower number of females in the largest size classes due to a differential growth rate of males and females (Wenner 1972), or (b) an artifact due to a differential catchability of males and females in traps. To test (a), we plotted the percentage of males in each 5-mm size class of the total catch. In species where males reach significantly greater sizes than females, such as in palinurids (Morgan 1980), male percentages tend to fluctuate around 50 in the small size classes, then decrease as adult females accumulate in one or a few size classes, and further rise as size increases until approaching 100% in the largest size classes (Wenner 1972; Herrnkind & Lipcius 1989). However, our curve showed higher percentages of males in most size classes, indicating that females were undersampled, and suggesting a differential catchability of males and females. This was further confirmed by a test of difference in catchability between population sub-groups (i.e., males and females) (Begon 1979), which was highly significant ($\chi^2 = 28.756$, df = 12, $P < 0.001$).

The most likely cause for this differential catchability is a different behavior of males and females (Lozano et al. 1982). Apparently, the protracted reproductive season of *P. guttatus* (Farrugio 1976; Sharp et al. 1997; Briones-Fourzán & Contreras-Ortiz 1999) results in females being overall less active than males, as evidenced by the higher occurrence of male *P. guttatus* in fixed gear, such as nets and traps compared to samples obtained by divers, who search actively for lobsters (Table 1). Sex ratios, then, may depend on the sampling method, the location, and the size

CL is carapace length; M is males; F is females range of individuals in the samples. Allowing for a higher proportion of males in the largest size classes, the 1.7:1 sex ratio of the *P. guttatus* sampled by Padilla-Ramos and Briones-Fourzán (1997) from fisher divers in Puerto Morelos over a fishing season (Table 1), appears more realistic than ours. Consequently, we applied the Fisher-Ford model separately to the male and female data, and obtained separate estimates of population sizes and survival for each sex (Begon 1979).

The estimated survival rates (ϕ) were 0.727 for males and 0.867 for females. The two tests for the constancy of ϕ showed that this assumption was not violated in any one period (month) for either sex, so the monthly χ^2s were added and further tested for their significance. For males, the overall result of test 1 was $\chi^2 = 18.504$ (df = 12, $P > 0.10$) and of test 2 $\chi^2 = 6.901$ (df = 12, $P > 0.75$). For females, the overall result of test 1 was $\chi^2 = 4.770$ (df = 12, $P > 0.95$) and of test 2 $\chi^2 = 13.840$ (df = 12, $P > 0.25$). Hence, the assumption of a constant survival rate for both males and females was reasonably supported.

Male population size ranged from 97 to 373 individuals, with higher values in November 1986, and from April to September 1987 (Table 2a). The size of the female population varied between 69 and 435, with higher values in April, and from June to November 1987 (Table 2b). When adding the male and female population estimates, higher abundances of adult *P. guttatus* occurred in April, and from June to November 1987 (Table 3). In contrast to the more heavily biased sex ratios in our samples, monthly sex ratios in the population varied from 0.3 to 2.8 males:1 female, with an overall sex ratio of 1.3:1 (Table 3).

The monthly population size was converted to density (number of lobsters ha^{-1}) and confronted with the monthly mean size of lobsters (Table 4). The mean size of *P. guttatus* was significantly different in time (F = 2.637, df = 13, 208; $P = 0.002$), with

smaller values from June to October 1987 than throughout the remaining months (Table 4). In this period, some of the highest population density values also occurred. The overall average population density of *P. guttatus* was 126 individuals ha^{-1}.

Reproductive Aspects

We recorded the reproductive stage of 202 female *P. guttatus* in the total sample. Of these, 85 (42.1%) were ovigerous. Ovigerous females occurred every month, except in August 1987. In general, the occurrence of ovigerous females was higher (39.3–65.4%) from December 1986 to July 1987, and lower (0–35%) in August to November 1987 (Table 4).

TABLE 4.

Panulirus guttatus. **Population characteristics over the study period. Mean carapace lengths were grouped with a Tukey's test for unequal sample sizes after a repeated-measures ANOVA. Population density was derived by dividing the total population size (males + females) estimated with the Fisher-Ford model by the surface area of the reef patches (2.5 ha).**

Of the 21 recaptured females, three changed from reproductive stage 3 to 6 in 13, 13, and 21 days, indicating an egg incubation period of 2–3 weeks. This agrees with Chitty (1973), who estimated the egg-incubation period of *P. guttatus* in less than 30 days. Evidence for repetitive breeding occurred in six females, which had different broods when captured and when recaptured after 25, 31, 46, 97, 101, and 240 days. Repetitive breeding of female *P. guttatus* has been reported before (e.g., Chitty 1973; Farrugio 1976; Sharp et al. 1997; Briones-Fourzán & Contreras-Ortiz 1999) and, in Puerto Morelos, large females (>50 mm CL) breed more times in a year than small females (<50 mm CL) (Briones-Fourzán & Contreras-Ortiz 1999). Based on the short incubation period, the large size (>50 mm CL) of all our recaptured females, and the repetitive breeding evidence from recaptured females, we conservatively propose an average duration of 90–120 days for a full breeding cycle in large females, i.e., up to 3–4 broods per year.

Growth

In total, 119 recaptures of males (57 uninjured and 62 injured) and 26 recaptures of females (19 uninjured and 7 injured) were considered in the growth analyses. Size range at capture of males was 47.8–81.1 mm CL, and of females 53.7–69.0 mm CL. Time between subsequent captures was 1–24 weeks in males, and 2–34 weeks in females. Only 19 males (10 uninjured, 9 injured) and three females (1 uninjured, 2 injured) grew between recaptures (Table 5). In general, injured individuals had smaller molt increments than uninjured individuals. Small uninjured males showed higher growth rates and molt increments than larger males, but their intermolt periods were similar. The uninjured female had a growth rate of 0.32 mm CL week^{-1}. Thirteen injured males and two injured females molted and regenerated between 1 and 5 appendages in periods of 4 to 17 weeks, but showed no increment in CL.

TABLE 5.

***Panulirus guttatus*. Summary of growth data for males (size range: 47.5–81.0 mm carapace length, CL) and females (size range: 53.7–65.3 mm CL) by size class and injury condition at time of release (uninjured: complete individuals; injured; individuals missing one or more appendages). For each sex and size class, average growth rate (mm CL week^{-1}) was estimated by dividing the increase in CL of recaptured individuals by the number of weeks at large. Average molt increments in CL were calculated as in Forcucci et al. (1994), by plotting each observation of change in CL against weeks at large and considering only those individuals that underwent one single molt. Intermolt interval was then calculated by dividing the average molt increment by the average growth rate.**

Panulirus argus

The mean size of *P. argus* (range: 49.0–123.6 mm CL; mean ± SD: 69.8 ± 12.7) (see Fig. 2b) was significantly larger than that of *P. guttatus* (range: 42.4–87.5 mm CL; mean ± SD: 63.1 ± 7.4 mm CL) (log-transformed data; $t = 8.055$, $df = 914$, $P < 0.0001$).

We caught 120 *P. argus* in site 1 (including recaptures) and only 22 in site 2. Overall, there were 48 males (size range: 49.0–123.6 mm CL) and 72 females (size range: 50.1–98.4 mm CL). Mean size of males and females was similar (mean ± SD of males: 70.3 ± 14.2 mm CL; of females: 69.5 ± 11.6 mm CL; $t = 0.362$, $df = 138$, $P = 0.716$).

In site 1, new individuals of *P. argus* (excluding recaptures) accounted for 35 males and 41 females (sex ratio 0.85:1). We tagged 33 males and 39 females, and recaptured 9 males (27%) and 14 females (36%). Most recaptures of *P. argus* were obtained within 15 weeks; only four individuals remained at large for longer periods (up to 31 weeks) (see Fig. 3b). No significant differences in time at large were observed between males and females ($\chi^2 = 2.92$, $df = 3$, $P > 0.25$). Distance of recapture varied from 20 to 150 m. Some individuals were recaptured more than once, yielding a total of 12 recaptures of males and 30 of females. Of these, four males (60.8–75.8 mm CL) and seven females (50.1–78.0 mm CL) grew. The average molt increment, intermolt period, and growth rate of males were, respectively, 5.2 mm CL, 8.4 weeks, and 0.67 mm CL week^{-1}; whereas those for females were 4.3 mm CL, 6.5 weeks, and 0.68 mm CL week^{-1}. These data were too scanty to attempt any further analyses on population size or growth, but indicate that individuals of *P. argus* were less abundant, had higher growth rates, and remained in the reef patches for shorter periods than individuals of *P. guttatus*. Also, in contrast to *P. guttatus*, there was no evidence of reproductive activity of *P. argus* in the coral patches: all female *P. argus* were in reproductive stage 1.

DISCUSSION

In the reef patches surveyed in this study, we caught over five times as many *P. guttatus* as *P. argus*. The underlying causes for these disparate results could be interspecific competition, a differential catchability in traps, or a real difference in abundance of both species. Competition is not likely to occur, because *P. argus* and *P. guttatus* do not seem to compete for food or shelter resources (Sharp et al. 1997; Lozano-Álvarez & Briones-Fourzán 2001). Although differences in catchability of both species cannot be discarded, we believe that our results reflect a true scarcity of subadult *P. argus* recruiting to the reef habitat. In Puerto Morelos, densities of algal juveniles of *P. argus* in the shallow vegetated reef lagoon are high (146–263 individuals ha^{-1}, Briones-Fourzán & Lozano-Álvarez 2001a), but the density of the subsequent postalgal juveniles is drastically reduced (0–31 individuals ha^{-1}), owing to a lack of crevice-type shelters throughout the reef lagoon (Briones-Fourzán & Lozano-Álvarez 2001b). This would further result in low numbers of subadult *P. argus* moving to the reef habitat. Over 80% of the individuals of *P. argus* in our sample were subadults (<80 mm CL) as opposed to the individuals of *P. guttatus*, which were all adults. In addition, each species appears to make a differential use of the reef habitat: subadult *P. argus* shelter in the reefs during the day, but forage at night in rubble areas or seagrass meadows adjacent to the reefs (Cox et al. 1997), whereas individuals of *P. guttatus* forage on the reef itself (Sharp et al. 1997) and never abandon this habitat completely.

Our estimates on population sizes and survival rates of *P. guttatus* were similar to those estimated in the Florida Keys (Sharp et al. 1997), but, although we did acknowledge the tag loss, our estimates may be biased owing to an unquantified tag-induced mortality. When analyzing the effects of the Australian tag on juvenile *P. cygnus* (40–75 mm CL), Chittleborough (1974) estimated an overall "tag loss" of 23% over 39 weeks, but he could not separate tag-induced mortality from tag loss. In addition, although the size range of Chittleborough's *P. cygnus* and our *P. guttatus* was similar, Chittleborough's tags had considerably larger toggles (14 mm long) than ours (9 mm). Mortality of *Homarus americanus* (43.5–97.5 mm CL) induced by sphyrion tags (similar to the Australian tags but with a steel anchor instead of a plastic toggle) was significantly lower (≤ 5%) in lobsters tagged during intermolt or premolt than in those tagged during postmolt (soft-shelled) (Moriyasu et al. 1995), a precaution we observed in our study. Lozano-Álvarez (1992), using exactly the same type of tag as ours on a population of juvenile and young adults of *P. argus* (25–90 mm CL), estimated a tag-induced mortality of 5%. If a similar tag-induced mortality occurred shortly after tagging in our individual *P. guttatus*, it might have not affected the estimates of survival, but it may have contributed to an underestimation of the population size (Begon 1979, Moriyasu et al. 1995).

Therefore, our population size values are probably underestimates. However, the estimates of survival rates for males (0.73) and females (0.87), and the average density of adult *P. guttatus* in our coral patches (126 lobsters ha^{-1}), were comparable to the mean densities of 118 and 115 adult *P. guttatus* ha^{-1} estimated by Sharp et al. (1997) in two patch reef areas in a lobster sanctuary in Florida, based on nighttime samplings by divers, with overall survival rates of 0.87 and 0.67 in each area. In contrast, in reef-crest areas of Bermuda, where a specific fishery for *P. guttatus* exists, Evans and Lockwood (1994) obtained a mean density of 29 ± 7.6 trappable *P. guttatus* ha^{-1}, but with an overall male:female ratio of 7:1.

The largest population sizes of adult *P. guttatus* in our study site were obtained in June to November. Within this period, the lowest percentages of ovigerous females and the smallest mean size of lobsters also occurred, suggesting a recruitment of small adults to the trappable population during the summer and early autumn. The juveniles of *P. guttatus* presumably live in the same habitat as adults (Sharp et al. 1997), but we have never observed individuals <34 mm CL during daytime divings in these reefs. However, the coral reef is a very intricate habitat, and the small phases of *P. guttatus* may hide deep within small recesses and crevices during the day, warranting future extensive surveys by nighttime divings to reveal their occurrence and their contribution to the whole population size.

Because *P. guttatus* is a rather sedentary species, we hypothesized that the population additions would be mostly ascribed to the recruitment of small adults. However, we cannot rule out entirely the contribution to the population additions and losses of movements of males and females throughout the reef habitat, and from and to our limited study area. Most of our individual *P. guttatus* were recaptured from distances <50 m, and our reef patches were relatively separated from adjacent reef habitats, but low-relief hard grounds between these and other patches may have been traversed by some individuals. In displacement experiments with tagged adult *P. guttatus*, Carrasco-Zanini (1985) and Lozano-Álvarez et al. (unpubl. data) estimated the home range of adult *P. guttatus* to lie within a 100 m radius along the reef tract, but some of their individuals were able to return to their initial shelters from up to 200 m. Evans and Lockwood (1994) documented an autumnal offshore migration, associated with reproductive activities, of females and young males of *P. guttatus* in an extensive reef habitat in Bermuda. However, the fore-reef habitat in our study area is neither as extensive nor as developed as in other coral reef areas (Ruiz-Rentería et al. 1998), so offshore migrations of *P. guttatus* are not likely to occur.

Sharp et al. (1997) proposed that the availability of suitable shelters in the reef habitat may be the primary factor controlling the abundance of *P. guttatus*. In our study patches, in addition to *P. guttatus* and *P. argus*, many other crevice-dwelling species (e.g., *Mithrax spinosissimus*, moray eels, groupers, triggerfish, octopuses, etc.) occur. However, some of these species are also potential lobster predators, as well as other species associated to the reef habitat. Predation-induced mortality was high within our traps, where confined lobsters were unable to escape predators, but the true magnitude of this type of mortality in the natural reef, to which we ascribe most of the population losses, will remain undetermined until specific studies on predator-prey dynamics are conducted in these reefs.

Protracted reproductive periods, indicative of repetitive breedings, are common in tropical palinurid species (Quackenbush 1994). In the coral reefs of Puerto Morelos, Briones-Fourzán & Contreras-Ortiz (1999) found that female *P. guttatus* <50 mm CL breed mostly during the winter and spring, whereas females >50 mm CL breed during the four seasons. These authors estimated the index of reproductive potential of *P. guttatus* by conservatively assuming one brood per year for all size classes. But if females >50 mm CL can breed three to four times per year as suggested by our results, their contribution to the overall egg production may be much higher than that estimated by Briones-Fourzán & Contreras-Ortiz (1999).

An effect of repetitive breeding on females is a decrease in their growth rates, due to a reduction in the molt increments and an increase in the intermolt periods (Hunt & Lyons 1986), but our data on female growth were insufficient to explore this assumption. Injuries have no clear effect on growth in some lobster species (Davis 1986; Forcucci et al. 1994), but in others injuries reduce molt increments (Brown & Caputi 1986). In our study, those injured *P. guttatus* that grew showed, in general, lower molt increments than uninjured individuals. Moreover, other injured individuals molted, as evidenced by their regenerated appendages, but without any increase in CL. Injured lobsters were mostly males, and the occurrence of detached appendages in our traps suggests that some were injured while in the traps, perhaps through aggressive interactions (Lozano-Álvarez & Briones-Fourzán 2001) or when trying to deter the predators that entered the traps. The real incidence of injuries among the population is undetermined.

Our male growth data, although scant and inconclusive, suggest that growth rates of male *P. guttatus* decrease as size increases, but few males grew during their time at large. In Martinique, most *P. guttatus* molt at least twice a year (Marfin 1978), whereas the average intermolt periods of our 10 uninjured males that grew (8–12 weeks) suggest the possibility of four to six molts per year. Applying the average growth values of uninjured males in Table 5, it would take a 48 mm CL male about 2.5 years to reach 80 mm CL. However, many individuals did not molt during similar or longer times at large (up to 24 weeks), and if this portion of males is also taken into account in the growth estimates, the results suggest that uninjured adult male *P. guttatus* may molt at least 2–3 times per year. The average molt increment of males over the entire size range of recaptured individuals was 2.8 mm CL. With these values, a 48- mm CL male *P. guttatus* would grow to 80 mm CL in about four years. More data are needed to improve these results, which nevertheless indicate that *P. guttatus* has lower growth rates than *P. argus* of similar sizes, because it would only take one year for a male *P. argus* to grow from 48–80 mm (Lozano-Álvarez et al. 1991b).

Most of the recaptures of *P. argus* were obtained within 15 weeks, suggesting that these patch reefs are a transitory habitat for these subadults, which would presumably emigrate further on to deeper offshore areas where the large adults dwell (Lozano-Álvarez et al 1991a). In contrast, some individuals of *P. guttatus* were recaptured over periods up to 50 weeks, suggesting that these patch reefs are a more permanent site of residence for *P. guttatus*.

Our results show that the coral reef patches at Puerto Morelos support a sizeable population of *P. guttatus* and are also an important habitat to the subadults of *P. argus*. In the future, more refined studies focused on the population dynamics of *P. guttatus* should include sampling by nighttime diving, a direct estimation of tag-induced mortality, tagging in a broader area, and increasing the sampling effort to obtain a larger set on growth data.

RESPONSES OF MIGRATING WESTERN ROCK LOBSTERS *PANULIRUS CYGNUS* (GEORGE, 1962) TO TWO DIFFERENT TAGGING RELEASE PROCEDURES

ROY MELVILLE-SMITH[1] AND YUK WING CHENG[2]

[1]*Western Australian Marine Research Laboratories, P.O. Box 20, North Beach, Western Australia, Australia 6020;* [2]*Western Australia Centre of Excellence in Industrial Optimisation, Curtin University of Technology, GPO Box U1987 Perth, Western Australia, Australia 6845*

ABSTRACT In the 1997/1998 season, 3,412 migrating 'white' sub-legal sized western rock lobsters were tagged at Jurien Bay (42–49 m depth), and Cervantes (92–133 m depth) on the Western Australian coast. Most lobsters (n = 2,245) were brought ashore to be tagged, held overnight in coffs, and released 18–24 hours after capture within 6 km and ±10 m depth from where they were taken. A smaller number (n = 1,167) were tagged and released at sea immediately after capture. Over three seasons, more animals tagged at sea were recaptured than those tagged ashore ($P < 0.01$). At both sites, lobsters tagged ashore moved significantly further and faster than those tagged at sea ($P < 0.01$). The correlation between the angle of movement and the speed of movement ranged from 0.25 to 0.42 ($P < 0.05$) for the two tag-and-release procedures and two sites. However, all the lobsters moved in a northerly to north-westerly direction. Growth increments in the first moult after release were unaffected by the different tag and release procedures (P = 0.08); loss of a single limb was, however, likely to result in a 22% decrease in the growth increment.

KEY WORDS: *Panulirus cygnus*, tagging, movement, mortality, growth, migration

INTRODUCTION

Over the last three decades, tens of thousands of western rock lobsters (*Panulirus cygnus*, George, 1962) have been tagged to estimate movement, growth, natural mortality and discard mortality. Tag and release programs are generally expensive, as they usually require deploying research vessels, chartering commercial fishing vessels, or purchasing part of a commercial catch. Often only selected size classes are required for tagging, therefore it would be more economical for commercial fishers to retain individuals with the required characteristics and in this way accumulate large numbers of the animals being targeted for tagging.

However, accumulating animals for later tagging would inevitably mean displacing them from their area of capture and previous research suggests that this can affect subsequent growth (Brown & Caputi 1983, 1984), recapture rates (Chittleborough 1974; Brown & Caputi 1983) and movement patterns (Chittleborough 1974) and may lead to nomadism (Herrnkind 1980).

The object of this investigation was to compare the results of two tag-and-release procedures: one where migrating lobsters were released to the waters where they were caught straight after capture; and the second to bring the lobsters ashore to be tagged, and return them to roughly the same area the next day. In both cases recapture rates, distance speed, direction of movement and growth increments have been compared for the two release procedures.

The lobsters tagged in this study were all migrating animals, known colloquially as 'whites' because they are paler than the dark red resident animals. For most of their lives, adult western rock lobsters show only limited movement; only during the white phase when the lobsters are 4–5 years old, do they move for any distance, migrating from the shallow inshore coastal reefs to the offshore breeding grounds (Morgan 1977; Phillips 1983). The migration takes place each year between late November and January. Tagging data have shown that, while most migrating animals move directly offshore, a significant number make more extensive longshore migrations, generally in a north-westerly direction (Phillips 1983; Cheng & Chubb 1998).

METHODS

Sampling

A total of 3,412 migrating sub-legal size "white" lobsters in the size range 65 mm to 77.9 mm carapace length were tagged and released west of Jurien Bay between 29 December 1997 and 4 January 1998 in 43–49 m and south-west of Cervantes between 29 December 1997 and 6 January 1998 in 92–133 m depth (Fig. 1, Table 1). The depths at Jurien Bay and Cervantes were chosen because they represented two different stages of the offshore migration, the animals in 43–49 m range being in the process of moving to deeper depths offshore and those at the Cervantes site being at the offshore limit of the migration run.

All of the lobsters used for tagging were caught during the course of commercial fishing. The experimental lobsters (Cervantes, n = 1,400 and Jurien Bay, n = 845) were kept alive in tanks with flow-through water circulatory systems and brought ashore to be tagged. After tagging, they were kept overnight in plastic fishing baskets tied to the side of the fishing boats. The next day, they were placed in tanks, taken to the fishing grounds and released (18 to 24 hours after capture) together in a single batch on suitable substrate within 6 km and ±10 m depth from the respective sites where they were caught (Table 1). GPS details of their release positions were recorded. The control lobsters (n = 1, 167) were tagged and released at sea within 12 minutes of capture and within 500 m of where they were caught (Table 1).

All lobsters were tagged ventrally with individually numbered Hallprint type TBA-1 internal anchor tags, as described by Melville-Smith and Chubb (1997). The tag number, size, sex, number of appendages missing, dates of capture and release, and position and depth of capture and release were recorded for each tagged lobster. Tagging at Cervantes and Jurien Bay was done by different people, both experienced at tagging lobsters; at each site the same person tagged at sea and ashore.

Tagged lobsters were generally recaptured by commercial fishers, although small numbers were caught by research and recre-

ational fishers. All tag recaptures were made during the fishing season, which extends from mid-November to 30 June. Fishers were encouraged to provide details of tagged lobsters by offers of a AUD$2 instant lottery ticket for information relating to any tagged animal recaptured. They were asked to record size sex, number of limbs lost, date, position and depth of capture.

Analysis

The percentage of tag recaptures to numbers tagged were compared for the two tagging sites and their release sites by a generalized linear model with binomial family (logit link). The mean time at large, distance from release sites and speed of movement were calculated. The last two were based on the shortest distance between the point of release and recapture. Animals were grouped by their times (one or two and three seasons) at large and any recaptured within 30 days of release were excluded from analyses calculating the mean time at large and distance from release sites, to avoid biasing the results by including migrating individuals. The second and third seasons were combined instead of being treated separately because published and unpublished data show that once western rock lobsters have undertaken their migration and have settled on the deep water spawning grounds, that thereafter their movements are limited. Combining the second and third years increased the power of the statistical tests.

Recaptured animals were analyzed for defined time periods at large by student-*t* tests to estimate the power of the test. General linear modeling was used to model the size of the first growth increment after release, with distance moved and loss of limbs treated as covariates; and sex, site of release and release procedure as factors.

The uniformity of the directional movement of lobsters tagged at sea and ashore was examined by a Rayleigh test (Zar 1998) and the mean angle of movement of the animals tagged by the two procedures relative to 0° (i.e., True North), was tested by a Watson-Williams test (Zar 1998). Angular-linear correlations for lobsters tagged at sea and ashore were determined by the method described in Mardia (1976) and Johnson and Wehrly (1977). Regression methods were used to establish the relationship of the angular movement to the maximum speed of movement.

RESULTS

Recapture Rate

The mean percentage of tagged rock lobsters that were recaptured from the two release sites and tagging procedures ranged from 7.4% to 12.6% (Table 1).

A generalized linear model showed that recapture rates were unrelated to the two release locations ($P = 0.38$), but that they were significantly correlated with the two tagging procedures ($P = 0.03$). A binomial test on two proportions (Zar 1998) produced a similar outcome. The overall recapture rate of lobsters tagged at sea was about 4% higher than those that were tagged ashore.

Time at Large

The time at large before recapture can influence comparisons of different tag-release procedures. For example, one group of lobsters may move further than another, not because of the experimental procedure, but because they were at large for longer. In the first season (to the end of June 1998) after release, animals that were tagged ashore were recaptured significantly later ($P < 0.03$;

TABLE 1.

Western rock lobsters tagged at sea and on shore at Cervantes and Jurien Bay on respectively 29 December 1997 to 6 January 1998 and 29 December 1997 to 4 January 1998, and recaptured by 30 June 2001.

	Tagging Procedure					
	Ashore			At Sea		
Release Sites and Depths	Release (n)	Recaptured (n)	Percentage Recaptured	Released (n)	Recaptured (n)	Percentage Recaptured
Cervantes (92–133 m)	1400	103	7.36	564	71	12.59
Jurien Bay (43–49 m)	845	79	9.35	603	72	11.94
Total	2245	182	8.11	1167	143	12.25

TABLE 2.

Days at large (Days) of western rock lobsters released at Cervantes and Jurien Bay in 1997/98 after tagging either at sea (n = 1167) or ashore (n = 2245). Results are for the sexes combined, recaptured by the end of the first, and second and third fishing seasons at large.

	Days Before Recapture							
	End of First Season (30 < *days* ≤210 After Release)				Second and Third Seasons (210 < *days* ≤(210 + 730) Days After Release)			
	n	Days (mean)	SE	P Value	n	Days (mean)	SE	P-value
Tagged at sea	81	103.12	2.41		72	419	9.14	
Tagged on shore	50	111.70	2.96	0.03	60	430.4	9.24	0.38

combined sexes) than those that were tagged at sea (Table 2). However, in the second and third seasons at large, there was no significant difference between the two groups (P = 0.38; combined sexes) (Table 2). Although the data have not been presented here, neither the release sites nor the sex of the lobsters produced different results.

Distance Moved

Lobsters that were tagged ashore moved greater distances on the whole than those tagged and released at sea. This difference was significant (P < 0.01) for recaptures at both Cervantes and Jurien Bay made by the end of the first season (Fig. 2). The trend remained clear when only recaptures made in the second and third seasons were considered, but was only statistically significant for the Cervantes data (Fig. 2). The substantial differences in the displacement of recaptured lobsters at the two sites and depths have precluded the data being combined in analyses comparing their movement.

Depending on whether they had been tagged at sea or ashore, lobsters that were tagged at Cervantes and that were at large for two or three seasons had moved about the same distances as those that had been at large for only one season (means ranging from 38.23-45.53 km for those released ashore, compared to 8.98–17.01 km for those released at sea, Fig. 2). This did not apply to lobsters released at Jurien Bay, where the one-season lobsters had moved shorter distances than the two or more season lobsters (means of 10.87 and 5.03 km for those released ashore and at sea respectively by the end of the first season, compared to 30.06 km and 15.78 km for those released ashore and at sea respectively at the end of the combined second and third seasons at large, Fig. 2). However, the proportional differences moved by the at-sea and ashore release groups at Jurien Bay was similar for those at large for one compared to two or more seasons, in all cases those tagged ashore moving two to three times further than those released at sea.

Speed

As there is little movement by western rock lobsters after their 'whites' migration phase which ends by late January, only data for recaptures made from 1 February to 30 June 1998 (i.e., within the first season after release) have been presented in Table 3. Bearing in mind the differences in distance moved between lobsters tagged at sea and ashore (Fig. 2), it is not surprising that the two groups showed significant differences in their speeds of movement at both tagging locations (Table 3).

Direction of Movement

Comparisons using a Rayleigh test of uniformity of movement showed that the lobsters did not migrate uniformly in one direction, regardless of whether they were tagged at sea or ashore. A Watson test to compare the mean angles of movement from the two treatments showed no significant difference for either those animals released in the intermediate depths at Jurien Bay (P = 0.2), or those released in the deep water at Cervantes (P = 0.6). In both cases the mean direction of movement was north to nor-nor-westerly.

Relationships Between Direction, Distance and Speed of Movement

Angular-linear correlations (Mardia 1976; Johnson & Wehrly 1977) used to determine whether distance or speed of movement is correlated with direction of movement, were determined separately for the two tagging sites and for the animals released at sea and ashore. Some, but not all, of the correlations comparing angle of movement to distance moved were significant (Table 4); however, angle of movement was significantly correlated (P < 0.05) with speed of movement in all cases.

A regression analysis comparing speed and angle of movement showed that, while the general direction moved was northerly, recaptured lobsters that had been tagged ashore had a more westerly component to their movement. Since the correlation between angle and speed of movement was higher for lobsters tagged ashore (0.34, 0.42) than at sea (0.25, 0.33), this indicates that migrating western rock lobsters moved fastest when heading in a north-westerly direction.

Growth Increment

The results from a general linear model of the growth increments of lobsters that were likely to have moulted once between release and recapture (i.e., only animals recaptured between February 1998 and July 1998) are shown in Table 5. Distance moved is treated as a covariate (P = 0.15), and sex (P = 0.46) and

TABLE 3.

Mean speed of movement of recaptured western rock lobsters tagged at Cervantes and Jurien Bay in December 1997 and January 1998 and recaptured between 1 February and 30 June 1998 (i.e., within the first season after release).

Release Site and Depth (m)	Tagging Procedure	Recaptured (n)	Speed (m/day)	S.E.	P = value
Cervantes	Ashore	27	392.1	55.64	
92–133 m	At sea	26	142.1	30.35	<0.01
Jurien Bay	Ashore	23	103.7	28.18	
43–49 m	At sea	55	52.52	4.50	0.01

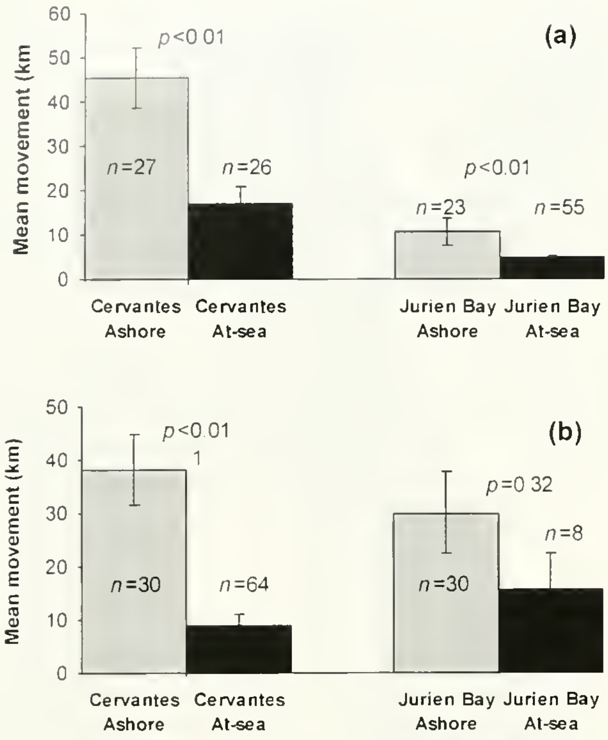

Figure 2. Mean distance western rock lobsters moved after tagging at Cervantes and Jurien Bay in December 1997 and January 1998 (a) by the end of the first season excluding the first month after release and (b) in the second and third seasons.

release procedure ($P = 0.08$) as factors; none had a significant effect on growth increment. However, region of release ($P = 0.03$) and the number of limbs lost at tagging ($P = 0.01$) did have a significant effect on growth increment. As only three recaptured lobsters had more than two lost limbs at tagging, nothing can be inferred about the effect of multiple limb loss on growth. However, it can be seen (Table 5), that the loss of a single limb is likely to result in a 22% decrease in growth increment.

DISCUSSION

The lower recapture rates of lobsters tagged ashore and released a day later, suggest that their mortality rates were higher than lobsters tagged and released at sea within 12 minutes of capture. Brown and Caputi (1983) noted that the length of time between capture and release had a detrimental effect on survival and growth of sub-legal size lobsters. However, in the present study every effort was made to limit the time of exposure out of water. After capture, the animals were stored on board in baskets submerged in dark, aerated wells in the hull as is commercial product. Once ashore, the lobsters were tagged immediately and then kept overnight in plastic baskets hung over the side of the boats in well-aerated surface water. For the return trip to the fishing grounds, they were stored in the same way as after capture.

Displacement of western rock lobsters from their home range probably increases their vulnerability to predation (Chittleborough 1974; Brown & Caputi 1983). Brown and Caputi (1983) further concluded that "when lobsters are migrating they are somehow affected by displacement more than they are affected by it in their non-migratory phase (p. 125)." When western rock lobsters make their offshore migration, they are thought to move in groups or "packs", rather than singularly (Gray 1992). There is some evidence of a survival benefit in groups, rather than single lobsters moving over the sand (Herrnkind 1969; Kelly et al. 1999). Displacing migrating lobsters from their groups by bringing them inshore to be tagged may, therefore, have increased their vulnerability to predation, at least until they could rejoin another group of migrating animals.

Even though a higher percentage of lobsters tagged ashore were recaptured significantly sooner (within the first season) than those tagged at sea, they had moved significantly further from their release site than had those tagged at sea. This group of shore-tagged lobsters had been at liberty for a shorter time, and therefore had less time in which to migrate. There is evidence that *Panulirus argus* and *P. cygnus*, can return to their resident homesite if displaced over a few hundred metres (*P. cygnus*; Chittleborough 1974, and *P. argus*; Herrnkind et al. 1975). Chittleborough (1974) and Herrnkind et al. (1975) both showed that displacing animals from their home range or a familiar region results in abnormal patterns of movement. Although he had no data on relocating migrating lobsters, Herrnkind (1980) speculated that moving them away from their characteristic migratory pathway could conceivably cause disorientation and wandering, which would distort tag-recapture studies.

The present study does not confirm Herrnkind's (1980) expectations: although the animals tagged ashore, that had both a delayed and displaced release, migrated further, their mean direction of movement was the same as that of the lobsters tagged at sea. This observation does not support the suggestion they wandered in a disorientated fashion. Furthermore, rock lobsters have been found to use magnetic fields to orient themselves (Lohmann et al. 1995). It seems that, despite the unusual treatment of most of the animals in this study, they retained their directional orientation during their time in captivity. The question as to why shore-tagged lobsters travelled further remains unresolved.

Previous western rock lobster tagging programs have shown that while most lobsters migrate less than 10 km from their point of release, many migrate up to several hundred kilometers, almost always in a north-westerly direction (Gray 1992). Furthermore, Cheng and Chubb (1998) report that migrating western rock lobsters tagged in deepwater move longer distances than those in shallow water. It is commonly accepted therefore, that most "white" migrating lobsters become resident in 40–90 m depths west or northwest of the shallows from where they started their migration, but that a minority that reaches deep water (>90 m) follows the contours northward, before peeling off inshore along the way to settle on the breeding grounds in depths of around 40–90 m.

The distance and direction moved by animals tagged in the depths reported in this study are consistent with the scenario suggested above. Those tagged in the middle depths (43–47 m) at Jurien Bay generally moved shorter distances than those in the deepwater (>90 m) at Cervantes. These middle depths (40–90 m) is where the resident breeding stock population occurs. Interestingly, lobsters at large for one season at Cervantes, whether tagged at sea or ashore, moved roughly the same distances as those at large for two or three seasons. In contrast, at Jurien Bay, lobsters recaptured in the second and third seasons had moved further than those recaptured in the first season. However, animals tagged at sea and ashore both moved greater distances in the second than in the first. The lack of difference in distances moved once the white migrating lobsters become resident (within the first season) sug-

TABLE 4.

Correlations between displacement and angle of movement, and speed and angle of movement of western rock lobsters tagged either ashore or at sea and released at one of two different sites.

Release Location	Tagging Procedure	Correlation Between Distance Moved and Angle of Movement	*P*-value	Correlation Between Speed and Angle of Movement	*P*-value
Cervantes	Tagged ashore	0.18	0.35	0.34	0.03
92–133 m	Tagged at sea	0.31	0.01	0.25	0.05
Jurien Bay	Tagged ashore	0.33	0.04	0.42	0.01
43–49 m	Tagged at sea	0.27	0.10	0.33	0.03

gests that the tagging-release procedure affects distance only in the first season.

The differences between the distance travelled by displaced lobsters (shore tagged) and those released where they were captured suggests that movement data from animals tagged during their migration phase be interpreted cautiously. The spatial and temporal displacement resulting from bringing the animals ashore to be tagged and releasing them at a distance from their catch site clearly has an effect. Smaller displacements, such as result from the drifting of tagging platforms or being held overnight in a pot when captured, might also affect the movement of lobsters tagged at sea during their migratory phase. Results from this study would therefore suggest that the effects of release procedures on the behavior of migrating lobsters, must be considered before biological conclusions are drawn.

No oceanographic data were collected, either at the tagging locations, or at the anchorages where the animals were held overnight. However, substantial amounts of environmental data have been collected on the western rock lobster grounds in the past, and it can be confidently assumed that differences in the salinity, temperature and oxygen concentrations in the coastal waters where the lobsters were held, compared to the offshore waters where they were caught, would have been well within the seasonal ranges experienced by the species. This does not preclude the possibility that the overnight acclimation of the animals to the changes in water conditions may have contributed to the different behavior of the at-sea and ashore tagged animals.

The mean speeds of movement recorded by the migrating animals tagged in this study are substantially slower than those (1.2 km per day) recorded by Cheng and Chubb (1998). Our speeds have been underestimated because all recaptures over the first season at large were used in the calculation, but western rock lobsters migrate only between late November and late January. The strong correlation between angle of movement, and both distance traveled and speed of movement, is a reflection of the lobsters that moved furthest (and therefore recorded the fastest speed of movement while at large) generally heading in the northwesterly direction almost parallel to the coastline, whereas those that moved least (and therefore recorded the slowest speed of movement while at large) generally heading in a northerly direction.

TABLE 5.

Results of a general linear model of growth increments of lobsters between February 1998 and July 1998 (one moult increment).

Name of Variable	Estimated	*P*-value
Intercept	4.28	0.00
Distance moved	0.00	0.15
Released procedure	−0.45	0.08
Released location	0.61	0.03
Sex	−0.19	0.46
Single limb loss at tagging	−0.94	0.01

Single growth increments of lobsters at the end of the first season (after their first moult) did not suggest that migrating animals tagged at sea grew either faster or slower than those held ashore overnight and displaced from their point of capture ($P > 0.05$). This result differed from that of Brown and Caputi (1984), who found that displaced undersize western rock lobsters of a larger size range than those used in this study, had significantly ($P > 0.05$) smaller growth increments than nondisplaced animals. Although the animals in this study would presumably have been stressed immediately after capture, during tagging and possibly while being held overnight, these affects have previously been shown (Melville-Smith et al. 1997) to be short-term and unlikely to affect the moult increment later in the season. The significant difference ($P = 0.03$) in growth increment between the two tagging sites is likely to be due to regional differences in growth, which are well documented in this fishery (Chittleborough 1976; Joll & Phillips 1984).

This study investigated the effects of different handling methods and, on the basis of the results, drew some conclusions about the scope for possible cost reduction in tagging programs by having fishers accumulate selected size-classes of migratory lobsters for tagging ashore. The result has shown that this approach would not be feasible for studying movement patterns or for purposes where recapture rates are critical to the result, such as estimating mortality and/or population sizes. However, growth increments were not significantly affected; if growth measurements were the only requirement from the data, then this cooperative approach between research and industry could result in affordable and reliable tagging projects. Comparative cost savings of tagging the cumulative catch of a number of fishers ashore, as opposed to a single fisher at sea is not possible, because the result is dependent on catch rates of the animals being selected for tagging and on the number of fishers accumulating that part of their catch.

ACKNOWLEDGMENTS

We thank Kim Brooks and Doug McCashney for tagging the lobsters in this study, the skippers and their crews for their help and the many fishers and rock lobster processors who returned the recapture details of tagged lobsters. Sonia Anderton ran the tagging data base, Mark Rossbach and Jim Christianopoulos did much of the field organization of staff and fishers. Lynda Bellchambers, Nick Caputi, Vivienne Mawson and Bruce Phillips offered useful suggestions for improving earlier drafts of this manuscript. The work was part funded by the Fisheries Research and Development Corporation (Project 96/108).

MUSHROOM TYROSINASE AS A CONTROL MATERIAL FOR PHENOLOXIDASE ASSAYS USED IN THE ASSESSMENT OF CRUSTACEAN "HEALTH"

A. BATTISON,[1] R. CAWTHORN,[2] B. HORNEY,[1] AND A. MACKENZIE[2]

[1]*Department of Pathology and Microbiology, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada;* [2]*Atlantic Veterinary College Lobster Science Centre, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada*

ABSTRACT Mushroom tyrosinase (E.C. 1.14.18.1) was evaluated as a control material for use in a plasma prophenoloxidase assay in the American lobster *Homarus americanus* as part of the assay's validation procedure. Reconstituted, lyophilized tyrosinase solution was stable for 72 h at 2–4°C. Percent recoveries were 94%, 120%, 113%, and 48% for "mid-range" activity dilutions and 93%, 94%, 87%, and 38% for "low-range" activity dilutions at 24, 48, 72, and 96 h, respectively. The activity of the reconstituted tyrosinase solution was stable for 4 wk when stored at −80°C, and percentage recoveries, compared to activity of the freshly reconstituted solution, were generally within 15% for both mid-range and "high"-activity dilutions. The between-run coefficients of variation (CVs) were 10.6% for the mid-range and 10.8% for the high-activity dilution over the 4-wk period. Enzyme activity was unstable when stored at −20°C. Mushroom tyrosinase is an acceptable control material for use in assays of phenoloxidase activity. Inclusion of this control material will provide a means to confidently compare results on a day-to-day or run-to-run basis when phenoloxidase assays are used in the assessment of crustacean "health."

KEY WORDS: prophenoloxidase assay, control, tyrosinase, crustacean, health

INTRODUCTION

The prophenoloxidase activating system (PPAS) and its active enzyme product, phenoloxidase (*o*-diphenol:O_2 oxidoreductase E.C. 1.14.18.1) are integral components of the innate defense system in crustaceans (Söderhäll et al. 1996; Söderhäll & Cerenius 1998; Sritunyalucksana & Söderhäll 2000). Dark pigmentation (melaninization) at sites of injury reflects prior generation of phenoloxidase, followed by the spontaneous formation of melanin (Söderhäll et al. 1996; Söderhäll & Cerenius 1998; Sritunyalucksana & Söderhäll 2000). Both the reactive quinone intermediates and the final melanin products formed during this reaction have antimicrobial and protective properties (Söderhäll et al. 1996; Riley 1997).

Determination of the activity of phenoloxidase in either whole hemolymph or hemocyte lysate supernatants has been used to assess the "health" or "immune" status of crustacean species (Hauton et al. 1997; Sritunyalucksana et al. 1999; Rodríguez & Le Moullac 2000). Commercial test kits[1] are available to detect phenoloxidase activity in whole hemolymph samples from shrimp. It is recognized that assays used in the assessment of crustacean health should be standardized (Bachère 2000).

Evaluation and validation of a laboratory test are required to confirm that an assay is performing within its defined parameters before it can be accepted for use in a diagnostic setting (Bellamy & Olexson 2000). This includes determination of the assay's reportable range, precision, accuracy, and reagent stability. Control materials are essential to monitor the performance of the assay (Westgard & Klee 1999). Inclusion of a control with each group of samples permits reliable comparison of the results obtained from samples analyzed during different runs. Ideally, control materials are derived from the same biological source as the samples that are being evaluated.When this is not possible, materials with similar properties can be substituted (Westgard & Klee 1999).

Most phenoloxidase assays are based on (or are modifications of) the method of Horowitz and Shen (Horowitz & Shen 1952; Aspán & Söderhäll 1995). During development of an assay to detect prophenoloxidase activity in plasma of the American lobster, *Homarus americanus* H. Milne Edwards, a control material was required. A purified source of lobster phenoloxidase having consistent activity was not available. Lyophilized mushroom tyrosinase was evaluated as a control material because of its similarities to phenoloxidase and commercial availability (Aspán & Söderhäll 1995).

MATERIALS AND METHODS

Mushroom tyrosinase (E.C. 1.14.18.1) stock solution was prepared by adding 2.5 mL of sodium phosphate buffer (0.2 M Na_2PO_4, pH 7.5) to 13 mg of lyophilized mushroom tyrosinase (Sigma Chemical Company, St. Louis, MO), giving a final concentration of approximately 10,700 units of tyrosinase activity per mL of solution. Serial dilutions of this reconstituted stock solution were used to determine assay linearity, sensitivity, and within-run precision as determined by calculation of coefficient of variation (%CV). A second stock solution, calculated to have similar activity per unit volume, was prepared from a different lot of lyophilized tyrosinase. This second solution was used to conduct refrigerated and frozen stability trials. Eight 150-µL aliquots were placed in 0.5-mL polypropylene microcentrifuge tubes (Fisher Scientific, Canada). Four aliquots were stored at −20°C, four aliquots were stored at −80°C, and the remaining solution was refrigerated (2–4°C), for stability trials.

To complete linearity and precision assessments, serial dilutions at 1:200, 1:400, 1:800, 1:1600, 1:3200, and 1:6400 of the stock solution were made using a 0.2 M sodium phosphate buffer, pH 7.5. Twenty microliters of each dilution was added to individual wells of a flat-bottomed tissue culture plate (Falcon Microtest 3072, Becton Dickinson and Company, U.S.A.). There were five replicates per dilution. Wells to be used as "substrate-free blanks", one well for each dilution, also received 20 µL of the appropriate tyrosinase stock dilution. Twenty microliters of phosphate buffer was placed in wells used as reagent blanks. Eighty microliters of sterile, distilled water was added to all wells using a multichannel pipette. One hundred microliters of the substrate solution, 3.8 mM dopamine (3-hydroxytyramine) (Sigma Chemical Company), was then added to all wells except for the substrate-free blanks. These wells each received 100 μL of sterile distilled water. Production of the gold-orange quinone intermediate was monitored every 11 sec (wavelength 470 nm) during a 5-min period in an automated spectrophotometer (SpectraMax, Molecular Devices Corporation, U.S.A.) after a 5-sec mixing cycle. The software package SoftMax™ (Molecular Devices Corporation, U.S.A.) was used for calculation of maximum enzyme activity (V_{max}), defined as the rate of maximal change in optical density (OD) of the reaction solution per minute (Δ mOD/min) over a user-defined time interval. The V_{max} used for all further calculations for each dilution was the mean V_{max} of the five replicates. Within-run coefficients of variation [%CV = (standard deviation/mean) × 100] were then calculated (Table 1).

---

[1] Spot On, DiagXotics Inc., Wilton, CT 06897.

Stability of the refrigerated stock solution was determined by calculating the percentage recovery for two dilutions, identified as having "low" and "mid-range" activities relative to the linear range of the assay, over a period of 4 days. Percent recovery was calculated as: [(measured activity at time "x"/initial activity at reconstitution) × 100] at 24, 48, 72, and 96 h (Table 2). Four replicate wells were used for each dilution.

Long-term frozen stability of the stock solution, stored at −20°C and −80°C, was evaluated by measuring enzyme activity in serial dilutions of a thawed (room temperature, 20–22°C) aliquot every week for 4 wk. Four replicate wells were used for each dilution. Percent recovery calculations were made for the aliquots stored at −20°C and −80°C (Tables 3a and 3b). Between-run (week to week) %CVs were calculated for each dilution of the aliquots stored at −80°C (Table 4).

The refrigerated stability of thawed stock solution, after storage at −80°C, was also evaluated. Enzyme activity was measured at 48 and 72 h post-thawing for two dilutions (mid-range and high activities). Percentage recoveries were calculated by comparing the activity after 2 and 3 days of refrigeration to the activity obtained immediately after thawing (Table 5).

RESULTS

No significant absorbance was detected in the substrate-free blank wells during the initial assays. Substrate-free blanks were not used for the remaining assays. Reagent blanks were used for all assays and also functioned as the plate blanks. The reaction curve was linear during minutes 2–4 of the 5-min monitoring period. V_{max} was determined from this 2-min period. Initially, a gold-orange product developed in all of the reaction wells containing the dopamine substrate and the mushroom tyrosinase. Subsequently, a black product also appeared in the wells. At first, only small amounts of the black product were present; however, with time, the gold-orange product was no longer visible and only the black product could be seen. The amount of this second product seemed proportional to the concentration of enzyme solution in the wells.

TABLE 2.

Refrigerated (2–4°C) stability of reconstituted mushroom tyrosinase.

	Initial Activity[b] (mOD/min)	Percent Recovery (%)[a]			
		1 day	2 days	3 days	4 days
Dilution no. 1	22.4	94	120	113	48
Dilution no. 2	12.3	93	94	87	38

[a] Percent recovery = (measured activity/initial activity) × 100.

[b] Represents the mean of four replicates.

The catechol oxidase activity of mushroom tyrosinase, as measured in this assay system, was linear, and had acceptable precision results, from 5.0 to 41.6 mOD/min when evaluated by serial dilution ($R^2 = 0.99$) (Table 1, Fig. 1). Using the activity of the 1:200 dilution as a starting point, the expected and observed (in parentheses) activities (mOD/min) for each further dilution were 20.8 (19.6) for the 1:400 dilution, 10.4 (9.3) for the 1:800 dilution, 5.2 (5.0) for the 1:1600 dilution, 2.6 (1.4) for the 1:3200 dilution, and 1.3 (0.4) for the 1:6400 dilution. The within-run CVs (n = 5 replicates), for each dilution were 1.3% for the 1:200 dilution, 0.8% for the 1:400 dilution, 5.0% for the 1:800 dilution, 6.5% for the 1:1600 dilution, 14.3% for the 1:3200 dilution, and 60.7% for the 1:6400 dilution (Table 1).

The stability of the freshly reconstituted reagent was acceptable (i.e., generally within 15% of the initial values) for up to 72 h after refrigeration, but decreased to an average of 43% of initial activity by 96 h (Table 2). Percent recoveries for a mid-range dilution at 24, 48, 72, and 96 h were 94%, 120%, 113%, and 48%, respectively. Percent recoveries for a low-activity dilution at 24, 48, 72, and 96 h were 93%, 94%, 87%, and 38%, respectively (Table 2).

The stock solution was unstable when stored at −20°C. The enzyme activity, calculated as a mean of all dilutions, decreased to 37%, 28%, 27%, and 21% of the initial activity of the freshly reconstituted reagent by weeks 1, 2, 3, and 4, respectively (Table 3a).

The stock solution was stable when stored at −80°C. The percent recoveries, average of mid-range (dilution no. 2) and high- (dilution no. 1) activity dilutions, by week, were 87% for week 1, 99% for week 2, 116% for week 3, and 106% for week 4 (Table 3b). The between-run CVs, over the 4-wk period, were 10.6% for the mid-range dilution and 10.8% for the high-activity dilution (Table 4). The refrigerated stability of the thawed stock solution was generally satisfactory for weeks 1–3, but tended to deteriorate by week 4 of storage at −80°C (Table 5).

DISCUSSION

The value of any assay resides in its ability to consistently provide accurate and precise results. An incorrect result can be

worse than no result at all. Assay validation includes quality control steps used to ensure that diagnostic tests perform within predetermined specifications. Control materials are used to monitor the assay's performance on a run-to-run basis. Ideally, such materials are derived from the same species as the samples to be analyzed; however, this is not always possible. Steps in assay validation usually include (but are not limited to): determination of the assay's reportable range; evaluation of assay precision by calculating both within-run and between-run coefficients of variation (%CV = standard deviation/mean × 100); and, determining the stability of the assay reagents and the sample under different storage conditions (Bellamy & Olexson 2000).

Phenoloxidase (*o*-diphenol:O_2 oxidoreductase E.C. 1.14.18.1) assays have been used to investigate and assess the health status of a variety of crustaceans in both research and commercial settings (Sritunyalucksana et al. 1999; Rodríguez & Le Moullac 2000). A stable source of enzyme to use as a control material was required in the development of a plasma prophenoloxidase assay for use in *H. americanus*. A commercial source of purified lobster (*H. americanus*) phenoloxidase is not available. Lobster hemocyte lysate supernatant preparations represented a highly concentrated source of prophenoloxidase; however, these were unsuitable due to their poor long-term storage characteristics and the inherent, inconsistent activity between preparations (unpubl. results, ALB).

Mushroom tyrosinase (E.C. 1.14.18.1) was evaluated as a potential alternative because of its similarity to phenoloxidase. Both enzymes have cresolase (monophenol monooxygenase) and catechol oxidase (polyphenol oxidase) activity (Aspán & Söderhäll 1995). Determination of the enzyme's copper content and location of conserved histidine residues indicates that arthropod prophenoloxidase belongs to the tyrosinase group of enzymes found in bacteria, fungi, and plants (Aspán & Söderhäll 1995). The reported long-term stability of frozen, reconstituted mushroom tyrosinase and its commercial availability made this enzyme an attractive alternative (Kertesz & Zito 1965).

Mushroom tyrosinase was readily soluble in the 0.2 M sodium phosphate buffer (pH 7.5) used in this assay system. Other studies have used a sodium cacodylate-based buffer. Sodium cacodylate is listed as a hazardous material and is a recognized carcinogen (Sigma-Aldrich 2001). The sodium phosphate buffer used herein presents minimal hazards, is readily available, and was compatible with this assay system. L-DOPA (3,4-dihydroxyphenyl-L-alanine), a commonly used substrate in phenoloxidase assays, was not compatible with the phosphate buffer. Dopamine (3-hydroxytyramine) was chosen as an alternate catechol. Dopamine has been identified as a preferred substrate for phenoloxidase from *Manduca sexta* (Sugumaran et al. 1999). This may also be true for other invertebrates. Mushroom tyrosinase converted the dopamine substrate to an orange-gold intermediate product, presumably the *o*-quinone, 4-(2-aminoethyl)-1,2-benzoquinone. This product was eventually replaced by a black precipitate (melanin), which is the expected result of activation of the PPAS *in vivo* (Söderhäll et al. 1996; Söderhäll & Cerenius 1998; Sritunyalucksana & Söderhäll

2000). An identical series of products is observed when either lobster hemocyte lysate supernatant or lobster plasma, after activation with trypsin, is used as the enzyme source for the assay.

The reconstituted tyrosinase solution was stable, when refrigerated, for up to 3 days as indicated by the percentage recovery studies (Table 2). Tyrosinase activity was stable for up to 4 wk when the reconstituted solution was stored at −80°C. Reconstituted mushroom tyrosinase was unstable when stored at −20°C, in contrast to a previous report (Kertesz & Zito 1965). The discrepant results found in this study may reflect differences in the buffers used for reconstitution. Overall, the refrigerated and frozen (−80°C) stability of reconstituted mushroom tyrosinase was considered acceptable for its use as an assay control material.

Ideally, control materials contain a predetermined amount of the enzyme being measured and are incorporated in a material (matrix) similar to the matrix of the sample to be analyzed. In this study, mushroom tyrosinase was reconstituted in a phosphate buffer. This would be the optimal situation when phenoloxidase activity is being measured in hemocyte lysate supernatants where a similar buffer had been used to prepare the lysates. Similarly, incorporation of the mushroom tyrosinase into whole hemolymph or plasma collected from normal, apparently healthy animals would be preferable when phenoloxidase activity is being measured in these types of samples. This was not evaluated in this study. When reconstituted in a sodium phosphate buffer, mushroom tyrosinase is a suitable control material for use in phenoloxidase assays, providing assurance that the assay is working correctly and permitting comparison of within-laboratory sample results on a run-to-run or day-to-day basis.

BAY SCALLOP (*ARGOPECTEN IRRADIANS*) POPULATION RESTORATION IN FLORIDA, USA: CULTURE VERSUS MANAGEMENT.

W. S. Arnold, Florida Marine Research Institute, Florida Fish and Wildlife Conservation Commission, 100 Eighth Avenue SE, St. Petersburg, FL 33701, USA.

Bay scallops have historically been widely distributed in Florida waters, comprising discrete populations from West Palm Beach on the Atlantic coast to Pensacola in the panhandle. In recent decades, many of those discrete populations have collapsed due to one or a combination of anthropogenic factors. In response to that collapse, recreational and commercial harvest restrictions have been implemented and a culture-based restoration program is underway. The restoration program is experimental in nature and includes a genetic component that is designed to provide information on the relative contribution of cultured scallops to the subsequent year-class.

Preliminary results of this ongoing study suggest that, despite a two-orders-of magnitude increase in mean scallop density within the targeted restoration area, active restoration has contributed little to this recovery. The lineage of fewer than 5% of the subsequent year-class can be traced back to the parental stock that was originally cultured. Instead, it appears that reductions in harvest intensity precipitated by a change in harvest regulations may be the primary contributor to the observed resurgence in scallop populations. Apparently, removal of fishing pressure on already depauperate scallop populations allowed for increased reproductive success and recruitment. If these results are verified through the final year of the study, they indicate that active intervention is not always required to instigate population recovery. Instead, effective and ecologically based management may suffice.

TESTING ALTERNATIVE STRATEGIES FOR ENHANCEMENT OF HARD CLAM (*MERCENARIA* SPP.) POPULATION IN FLORIDA, USA WATERS.

W. S. Arnold, Florida Marine Research Institute, Florida Fish and Wildlife Conservation Commission, 100 Eighth Avenue SE, St. Petersburg, FL 33701, USA.

Although lacking the history of its northern counterparts, the hard clam fishery in Florida became a significant contributor to US clam landings during the 1980s and early 1990s. Most Florida landings have been realized from the Indian River lagoon. In the late 1990s, the clam population in the lagoon almost completely collapsed in response to increased rainfall associated with ENSO. Salinity has since "recovered" to a level suitable for hard clam survival, but the clam population has shown no concomitant recovery. Active intervention may be required to increase clam population abundance to a level at which the fishery is again profitable.

Three methods have been compared for their suitability to increase clam abundance. Spawner transplants involve the harvest of widely dispersed adult clams followed by the release of those clams in a relatively small area. This approach is designed to concentrate reproductively active clams, thereby increasing fertilization efficiency and the production of larval clams. Seeding involves planting various size classes of clams under protected conditions, again with the goal of increasing fertilization efficiency by creating dense clumps of actively spawning clams. Larval injection involves spawning clams in the hatchery, fertilizing the resultant eggs, and releasing the developing embryos within a preselected area of the lagoon. Preliminary results suggest that larval injection can increase abundance of larval clams by several orders of magnitude, but there is as yet no evidence that any of the three strategies has actually led to increased recruitment of hard clams in the lagoon.

EFFECT OF MACROALGAL MATS ON BURIAL DEPTH OF SOFT SHELL CLAMS.

Lise M. Aulfrey,[1] **Shawn M. C. Robinson,**[2] and **Myriam A. Barbeau,**[2] [1]Department of Biology, University of New Brunswick, Bag Service 45111, Fredericton, NB, E3B 6E1, Canada; [2]St Andrews Biological Station, 531 Brandy Cove Road, St Andrews, NB, E5B 2L9, Canada.

Green macroalgal mats are becoming prevalent on important soft-shell clam (*Mya arenaria*) harvesting beaches in southwestern New Brunswick, Canada. We investigated the effect of macroalgal mats on burial depth and body condition of clams in the field (2 sites with high algal cover) and laboratory. In the field, we located patches covered with algae and clear of algae at each site. We measured burial depth by digging trenches and measuring the distance between the anterior edge of the clam and sediment surface. We then collected the clams for body condition analysis. Burial depth was significantly lower for clams under macroalgal mats than for those in clear areas. Clam body condition was generally lower under algae than not under algae. In the lab, clams (4/aquaria) were placed in mud (10 cm deep) and covered either with 0, 2 or 6 cm of macroalgae. Clams under algae de-burrowed after a few days. Clam body condition and various abiotic variables are being measured in the lab and will be analysed in the near future.

PROTECTING AND RESTORING COMMERCIAL SHELLFISH BEDS IN KITSAP COUNTY, WASHINGTON.

Leslie Banigan, Environmental Health Specialist, Bremerton-Kitsap County Health District, 109 Austin Drive, Bremerton, WA 98312, USA.

Kitsap County, located in the central Puget Sound area of Washington State, developed a Surface and Storm Water Management (SSWM) Program that successfully identifies and corrects nonpoint pollution affecting shellfish areas. The Program's success is due to:

1. Political Support: In 1992, Washington passed legislation requiring counties to address water pollution sources causing shellfish closures. In 1993, the Health District received local

political support to develop Kitsap County's SSWM Program, a comprehensive four-agency team to address nonpoint pollution.
2. Financial Support: SSWM provides ongoing stable funding for the Health District's Pollution Identification and Correction (PIC) Program.
3. Effective Public Outreach: An effective outreach program was developed to help inspectors gain access to private property.
4. Enforcement Capability: The Health District developed regulations addressing failing on-site sewage systems and improper animal manure management.
5. Standardized Procedures: The Health District uses an objective system of ranking water quality problem areas and has a detailed procedures manual.

In 1996, the State closed a portion of Port Gamble Bay to shellfish harvesting. The Health District completed a PIC project in the watershed. In 1999, the State upgraded the commercial shellfish beds to "approved" status.

Burley Lagoon was closed to shellfish harvesting in early 1999. Due in large part to PIC work conducted by the Health District, one-half of Burley Lagoon was re-opened to shellfish harvest in 2001.

INCREASING MUSSEL SHELL THICKNESS BY RELAYING TO IMPROVE RESISTANCE TO CRAB PREDATION.

Helen A. Beadman,[1] **M. J. Kaiser**[1] and **R. I. Willows,**[2] [1]School of Ocean Sciences, University of Wales-Bangor, Menai Bridge, Gwynedd, LL59 5BP, UK; [2]National Centre for Risk Analysis and Options Appraisal, Steel House, 11 Tothill Street, London, SW1H 9NS, UK.

The mussel cultivation industry is currently the fastest expanding and most valuable sector of the shellfish aquaculture industry in the United Kingdom. One of the constraints of the potential continued success and expansion of the industry is an unpredictable supply of seed mussels for relaying. It is suggested that a possible solution to this problem is to lay seed in times of abundant spatfall on high shore areas where they can ongrow. In subsequent years when spatfall is low these mussels can then be transferred further downshore to allow faster growth to marketable size. A further advantage of growth in high shore areas is the development of a thicker shell that aids resistance to crabs predation.

The aim of this study is to determine how the difference in mussel shell thickness achieved by growth at different heights on the shore can be related to resistance to crab predation and how this changes when mussels are relaid at different tidal heights. This has been achieved through an experimental approach relaying mussels from high shore, intertidal and subtidal areas to the intertidal. Shell thickness is determined through direct means and indirectly through crab predation experiments and shell compression. Results show a significant difference between mussels grown at different shore heights and associated differences in shell compression strengths and resistance to crab predation. Mussels grown at lower shore levels initially displayed thinner shells, of lower compression strength and were preferentially predated upon by crabs.

PUBLIC STOCK ENHANCEMENT OF SOFT-SHELL CLAMS, *MYA ARENARIA*, IN MAINE, USA: THE ROLE OF COMMUNITY-BASED AQUACULTURE, APPLIED RESEARCH, AND TECHNOLOGY TRANSFER IN SHELLFISH RESTORATION.

Brian F. Beal, Division of Environmental and Biological Sciences, University of Maine at Machias, Machias, ME 04654, USA.

In Maine, USA, the intertidal zone is legally owned by the coastal community adjacent to it. For 50 years, commercially important soft-shell clams, *Mya arenaria*, residing in these tidal flats have been co-managed by communities and the state's marine resources department. Clam landings have been cyclical varying from 3,100 metric tons (t) in 1950 to 658 t in 1959, to 3,500 t in 1977 to 800 t in 1997. Historically, management has been based on the vagaries of natural recruitment and the strength of a particular 0-year class.

Beginning in 1987, the first-ever soft-shell clam restoration program in the US was established through the Beals Island Regional Shellfish Hatchery (BIRSH) whose mission is to enhance Maine's soft-shell clam and other shellfish resources through aquaculture, applied research, technology transfer and public education. BIRSH produces 5–10 million 8–12 mm seed clams annually, and, over the years, these cultured individuals have been planted in approximately 50 of the state's 100 coastal communities that manage their shellfish beds.

BIRSH has been the focal point of Maine's research and outreach on soft-shell clam ecology during the past 15 years and has been done at the request and in conjunction with coastal communities. Research projects have tested the interactive effects of planting date, seed size and density, type and aperture of protective netting and how these factors vary spatially and temporally. Generally, seed clams (>10 mm) should be planted during April, at the beginning of the growing season, and protected with flexible netting (6.4 mm).

DESIGN AND CONSTRUCTION OF SUBTIDAL OYSTER REEFS: EVALUATING EFFECTS OF REEF SCALE.

Alan J. Birch, M. W. Luckenbach, P. G. Ross, R. Gammisch, and **J. Brubaker,** College of William and Mary, Virginia Institute of Marine Science, and **J. A. Wesson,** Virginia Marine Resources Commission, USA.

Restoration of oyster reef habitat in mid-Atlantic estuaries is requisite for restoring oyster fisheries and recovering lost ecological services. Recent evidence suggests the importance of establishing proper vertical relief and interstitial space in the initial placement of substrate. A third component of reef architecture that has yet to be investigated is the aerial extent or scale of reefs. We are currently evaluating the effects of scale on various components of communities that develop on high relief reef bases ranging in size from 400 m^2 to 8000 ^{2}. As a result, accurate physical descriptions of the constructed reefs are important to meaningfully quantify reef scale.

We present some preliminary design and construction aspects of three dimensional subtidal reefs in the Rappahannock River, a tributary of the Chesapeake Bay. Because of their subtidal nature, describing the reefs physical characteristics becomes difficult. Subsequently, Side-scan sonar mapping, bathymetry surveys and current velocity mapping were conducted during the first year after construction and will be continued in subsequent years as the reefs develop.

From a management aspect, where potential substrate is limiting and expensive, any ecological advantages or disadvantages derived from allocating resources to many small vs. several large reefs can have direct economic impacts on restoration efforts. Furthermore, identification of details of the physical characteristics that may help achieve restoration goals can be extremely important in providing resource managers with the information that can aid future reef design criteria.

THE MUCK STOPS HERE A COMMUNITY DECIDES.

C. Boldt, Union Bay Liquid Waste Management Committee, P.O. Box 32, Union Bay, British Columbia, Canada, V0R 3B0.

What does an ocean side community do when:

- residents cannot safely harvest shellfish from its beaches for over 7 years?
- a quiet, community walk lets you know who is washing clothes, who is having a shower, who has flushed the toilet?
- its ditches are unsafe for child's play
- its ditches are overgrown with water cress costing $1000's of dollars to government to clean out?
- kids swimming on local beaches can be a health issue?
- over 60% of septic fields are failing?

Well, one community said "Enough is Enough!" While its neighbour were saying NO to a 1997 valley wide referendum on a solution to liquid waste problems, Union Bay said "Yes".

Union Bay has worked hard to involve, inform, educate and enlist residents, local credit union, local businesses, politicians and government agencies from all levels to develop a solution.

Working with major funding from Georgia Basin Ecosystem Initiative, Environment Canada and provincial grants, Union Bay has developed a liquid waste treatment solution which will ultimately turn waste to wealth, using liquid waste, including a campus for post-secondary institutions to support their environmental program, enhance salmonid habitat, provide an interpretive centre.

Community process has been the key to significant funding for this project and it has created a climate of acceptance and support for rural grassroots, community-based planning. This process has been accepted by the Regional District of Comox-Strathcona and adopted in at least three other rural communities in the Comox Valley.

ACOUSTIC SEABED CLASSIFICATION FOR SHELLFISH HABITAT MAPPING.

William T. Collins, Quester Tangent Corporation, Sidney, BC V8L 5Y8, Canada.

The amplitude and shape of an acoustic signal reflected from the sea floor is determined mainly by the sea bottom roughness, the density difference between water and the sea floor, and reverberation within the substrate. Remote classification of the sea bottom requires an acoustic data acquisition system and a set of algorithms that analyze the data, determine the seabed type and relate the results of the acoustic classification to the physical properties of the marine sediments. Quester Tangent Corporation has successfully combined high-speed digital signal processing technology with multivariate statistical analysis to create the QTC VIEW seabed classification engine. The QTC VIEW captures and digitizes the seabed echo from a conventional echo sounder, processes, analyses, displays and records acoustic waveform data characterizing the sea floor. The output is a set of point data representing sea floor acoustic diversity. The georeferenced classifications can then be objectively correlated with other data such as sediment properties or directly to fish census.

The technology has been applied world wide to map marine sediments for a variety of applications. It has been used for mapping substrate in support of benthic habitat characterization. The technology can also be configured for use in water depths less than 5 m. Examples of oyster mapping projects in West Galveston Bay, Texas and Chesapeake Bay, Maryland are highlighted. Strategies for the integration of acoustic and nonacoustic data are included.

OYSTER POPULATION RESTORATION IN CARAQUET, N.B.; PHASE II, OPTIMIZING PRODUCTIVITY.

Paul Cormier, T. Landry, and **J. F. Mallet.** Department of Fisheries an Oceans, GFC, P.O. Box 5030, Moncton N.B., E1C 9B6, and Department of Agriculture, Fisheries and Aquaculture, 22 Boul. Saint-Pierre, Caraquet, N.B. E1W 1B6, Canada.

A decrease in the productivity of oysters in Caraquet Bay, N.B. is generating some interest in restoration projects. This bay represents the most northern location with a sustainable oyster (*Crassostrea virginica*) population. The first phase of this initiative provided invaluable information on the distribution, abundance and population structure of oyster beds. Over 60% of the oysters found in this bay are pre-recruits to the fishery (35–75mm). These oysters are mainly found in the northern portion of the main bed, which has a relatively low abundance of commercial size oysters (>75mm) and. is locally renown for its "stunted growth oysters". Samples of oysters from this location where transferred at four stations in the bay and monitored for growth and conditioning. Results are suggesting that the growth limitation of these oysters is associated with the geographical location and even more to the bottom conditions. Management strategies will be developed to optimize the productivity of oyster from this highly successful recruitment location, which offers limited possibility for commercial production.

ABSTRACT THEME AREA: A. Craig, and **C. Downs,** EnVirtue Biotechnologies, Inc. 2255 Ygnacio Valley Rd., Suite H-1, Walnut Creek, CA 94598, USA.

Using the tools of proteomics and molecular diagnostics, one of our primary goals is to determine if environmental factors are affecting shellfish susceptibility to infections. This strategy of research can also aid in answering other important issues to shellfish husbandry such as why some shellfish cultivars or strains are more susceptible to infection than others and the cellular mechanisms responsible for disease resistance? Proteomics and functional genomics can be used to discover novel and appropriate molecular biomarkers that can aid in diagnosing the health status of a crop, develop powerful biomarkers to aid in predicting crop yield, and aid in developing genetic markers for advantageous cultivar traits. Finally, understanding the cellular and biochemical mechanisms of shellfish disease may allow for the development of practical measures or treatments to limit disease.

SIDE SCAN SONAR AS A MANAGEMENT TOOL IN MISSISSIPPI. Dale Diaz, K. Cuevas and **W. S. Perret,** Office of Marine Fisheries, Mississippi Department of Marine Resources, 1141 Bayview Avenue, Suite 101, Biloxi, MS 39530, USA.

Oyster harvest from Mississippi reefs provide jobs for numerous fishermen and contribute substantially to the economy. Proper management of these reefs is vital for continued harvest. Enhanced management techniques (i.e. cultch planting) should help to ensure even greater future production. Cultch planting is a key component of management measures conducted by the Mississippi Department of Marine Resources (MDMR). The use of sounding poles, tongs, dredges or scuba equipment gauged the effectiveness of different cultch planting methods. These methods are not efficient techniques when surveying large areas for coverage rates or distribution of materials.

Using side scan sonar to monitor cultch plants has a number of advantages over these previously used methods. Side scan sonar can cover large areas in less time, provide accurate measurements of coverage, and simultaneously provide differential GPS coordinates. The information acquired from side scan sonar provides a long-term record, which can be used to detect changes due to environmental catastrophes, vessel groundings and harvest pressure. A side scan sonar survey was performed on two cultch plant sites located in the western MS Sound, St. Joe Cultch Plant and Pass Christian Cultch Plant. The St. Joe Cultch Plant site was surveyed before and after cultch planting. On the Pass Christian Cultch Plant only a post side scan sonar survey was conducted. The data was processed and input in a mosaic software program for further analysis. This study will demonstrate the abilities of side scan sonar as a management tool for oyster reef management.

CELLULAR-PHYSIOLOGICAL ASSESSMENT OF BIVALVES AFTER TEN YEARS OF CHRONIC EXPOSURE TO SPILLED EXXON VALDEZ CRUDE OIL USING A NOVAL MOLECULAR DIAGNOSTIC BIOTECHNOLOGY. Craig A. Downes,[1] Charles E. Robinson,[1] Arnold Huang,[1] Gary Shigenaka,[2] and **John E. Fauth,[3]** Envirtue Biotechnologies, Inc., 2255 Ygancio Valley Rd., Suite H-1, Walnut Creek, CA 94598, USA; [2]Hazardous Materials Response Division, US National Oceanic and Atmospheric Administration, 7600 Sand Point Way NE, Seattle, WA 98115, USA; [3]Department of Biology, University of Charleston, 66 George Street, Charleston, SC 29422, USA.

The objective of this study was to determine the cellular physiological status of the bivalves *Mya arenaria* and *Mytilus trossulus* in an area impacted by a ten-year chronic exposure of spilled Exxon Valdez crude oil in Prince William Sound.

Bivalves were collected from a well characterized impacted site on Knight Island and from a nonimpacted site north of Bainbridge Island. We used a novel biotechnology known as the Envirtue Molecular Diagnostic System™ (EMDS) to determine if bivalves were (1) physiologically stressed, (2) the nature of the altered physiological state, and (3) whether the organisms were responding specifically to an exposure to polyaromatic hydrocarbons (PAH). Molecular diagnostic analysis indicated that bivalves at the impacted site were stressed, experiencing both an oxidative and xenobiotic stress, resulting in increased protein turnover and chaperone activity. Further, bivalves from the impacted area were responding specifically to a PAH xenobiotic exposure and accumulating DNA-PAH adducts. Finally, species-specific responses were observed that were related to the spatial-habitation characteristics of each species.

We conclude that bivalves inhabiting an area impacted by crude oil from the Exxon Valdez spill of 1989 are still adversely affected by the spill's remnants.

OYSTER AQUACULTURE AS FISH HABITAT IN PACIFIC NORTHWEST COASTAL ESTUARIES. Brett Dumbault,[1] D. Armstrong,[2] G. Hosack,[2] and B. Semens,[2] [1]Washington State Department of Fish and Wildlife, Willapa Bay Field Station, P.O. Box 190, Ocean Park, WA 98640, USA; [2]School of Aquatic and Fishery Sciences, Box 355020, University of Washington, Seattle, WA 98195, USA.

Increased pressure on traditionally managed stocks of marine and anadromous fish, calls for protection of essential fish habitat under the *Magnuson-Stevens Act,* and recent listings of several salmonid stocks under ESA have brought aquaculture activities that take place in coastal estuaries under increased public scrutiny.

We initiated a study designed to examine the ecological role that oyster aquaculture plays as habitat in coastal estuaries of the Pacific Northwest. The goal of the project is to identify and quantify beneficial and adverse impacts of shellfish farming on eelgrass, juvenile salmonids, and other selected estuarine fauna and flora and to develop farming practices and recommend management protocols that protect or enhance those resources. We present results of initial fish and invertebrate sampling in selected habitats from Willapa Bay during Spring and Summer 2001 and an experiment designed to examine the effects of oyster harvesting on eelgrass habitat. We make a plea to managers to consider oyster aquaculture areas as fish habitat on a broader estuarine scale.

DEMONSTRATION AND EVALUATION OF COMMERCIALLY IMPORTANT BIVALVE CULTURE AND STOCK ENHANCEMENT METHODS IN REHOBOTH AND INDIAN RIVER BAY, DELAWARE (1998–2001). John William Ewart,[1] J. Alderman[2], and K. Maull,[2] [1]Delaware Sea Grant Marine Advisory Service, Graduate College of Marine Studies, University of Delaware, 700 Pilottown Road, Lewes, DE 19958, USA; [2]Delaware Center for the Inland Bays, 467 Highway One, Lewes, DE 19958, USA.

Delaware's coastal lagoons, known locally as "inland" bays, have been experiencing the impacts of chronic eutrophication and sediment erosion resultant from several decades of sustained nutrient input and development from within the surrounding watershed. The Delaware Center for the Inland Bays (CIB) was established as a nonprofit organization in 1994 to oversee the implementation of the Inland Bays Comprehensive Conservation and Management Plan and to facilitate a long-term approach for the wise use and enhancement of the watershed. The James Farm Ecological Preserve, a 150 acre property with frontage on Indian River Bay, was established in 1998 to serve in part as a demonstration site for beneficial land use practices and similar watershed based activities such as shoreline stabilization, habitat creation/protection and shellfish stock enhancement to improve water quality. In 1998, the CIB initiated an ongoing program to evaluate and demonstrate the technical feasibility of using aquaculture methods to maintain or improve populations of commercially viable bivalves and to create additional habitat for shellfish and other species. Current field demonstration activities include low density plantings (1–2/square foot) of hard clams (*Mercenaria mercenaria*), for stock enhancement and recreational fishery improvement; monitoring oyster growth, survival and prevalence of MSX and Dermo disease in eastern oysters (*Crassostrea virginica*) held in off-bottom transient gear, submerged trays and Taylor floats; construction and deployment of a Floating Upweller System (FLUPSY) for nursery culture of bivalve seed; and establishment of a 1/4 acre oyster reef to monitor growth, survival, disease prevalence and habitat development.

MOLECULAR DETECTION OF FECAL *BACTEROIDES* AS SOURCE INDICATORS FOR FECAL POLLUTION IN WATER. K. G. Field, Oregon State University, Department of Microbiology, Corvallis, OR 97331, USA.

Fecal contamination of shellfish environments afflicts many regions worldwide, and carries numerous risks to human health. Fecal bacteria, pathogenic protista and viruses may be highly concentrated in shellfish. Often the problem can't be corrected, because standard methods of measuring fecal pollution in water do not distinguish its source. We have developed a PCR-based alternative method of fecal source discrimination. The method consists of amplifying 16S rRNA gene fragments of the fecal anaerobic *Bacteroides-Prevotella* group with specific primers. Because *Bacteroides* is restricted to gut habitats, its presence in water indicates fecal pollution. Molecular detection circumvents the complexities of growing anaerobic bacteria. We identified *Bacteroides* length-heterogeneity PCR (LH-PCR) and terminal restriction fragment length polymorphism (T-RFLP) ribosomal DNA markers unique to either cow or human feces, and recovered the same unique fecal markers out of polluted natural waters. We cloned and sequenced the markers and used the sequences to design PCR primers that reliably discriminate human and ruminant sources of fecal contamination. New primers under development will distinguish elk/deer, horse, pig, chicken, duck/goose, beaver, and harbor seal fecal pollution. With this approach, sensitivity is greater than fecal coliform assays. The method does not require culturing bacteria, allows for small sample size and easy sample handling, is comparable in complexity to standard tests carried out in food safety and public health diagnostic labs, and lends itself to automation and high-throughput.

HABITAT RESTORATION AND SHELLFISH STOCK ENHANCEMENT INITIATIVES IN NEW JERSEY. Gef Flimlin,[1] and Michael P. Stringer,[2] Rutgers Cooperative Extension, 1623 Whitesville Rd., Toms River, NJ 08755, USA; [2]NY/NJ Baykeeper, Bldg. 18, Sandy Hook, Highlands, NJ 07732, USA.

New Jersey has been a major shellfish production state since colonial times. The Raritan Bay area once boasted a 400-boat oyster fleet from the town of Keyport alone. However, industrial pollution, water quality degradation, and the onset of MSX and Dermo have practically eliminated natural oyster stocks in most areas.

Efforts over the past three years have lead to the establishment of two reefs, one on the Liberty Flats near the Statue of Liberty and one off the shore of Keyport. These shellstocked reefs have had cultured oyster seed placed on them and a monitoring program has begun. Another effort is underway in the Mullica River, the last area on the state's Atlantic Coast side to produce oysters, to restock the public beds with natural oysters from the seedbeds upriver. This area will be proposed for a larger scale project for a Community Based Restoration Program in the year to come.

The Baykeeper and Rutgers Cooperative Extension have been working with the Baymen's Protective Association and the New Jersey Shellfisheries Association, two shellfish industry groups, to propel these initiatives. Primary and secondary school education projects explaining the benefit of oyster restoration and aquaculture are being done to garner more support for the projects. It is envisioned that eventually the industry will reap the benefit of these projects when the reefs may be harvested in the future.

NEW DIRECTIONS FOR SHELLFISH PROTECTION IN PUGET SOUND. Stuart D. Glasoe, Office of the Governor, Puget Sound Water Quality Action Team, PO Box 40900, Olympia, WA 98504, USA.

The Puget Sound Water Quality Management Plan serves as a cornerstone for shellfish protection in Puget Sound. First adopted in 1987, the plan employs a suite of strategies to raise awareness, change behaviors and build and strengthen systems to protect the health of Puget Sound.

Although the plan was designed with the dual goal of protecting and reopening shellfish beds, early trends were daunting. Between 1987 and 1989 alone, nearly 33,000 acres of commercial beds were downgraded as a result of declining water quality and more intensive monitoring. Trends shifted dramatically in the 1990s as restoration efforts successfully upgraded over 13,000 acres, offsetting nearly identical acreages downgraded during the period. These results show that the strategies are paying off even in the face of rapid population growth, but they also reveal an unsustainable emphasis on reactive, restoration techniques.

The region must now shift gears and make better use of proven approaches to more effectively and permanently prevent contamination of shellfish growing areas. These include better land use planning under the Shoreline Management Act and Growth Management Act to preserve shellfish areas as critical areas and natural resource lands; greater use of pollution prevention measures such as low impact development practices and on-site sewage maintenance programs; widespread creation of surface water utilities to fund local services and projects; early detection and rapid response to emerging water quality problems; and better communication with all audiences to raise awareness on the impacts and tradeoffs associated with pollution and urbanization in shellfish watersheds.

SEMIAHMOO BAY WATER QUALITY PROJECT: PHASE 1 FINDINGS. Heather Goble, Shellfish Project Coordinator, Georgia Basin Ecosystem Initiative, Clean Water Action Plan, 224 West Esplanade, North Vancouver, BC, V7M 3H7, Canada.

We have now completed Phase 1 of a three-year action plan to identify the major sources of contamination to Boundary Bay and propose subsequent actions required to mitigate and remediate the prohibited status of the shellfish growing waters in this area. The objective of Phase 1 of the Semiahmoo Bay Water Quality Project was to characterize non-point source contamination patterns within Semiahmoo Bay. We sampled 19 beach locations along the shoreline as well as 32 natural and manmade storm water drainages into Semiahmoo Bay.

Precipitation levels had a positive correlation with bacteriological counts for both outfall and ocean sampling sites. This indicates contamination in storm water outfalls had a direct impact on water quality along the shoreline of Semiahmoo Bay. Ocean sites demonstrated fecal coliform counts that consistently exceeded acceptable standards for shellfish growing waters and occasionally exceeded accepted standards for recreational water quality. The majority of outfalls had fecal coliform counts that occasionally reached values associated with sewage-impacted waters.

Boundary Bay sediments and shellfish were tested for common metals and organics that may adversely affect growing areas. The levels of heavy metal residues and organochlorines in shellfish were found to be within acceptable limits. However the tests for lead and arsenic levels were inconclusive and the shellfish will be retested using different parameters.

Phase 2 of the Semiahmoo Bay Water Quality Project will conduct contaminant investigations to reduce the impact of contaminated drainage systems on the shellfish growing waters of Semiahmoo Bay.

REMOTE-SET ALTERNATIVE SUBSTRATE ON LEASED GROUND: AN INNOVATIVE APPROACH TO REEF RESTORATION. William Goldsborough,[1] Stew Harris,[1] D. Jackson,[1] D. W. Meritt,[2] and S. Tobash,[2] [1]Chesapeake Bay Foundation, 6 Herndon Avenue, Annapolis, MD 21403, USA; University of Maryland, Center for Environmental Science, Box 775, Cambridge, MD 21613, USA.

Oyster reef restoration in Chesapeake Bay faces a variety of challenges that will require new and innovative approaches. Among the challenges are: identifying sanctuary locations, obtaining suitable substrate, establishing oysters on the substrate, and protecting the site from poaching.

Thousands of acres of Bay bottom are currently under lease from the states of Maryland and Virginia. Much of this ground is not being actively farmed and may be available for establishing reef sanctuaries under agreement with leaseholders.

Oyster shell is considered the best reef material, but supplies of shell are dwindling. The scale of reef restoration now anticipated will require development of alternative materials. Marine limestone rock (marl) has been shown to be a good setting substrate and may prove to be a valuable substitute for shell in reef construction. A second valuable function that marl may provide is that of a physical obstruction to poaching with traditional harvest gear.

In a pilot project undertaken in the Nanticoke River, a tributary of Chesapeake Bay in Maryland, marl rocks were set remotely with hatchery-produced larvae and distributed on a one-acre area of leased ground to create a field of mini-reefs. In the process a new and promising approach to reef sanctuary creation was developed.

RESTORATION OF THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA*) THROUGH A VOLUNTEER PROGRAM IN MOBILE BAY, ALABAMA.

Kimberly A. Hamilton, D. LaDon Swann, Richard K. Wallace, Yolanda J. Brady, David B. Rouse, Scott Rikard, and **Holly Hall,** Department of Fisheries and Allied Aquacultures, Auburn University, Auburn, AL 36849, USA. E-mail: hamilka@acesag.auburn.edu

Restoration programs for the eastern oyster, *Crassostrea virginica*, in Mobile Bay, Alabama are used to increase the number of oysters on remaining beds and to renew ecological functions such as providing habitat and water filtration. To educate the general public of the ecological importance of oysters and oyster restoration efforts, an oyster gardening program was created for restoration of natural and constructed reefs. The volunteer program was implemented in Mobile and Baldwin counties along Mobile Bay and monitored for 7 months beginning in May 2001.

A total of 30 volunteers representing sites located in unrestricted oyster harvesting waters were provided a Taylor float and 1,000 oyster spat per volunteer. The 36.2 mm spat were provided to the first 15 volunteers and 12.5 mm spat were provided to a second group of 13 volunteers. Spat were stocked into the Taylor float (surface area of 0.74 m^2) and tied to a pier, piling, or weight. Growth and condition of oysters in Taylor floats were compared and correlated with water quality parameters (temperature, dissolved oxygen, salinity, and water clarity) between each site.

REPRODUCTIVE SANCTUARY FOR THE NORTHERN QUAHAUG, *MERCENARIA MERCENARIA*, IN PRINCE EDWARD ISLAND.

Matthew Hardy,[1] **T. Landry,**[2] and **A. Boghen,**[1] Université de Moncton, Moncton, N.-B., E1A 3E9; [2]Department of Fisheries and Oceans Canada, Science Branch, Maritime Region, Moncton, N.-B., E1C 9B6, Canada.

West River was historically one of the most productive estuaries for quahaugs in PEI. However, due to the construction and subsequent removal of a causeway, in addition to extensive fishing, stocks are now considered to be too low to sustain the present level of commercial harvesting. Density estimates in West River ranged from 1.37 to 2.52 quahaugs · m^{-1}, which are low in relation to other quahaug producing areas.

Several years of research lead to the establishment of a reproductive sanctuary for large quahaug in the subtidal zone of West River. This was based on results showing that reproductive success could be optimized through low-level and inexpensive interventions. Large quahaugs are advantageous as broodstock because they have high fecundities and they are not significantly affected by high stocking densities. *In vitro* fertilization experiments showed that reproductive success increased significantly with higher gamete concentration and lower gamete ages. These related directly to the distance between a spawning pair of adults. The subtidal zone also provides ecological and socio-economic benefits.

This type of enhancement offers certain advantages over hatchery produced seeding programs. Preliminary work tends to indicate that the sanctuary concept could be an effective restoration or enhancement technique for the quahaug. Plankton tows showed a greater presence of quahaug larvae in West River, following the establishment of the sanctuary, compared to previous years and other estuaries. Ultimately, it might be possible to enhance overall productivity to sustainable levels through properly managed broodstock areas.

STATUS OF SHELLFISH ENHANCEMENT IN ALASKA.

J. Hetrick, Chugach Regional Resource Commission, 4201 Tudor Center Drive, Anchorage, AK 99508, USA.

The Alaskan shellfish aquatic farm industry has been growing steadily with an increase in the number of farms and an instate shellfish hatchery for production of indigenous species. Recent attempts by native villages and local communities to enhance beaches for subsistence and recreational groups have been mired in bureaucratic gridlock. At issue is a directed use of a public resource, management of enhanced stocks and their interaction with standing stocks and the lack of enabling legislation for shellfish enhancement. An outline and review of projects completed and underway will be presented.

INNOVATIVE COMMUNITY PROCESSES PRODUCE INTEGRATIVE MANAGEMENT TOOLS.

Barbara Joughin[1] and **William Heath,**[2] [1]Comox Valley Project Watershed Society, Box 3007, Courtenay, BC, V9N 5N3, Canada, [2]BC Ministry of Agriculture, Food and Fisheries, 2500 Cliffe Avenue, Courtenay, BC, V9N 5M6, Canada.

Baynes Sound, located in western Canada on the east coast of Vancouver Island, is a highly productive area for shellfish culture, salmon, herring and waterbirds. Over the past decade, Baynes Sound has experienced increasingly degraded water quality from non-point source pollution, as well as loss and degradation of sensitive wild habitat. The Baynes Sound Round Table was formed in 1994 to improve water quality in Baynes Sound, and has guided a series of collaborative community stewardship projects that address threats to environmental and economic health in Baynes Sound. These projects create opportunities for citizens, governments and shellfish growers to work together to identify and remediate non-point source pollution impacts in Baynes Sound. Hundreds of citizen volunteers have participated in recent stewardship programs. Community involvement and stakeholder collaboration have established a strong foundation for proactive and integrated remedial planning and programming. An important tool has evolved from the Baynes Sound process - the development of the 'State of the Sound' Program. The State of the Sound Program is a long term monitoring, reporting and planning process that measures and reports the health of Baynes Sound. The program uses a geographic information system (GIS) to gather and analyse data for water quality and other indicators. Results are used to plan actions, and are communicated to the community to help increase public awareness and involvement. Information becomes accessible, 'crisis control' is replaced with comprehensive management, and an effective tool is available to assist with planning processes such as local liquid waste management programs.

ADVANCES IN SHELLFISH SAFETY ASSURANCE AND PARTICIPATION IN SANITARY GROWING WATER MONITORING PROGRAMS BY THE BC SHELLFISH AQUACULTURE INDUSTRY.

Brian Kingzett, Kingzett Professional Services Ltd, 321 St. Julian, St. Duncan B.C. V9L 3S5, Canada.

The BC Shellfish Growers Association (BCSGA) represents the majority of shellfish production in British Columbia. Promoting shellfish safety and involvement in the growing water management have become significant aspects of the work of the association and its members. Decreases in regulatory monitoring budgets and increased demands for service by shellfish aquaculturists have led to proactive industry partnerships and programs. These involve industry participation in monitoring for *Vibrio parahaemolyticus*, an industry driven farm based *Vp* control program, involvement in sanitary growing water monitoring and remediation, and maintenance of marine biotoxin sentinel sites. Currently the BCSGA is participating in a national program developing standard methodologies and curriculum for industry growing water sampling and farm based HACCP for shellfish culturists.

DEVELOPMENT OF INTENSIVE DEEPWATER OYSTER CULTURE SYSTEMS IN BRITISH COLUMBIA.

Brian Kingzett, Kingzett Professional Services Ltd, 321 St. Julian, St. Duncan B.C. V9L 3S5, Canada.

Socio-political reasons have restricted the growth of the shellfish culture industry in British Columbia during the last decade. The industry is relatively small and recent growth has primarily come about on small deep-water sites. Shellfish growers in British Columbia have developed a series of approaches to developing intensive oyster production in deep-water (off bottom) culture systems. This has involved adapting international techniques and developing unique technologies, which allow significant production from small areas.

USING INNOVATIVE STORMWATER CONTROLS FOR WATER QUALITY IMPROVEMENTS AND OYSTER HABITAT RESTORATION IN THE BARATARIA-TERREBONNE NATIONAL ESTUARY.

K. E. Landrum,[1] **K. M. St. Pe,**[1] **B. Ache,**[2] and **F. Kopfler,**[3] [1]Barataria-Terrebonne National Estuary Program, P.O. Box 2663, Nicholls State University, Thibodaux, LA 70310, USA; [2]Battelle, 191 East Broad Street, Suite 315, Athens, GA 30601, USA; [3]EPA/Gulf of Mexico Program, Stennis Space Center, Building 1103, Room 202, MS 39529, USA.

The loss of nearly 22 square miles of emergent wetlands per year in the Barataria-Terrebonne National Estuary represents the imminent loss of a nationally significant wetland resource and threatens the area's unique culture and local infrastructure. Opportunities exist for rerouting some of the estuary's 260 stormwater pump station outfalls within the estuary to improve the water quality associated with these discharges prior to entering historically productive oyster grounds. Runoff from rural and agricultural areas are collected in borrow canals within the existing levee systems and are generally pumped into large man-made canals to ensure rapid evacuation of stormwater.

The Barataria-Terrebonne National Estuary Program and EPA's Gulf of Mexico Program are spearheading efforts to monitor and assess changes in estuarine vitality near rerouted pump station outfalls to demonstrate the benefits of this unique process. Qualitative evidence of the positive effects of the redistribution of stormwater into adjacent wetland areas is visually evident throughout both basins, although only limited quantitative assessment has occurred. Redirecting discharges so that freshwater is retained in adjacent wetlands rather than moved through them has been demonstrated to maintain lower salinities, promote vigorous plant growth through nutrient uptake, and lead to pathogen degradation. Numerous studies provide evidence of wetland uptake of pollutants and nutrients in constructed wetlands and riparian fringes, and the enhancement of marshes adjacent to hurricane protection levees would provide additional storm surge protection for properties and local infrastructure.

WATER QUALITY IMPROVEMENT: A FOCUS ON NEW TECHNOLOGIES. **Kevin L. LeBlanc,** Fisheries and Oceans Canada, Gulf Fisheries Centre, 343 University Street, Moncton, New Brunswick, E1C 9B6, Canada.

Water quality improvement requires effective monitoring, financial support, partnerships, remediation and bio/socio-economic planning. However, tools that clearly define sources of contamination remain the backbone for effective water quality improvement. Sewage is typically measured through the use of an indicator species such as faecal coliform bacteria, but effective remediation requires a clear link to the source of pollution. The South-western New Brunswick Clam Resource Committee (CRC), New Brunswick, Canada, has improved water quality and monitoring for the reclassification of shellfish growing areas since 1995 using the above mentioned strategies. By 2001, the CRC has increased the overall shellfish growing area by 27%. However, an additional 38% of shellfish growing areas, equivalent to 434 hectares (1,074 acres), could be available for harvest if the identification of the actual source of fecal coliform was possible. Tools such as genetic markers and gene sequencing of bacteria are examples of new approaches in differentiating between different sources of fecal coliform. These innovations will be critical in establishing feasible and effective courses of remediation in shellfish growing areas. Furthermore, such advances could lead to the development of molecular-based kits for monitoring activities, similar to those used for biotoxin monitoring. The continued development of science in these fields is necessary for the continued success of water quality improvement initiatives.

COMMERCIAL-SCALE OYSTER PRODUCTION FOR REEF RESTORATION AND STOCK ENHANCEMENT. **A. T. Leggett, A. Blow, W. Goldsborough, R. D. Brumbaugh,** Chesapeake Bay Foundation, 142 W. York Street, Suite 318, Norfolk, VA 23510, USA.

Oyster restoration in Virginia has focused on the construction of three-dimensional reefs made from oyster shells since the early 1990s. Since 1997, the Chesapeake Bay Foundation (CBF) has assisted with his effort by organizing and training citizens and students to grow oysters (*Crassostrea virginica*) using small-scale aquaculture techniques. To date, approximately 1.1 million oysters have been grown using these small-scale techniques, and stocked on Virginia Sanctuary reefs.

In 2000, CBF initiated the Virginia Oyster Aquaculture Program to complement these volunteer-based efforts by producing an additional one million oysters per year for Virginia reefs. A commercial-scale oyster farm was designed and put into operation growing oysters in ADPI mesh bags contained in commercial oyster trays stacked on PCV racks. The oysters were placed directly in the trays when they reached an appropriate size (>25 mm) with approximately 1,500 oysters per tray. After eleven months, over 930,000 oysters (mean size = 52 mm) were harvested using volunteer labor and transplanted onto eight sanctuary reefs. Survival to transplanting for the three stocks used in the program was approximately 85%, and first year capital expenses were approximately $62,400. The oysters produced through this program were used as in-kind match for newly appropriated federal funds dedicated to Virginia oyster restoration. Future considerations of the program include genetic aspects of the oyster stocks used and the application of new techniques including the use of a floating upweller (FLUPSY) for the nursery phase of the grow-out.

PROTECTION AND RESTORATION: WASHINGTON STATE SHELLFISH PROGRAM. **Donald Lennartson,** Office of Food Safety and Shellfish Programs, Washington State Department of Health, 7171 Cleanwater Lane, Building 4, Olympia, WA 98504, USA.

The Washington State Department of Health oversees 126 shellfish growing areas with over 1,400 marine water sampling stations. The state shellfish industry produces over 80% of the shellfish harvested on the west coast, not including geoducks. This rich shellfish resource faces a range of threats, from rural land use activities to rapid urban growth. Prevention of classification downgrades and the restoration of water quality require careful planning, strong technical skills, tough regulatory tools, and creative partnerships among local, tribal, state, and federal agencies.

The stimulus for shellfish restoration activities was the innovative Puget Sound Water Quality Management Plan, whose purpose is "to restore and protect the biological health and diversity of Puget Sound". A major component of this ongoing Plan is the Shellfish Protection section, which outlines seven action elements, the first two of which address shellfish protection policy and the restoration of commercial shellfish beds.

In keeping with the spirit of the Plan, the Department of Health initiated an Early Warning System, a proactive measure which alerts county governments to the threat of classification downgrades. If preventative measures fail and a downgrade does occur, state law requires the county to establish a Shellfish Protection District, and a Closure Response group is convened to formulate actions in the watershed to identify and correct the pollution sources.

ABALONE RESTORATION THROUGH COLLABORATIVE PARTNERSHIPS IN BRITISH COLUMBIA. **B. G. Lucas,** and **A. Campbell,** Stock Assessment Division, Science Branch, Fisheries and Oceans Canada, Pacific Biological Statio, Nanaimo, BC V9R 5K6, Canada.

Diverse stakeholder groups are collaborating to test potential methods to restore threatened abalone populations in British Columbia. Fisheries and Oceans Canada is working with six groups throughout coastal BC in an attempt to halt further decline of abalone stocks and restore populations to self-sustaining levels.

Five aquaculture projects are underway to develop the culture technology required to provide northern abalone seed for pilot restocking experiments. In addition, four projects are currently promoting local community stewardship of abalone resources through public education, increased awareness and, in some cases, experimental manipulations of wild abalone populations. These projects are providing training and employment in local communities which have been impacted by declining opportunities in the fishing industry.

SITE ASSESSMENT, SELECTION AND MONITORING METHODS FOR ABALONE RESTORATION NEAR KITKATLA, BRITISH COLUMBIA. **B. G. Lucas, A. Campbell,** and **D. Brouwer**, Stock Assessment Division, Science Branch, Fisheries & Oceans Canada, Pacific Biological Station, Nanaimo, BC V9R 5K6, Canada.

Several pilot projects are currently underway to attempt to restore abalone populations in British Columbia (BC). Near Kitkatla, on BC's north coast, an extensive process of assessing, selecting and surveying sites for pilot abalone rebuilding experiments was recently completed. General areas for potential experiments were selected in conjunction with local First Nation advisors and Fisheries & Oceans Canada staff.

In September 2000, five divers spent 7 days conducting preliminary surveys to locate specific areas of suitable habitat that met predetermined site selection criteria. After analysis of the survey results, 16 potential sites with similar characteristics were chosen. In April 2001, three dive teams spent 6 days permanently marking 15 sites and collecting detailed baseline information at those sites.

The proposed experiments will test the survival and recapture rates of seeded juvenile abalone while examining the effects of sea urchin sizes and densities in the experimental plots. Long term monitoring of the sites is expected to continue for at least five to ten years after the experiments begin.

EFFECTS OF REEF ARCHITECTURE AND SCALE ON FISH UTILIZATION OF OYSTER REEFS IN VIRGINIA. **Mark W. Luckenbach, J. Nestlerode, P. G. Ross** and **A. J. Birch**, College of William and Mary, Virginia Institute of Marine Science, Eastern Shore Laboratory, Wachapreague, VA 23480, USA.

Current efforts to restore oyster reefs in the Chesapeake Bay are directed toward establishing self-sustaining reef sanctuaries that provide valuable ecological functions, such as benthic-pelagic coupling and support of increased diversity and production of macrobenthos and finfish. Recent evidence has revealed the importance of two components of reef architecture—vertical relief and interstitial space—on the development of oyster populations on restored reefs. We will present data which show that finfish utilization varies between "reefs" with and without viable oyster populations. A third component of reef architecture—aerial extent or scale—is expected to affect both reef development and utilization by fish. In conservation biology this topic has often been characterized as the SLOSS (Single Large or Several Small) debate, but is more generally about optimizing the scale of a bio-reserve or sanctuary to support the desired species. To investigate this issue for oyster reefs we have initiated a large-scale restoration experiment in the Chesapeake Bay. In a replicated block design, we have constructed high relief reef bases ranging in size from 400 sq m to 8000 sq m and are characterizing the development of resident and transient assemblages of organisms on the reefs. We will present data from the first year of the study on finfish utilization of these reefs.

THE ROLE OF AQUACULTURE IN THE RESTORATION EFFORT TO SAVE WHITE ABALONE (*HALIOTIS SORENSENI*) IN CALIFORNIA. **Thomas B. McCormick**, Channel Islands Marine Resource Institute, 323 E. Matilija Street, Ojai, CA 93023, USA.

Stocks of white abalone (*Haliotis sorenseni*) in southern California declined precipitously from an average of 2,000 to 10,000 abalone per hectare in the to 1.6 per hectare in the 1990s. A short-lived fishery in the 1970s landed 270 metric 1970s tons from depths of 20 to 50 m. The fishery was closed in 1997 and in 2001 the white abalone was listed as an endangered species, the first marine invertebrate to be so classified in the USA.

The White Abalone Working Group was formed by federal and state agencies, scientists, universities, non-profit organizations, and mariculturists as a proactive step towards preventing the extinction of white abalone. The group developed the following four-step plan for recovery of the species: (1) survey historic fishing grounds to locate survivors; (2) collect and hold adults as breeding stock; (3) produce a new generation of young adult abalone in the hatchery; and (4) introduce hatchery grown adult animals into refugia to reestablish self-sustaining wild populations.

Success has been achieved in maintaining and spawning white abalone in captivity. Abalone cultivation systems incorporate the use of the red macrophyte, Pacific dulse (*Palmaria mollis*) as both a nutritious feed and biofilter. Large numbers of juveniles are being raised using commercial techniques. This program differs from other enhancement efforts in that the abalone will be raised to adult size (10 cm shell length) prior to release. Larger animals such as this should be better able to resist predation and are capable of spawning immediately.

BOAT WASTE AND SHELLFISH CLOSURES: A COMPARISON OF CANADIAN AND UNITED STATES POLICIES.

Jim Mclsaac, Coastal Enterprise and Resource Cooperative Association, 202–1931 Mount Newton X Rd., Sidney, BC V8M 29A, Canada.

Diseases such as hepatitis, typhoid and cholera have been transmitted by untreated boat sewage. Popular beaches and shellfish areas attract boaters; the resulting contamination from boat sewage creates health concerns for millions of shellfish lovers. Swimmers that frequent contaminated waters have been known to develop skin rashes, amoeba dysentery, and parastic worm diseases. Boat sewage has closed beaches and shellfish harvesting areas around the world.

In 1991, the Canadian government passed the Pleasure Craft Sewage Prevention Regulations intending to protect the marine environment from the negative impacts of sewage disposal. Since passing the Regulations, nine west coast marine waterbodies have been designated no-discharge zones (NDZ). A further 54 marine sites have been recommended for NDZ and are under review. However, no reduction in breach or shellfish closures has been noted.

In contrast, the United States Congress passed the *Clean Vessel Act* in 1992. Today, all vessels inside US waters are required to have a marine sanitation device. Seven states have all their surface waters designated as NDZ. An additional eleven other states have segments of their waterbodies designated as NDZ. Washington and Massachusetts have already identified a reduction in beach and shellfish closures.

With intentions from both federal governments so evident, why are the results so different? In the United States, the *Clean Water Act* and the *Clean Vessel Act* clearly lay out areas of jurisdictional responsibility and financing arrangements. Implementation plans are in State control where boat waste disposal plans were developed. In Canada, boat waste policies are caught in multi jurisdictional bureaucracies with overlapping acts and conflicting regulations, resulting in no boat waste disposal being developed.

SUCCESSION IN MUSSEL COMMUNITIES: THE IMPORTANCE OF WHAT IS MEASURED.

C. W. McKindsey, Environmental Sciences Division, Department of Fisheries and Oceans, Maurice Lamontagne Institute, 850 Route de la Mer, PO Box 1000; Mont-Joli, QCG5H 3Z4, Canada.

This study examines the community of organisms in crevices in the St. Lawrence estuary, Canada, through succession and shows how extrapolations from the study of a limited number of organisms to the entire community of macro-invertebrates may not be valid.

I first examined how varying the lower size limit of the organisms considered in the analyses (organisms >0.5, 1, 2, 4, and 8 mm) alters the observed trends in community structure (richness and diversity) through succession. Diversity was maximal in mid-succession for the >2 and >4 mm size groupings but continued to increase through succession for the >1 and >0.5 mm groupings whereas richness always increased through succession for all groupings. Examining one of four distinct zones in crevices gave the same result as examining the total community, improving sampling efficiency. However, the other three zones did not show this predictive power.

I then examined whether variation in richness and diversity through succession was a function of the structural heterogeneity (SH) provided by the dominant taxa or of the age of the communities *per se*. This was done by comparing control crevice communities at four successional stages to ones that had been modified such that only the dominant species remained following a brief period to allow for colonization (mimic crevices). Within three months, control and mimic communities resembled each other in terms of both diversity and richness and the trends mirrored those observed four months early, thus supporting SH. Nonparametric multivariate analyses supported these conclusions.

AN ARCHAEOLOGICAL PERSPECTIVE ON THE CULTURAL SIGNIFICANCE OF SHELLFISH RESOURCES TO FIRST NATIONS IN THE GEORGIA BASIN.

Eric McLay, Archaeologist, Hul'qumi'num Treaty Group.

Archaeology offers an invaluable perspective toward understanding the fundamental importance of shellfish resources to coastal First Nations in British Columbia. This study examines the relationship between archaeological site locations and shellfish resources on Valdes Island, a large southern Gulf Island in the Georgia Basin, British Columbia. A close association is observed to exist between the location, size and content of archaeological shell deposits and the distribution of local shellfish resources.

It is argued that Central Coast Salish settlement patterns on Valdes Island demonstrate a precontact economic orientation toward exploiting productive coastal resource zones, particularly sandy intertidal habits, where populations aggregated to collect localized, predictable and abundant bivalve shellfish and other sandy foreshore resources. This archaeological study has important implications for modelling strategies of precontact settlement and subsistence in the Georgia Basin, and for considering the cultural significance of shellfish resources to modern First Nations.

RESTORING OYSTERS TO THE CHESAPEAKE BAY: A COORDINATED EFFORT INVOLVING GOVERNMENT, UNIVERSITIES, COMMUNITY GROUPS, AND INDUSTRY.

Donald W. Meritt,[1] S. Tobash,[1] C. S. Frentz,[2] W. Goldsborough,[3] and **S. Reynolds,[3]** [1]University of Maryland, Center for Environmental Science, Box 775, Cambridge, MD 21613, USA; [2]Maryland Oyster Recovery Partnership, Box 6775, Annapolis, MD 21401, USA; [3] Chesapeake Bay Foundation, 6 Herndon Avenue, Annapolis, MD 21403, USA.

Once the world leader Chesapeake Bay oyster harvests are near all-time lows today. Overexploitation, disease and habitat loss have all contributed to this decline. Traditional techniques of spreading shell to collect spat are no longer reliable to produce consistent numbers of high quality oyster seed because, oyster diseases are highest in areas where natural spatfall is most abundant.

Utilizing hatcheries and a strategy designed to minimize the risk of infection, oyster seed have been produced with little or no Dermo. Hatchery spat have been used to accomplish a wide range of objectives including supplying citizens growing oysters for restoration, re-seeding harvest grounds in areas sensitive to disease, involving commercial oystermen in restoration, and establishing ecological sanctuaries. This program has grown dramatically over the past decade and now is responsible for planting tens of millions of oyster spat each year.

The Maryland Oyster Recovery Partnership along with the University of Maryland Center for Environmental Science, the Chesapeake Bay Foundation, Maryland Watermen's Association and local community groups have been successful in producing the seed oysters, preparing the bottom, and planting the seed in a coordinated effort.

OYSTER RESTORATION IN CHESAPEAKE BAY: I CRITERIA FOR SITE SELECTION.

Donald W. Meritt,[1] **S. Tobash,**[1] **K. T. Paynter,**[2] and **T. Koles,**[2] [1]University of Maryland, Center for Environment Science, Box 775, Cambridge, MD, 21613, USA; [2]Department of Biology, University of Maryland, College Park, MD 20742, USA.

Interest in restoring historical oyster reefs or in creating new oyster reefs in Chesapeake Bay has heightened in recent years. The state of Maryland has a long history of activities aimed at oyster repletion for the public fishery. Additionally, private oyster culture was once a major producer of market oysters in the Bay region. Disease, overharvest, and habitat loss have all contributed to the decline in oyster populations and the resultant harvests are at near all time lows.

The economic importance of a healthy oyster fishery to waterfront communities is well documented. Of more recent interest is the concern for the ecological role of healthy oyster communities to the overall health of the Chesapeake Bay. Oyster restoration for non-commercial uses is becoming more commonplace while the more traditional repletion program activities are being modified in an attempt to become more efficient.

Many community groups find it desirable to have an oyster reef in their local area. Not every site is suitable for oyster reef construction. Many exhibit some but not all of the characteristics needed for successful oyster growth and survival. Success of any given project depends upon accurate assessment of these characteristics and the use of proper construction techniques.

GENETIC MONITORING OF OYSTER STOCK ENHANCEMENT IN THE CHOPTANK RIVER, CHESAPEAKE BAY, MARYLAND, USA.

C. A. Milbury, and **P. M. Gaffney,** Graduate College of Marine Studies, University of Delaware, 700 Pilottown Road, Lewes, DE 19958, USA.

The increased spread of parasitic diseases (primarily MSX and Dermo), in conjunction with overharvesting, has led to the rapid decline of many Eastern oyster (*Crassostrea virginica*) populations, especially in Chesapeake Bay. Regional variation in disease resistance to these parasites may be useful in restoration efforts. In collaboration with the University of Maryland Horn Point Lab, we have proposed to assess the success of recent enhancement efforts within the Chesapeake Bay using molecular genetic markers.

In 1997, oysters propagated from Louisiana broodstock were planted at ten sites within the Choptank River, Maryland. *C. virginica* exhibits regionally diagnostic DNA profiles in the form of North Atlantic, South Atlantic, and Gulf Coast 16s mitochondrial haplotypes. The presence of the Gulf Coast haplotype in newly settled spat confirms the survival and propagation of the Louisiana broodstock. DNA sequencing techniques developed by Pyrosequencing Inc. were used to determine the mitochondrial haplotypes of a large number of oyster spat collected at several bars throughout the Choptank River estuary. This rapid, mass screening method revealed that 94% of spat collected were of the North Atlantic haplotype and approximately 5% were South Atlantic. Of 2,466 spat screened, four possessed the Gulf Coast haplotype (0.2%). Haplotype identifications were confirmed using restriction fragment length polymorphisms in other regions of the mitochondrial genome. The use of these genetic markers has enabled us to assess the survival, propagation, and dispersal of the Louisiana oyster stock within the Choptank River, Chesapeake Bay.

OPEN SAANICH INLET SHELLFISH BEDS: A COLLABORATIVE APPROACH.

Rob Miller, RLN Cameron, Environmental Programs, Capital Regional District, 524 Yates Street, Victoria British Columbia, V8W 2S6, Canada.

The Saanich Peninsula and Inlet are located on the southern tip of Vancouver Island near Victoria, British Columbia. The Saanich Inlet shellfishery is an important food source to three Saanich Peninsula First Nation Bands and the community. Many of the shellfish beds on the east coast of Saanich Inlet are closed for harvesting due to elevated levels of fecal coliform bacteria. The primary method of fecal coliform transmission from the land to the marine environment is stormwater.

The Capital Regional District (CRD) Stormwater Quality program works to limit the impacts of stormwater runoff to the environment and public health and protect freshwater and nearshore marine ecosystems. In 1999, Environment Canada and the CRD established a project titled *Open Saanich Inlet Shellfish Beds* (*OSISB*). This collaborative project will run until 2003 and involves all levels of government and the community working towards opening shellfish beds.

Under this project, the sources of fecal coliform contamination responsible for shellfish closures are identified. The jurisdiction(s) involved then work toward their reduction/elimination.

Limited nearshore marine sampling is also undertaken to determine fecal coliform levels near shellfish beds and their association with stormwater. The data are particularly relevant to monitoring changes over time and measuring the success of efforts to open shellfish beds.

Since the project began there has been a significant decrease in the number of stormwater discharges with high fecal coliform levels along this 27 kilometer coastline. Limited marine nearshore sampling has also shown a significant reduction in fecal coliform levels.

HYDROACOUSTIC SEABED CLASSIFICATION TECHNOLOGY APPLIED IN SHELLFISH PRODUCTIVITY RESEARCH.

Marc Ouellette and **T. Landry**, Fisheries and Oceans Canada, Gulf Fisheries Centre, Science Branch, Moncton, NB, E1C 9B6, Canada.

A good understanding of the relation between shellfish population dynamics and their habitat is essential in order to develop successful enhancement and/or restoration methods for our natural populations through shellfish or habitat management. The physical, chemical and biological characteristics of the seabed are key elements in shellfish productivity. In the past, this element has proven to be difficult and expensive to evaluate in part due to our inability to efficiently classify seabed on a large scale. With the recent development of new data acquisition and analysis tools (Global Positioning System, Geographic Information System, geostatistics and hydroacoustics), however, it is now possible to map seabed areas within a reasonable time and financial framework. Most importantly, these new technologies are capable of providing accurate and repeatable measurements. This will provide us with the ability to measure spatial and temporal variation of the benthic assemblage in relationship to mollusc productivity.

A new shallow water seabed classification system, QTC View (Series V), is being used for the first time to survey sites in the Gulf of St. Lawrence and Fundy Bay were research is presently being carried out on,oyster bed restoration, quahaug population management and mussel farming.

THE LIVING VENEER: CHARACTERIZING HABITAT STRUCTURE CREATED BY OYSTERS.

Paynter, **Kennedy**, and **Elizabeth Flynn**, Department of Biology, University of Maryland, College Park, MD 20742, USA.

Oyster reefs, like coral reefs, are biogenic structures. The settlement and growth of oysters create them. Therefore, the density of settlement, growth rate, and the mortality rate of oysters on a given reef will greatly affect the structure of the reef and the habitat created. Natural densities of oysters up to 1,000 individuals/m^2 have been reported while the mean density of exploited reefs in Maryland is less than 3 oysters/m^2. Although the large-scale, three-dimensional relief aspects of oyster reefs has received much attention, the structure created by oysters themselves—the spaces among and between living oysters—is less well studied.

We have attempted to characterize the habitat created by different densities of oysters both in the lab and in the field. A variety of approaches are available for this kind of measurement including estimates of the "space" created by oyster shells in various assemblages, a chain index, and fractal dimension. While interstitial volume was not significantly different between clumps and loose shell, chain indices and fractal dimension estimates were quite different. Seabed roughness may also be a useful measure as it takes into account shell height and nearest-neighbor distances. Such characterization is important to understand the relationship between physical structure and habitat value. We hope to associate the structural differences between reefs with benthic fauna associated with them as an assessment of habitat value.

OYSTER RESTORATION IN CHESAPEAKE BAY: II. IMPACTS OF WATER QUALITY AND DISEASE.

Paynter,[1] **Kennedy**,[1] **T. Koles**,[1] **D. Meritt**,[2] and **S. Tobash**,[2] [1]Department of Biology, University of Maryland, College Park, MD 20742, [2]Horn Point Laboratory, Center for Environmental Sciences, University of Maryland, Cambridge, MD 21613, USA.

The siting of oyster restoration projects is typically guided by several considerations. Physical habitat present (ie., "hardness of the bottom") is typically the first consideration. Local disease prevalence is sometimes assessed and water quality is usually assumed. Dissolved oxygen (DO) levels are typically not measured prior to restoration.

Oxygen dynamics in shallow zones of estuaries are not well understood. While general trends typical of eutrophic systems are apparent including surface overproductivity, stratification, and deep anoxia, relatively little attention has been paid to water quality in shallow (<6m) nearshore, sub-littoral zones. Furthermore, the effects of hypoxia (<4mg O_2/l) on benthic communities and organisms are not well understood. We have observed chronic hypoxia on many oyster reefs in Chesapeake Bay. One reef was exposed to <3mg 0_2/l for nearly 72 h with only 2 or 3 brief (<30 min) episodes of higher DO. DO levels measured by continuous monitoring at this reef were <5 mg/l 90% of the time throughout August and September, 2000, and May and June, 2001. DO levels measured in 2001 at approximately 30 other reefs throughout the Maryland portion of the Bay was typically <5 mg/l and often <3 mg/l. These levels of hypoxia could have important detrimental affects on restoration projects.

EARLY COMMUNITY DEVELOPMENT OF OYSTER REEFS IN VIRGINIA: EFFECTS OF REEF SCALE.

P. G. Ross, M. W. Luckenbach and **A. J. Birch,** College of William and Mary, Virginia Institute of Marine Science, Eastern Shore Laboratory, Wachapreague, VA 23480, USA.

Traditionally, oyster reef restoration in the Chesapeake Bay region has primarily focused on oyster production. Increasingly, however, efforts have included restoration of associated communities and the overall ecological function of self-sustaining reefs as management goals. The communities that develop in association with oyster reefs in Chesapeake Bay, VA have been shown to be diverse and ecologically important. Additionally, reef architecture, such as vertical relief and interstitial space, has been shown to be important to developing and maintaining community diversity. Another, previously unaddressed architectural component, aerial extent or scale, is also expected to affect community development. In a replicated block design, we have constructed high relief reef bases ranging in size from 400 sq m to 8000 sq m and are characterizing the development of the associated resident and transient assemblages of organisms. We will present data evaluating early community development on these different scale subtidal reefs. We compare reefs of differing scales (i.e., small versus medium versus large size reefs), but also make comparisons within a reef (e.g., inner portions of reef base versus reef edge). Substrate for constructing reefs is often limiting and expensive and resource managers face tough decisions on how to allocate scarce resources (e.g., construct several large or many small reefs). When maximizing diversity and ecological function of reefs is a management objective, knowing the impact of reef scale can be a valuable asset for making such decisions.

GENETIC AND PATHOGENIC ASPECTS IN SHELLFISH RESTORATION OF SCALLOP POPULATIONS.

Rejean Tremblay, and **T. Landry,** UQAR-MAPAQ, Centre Aquacole Marin, Grande-Riviere, Que., G0C 1V0; Gulf Fisheries Center, DFO, Moncton, N.B., E1C 9B6, Canada.

With recent declines in the scallop fishery in Atlantic Canada, several projects on stock enhancement are being conducted. The success of shellfish population restoration is directly related to the fitness of the scallop seed. Results obtained from restoration activities of Giant scallops (*Placopecten magellanicus*) populations will be used to discuss of the impacts of genetic and pathogenic aspects on the fitness of scallops and the success of these activities. Factors that will contribute to reduce the overall genetic variability may compromise the capacity of a species to adapt to environmental changes and to resist to pathogens. Thus, the long-term survival of that species may be compromise. Indeed, if genetic variation within individual populations is reduced, there will be less of a basis for future adaptation within a given population. Genetic changes often occur during the hatchery process. In Quebec, scallop enhancement activities are carried out using juveniles produced in hatchery, or collected over scallop beds and that are either re-released in the same area or transfer to other areas. The impacts of all these practices on genetic variability of populations are not known. The genetic of shellfish produced in hatchery are frequently altered through inbreeding, selective breeding or domestication with an overall reduction in genetic variability. This can also be true for seed collected on artificial collectors. These enhancement activities could result in hybridization, with the possibility of reducing the genetic variation and hence, the fitness of the enhanced population.

WATER QUALITY AND OYSTER HEALTH (*CRASSOSTREA VIRGINICA*): AN INTEGRATED APPROACH TO DETERMINING HABITAT RESTORATION POTENTIAL.

Aswani K. Volety,[1] **S. Gregory Tolley,**[1] and **James T. Winstead,**[2] [1]Florida Gulf Coast University, Division of Ecological Studies, 10501 FGCU Blvd. S., Fort Myers, FL 33965, USA; [2]U.S. Environmental Protection Agency, Gulf Ecology Division, 1 Sabine Island Drive, Gulf Breeze, FL 32561, USA.

The influence of water quality and season on disease prevalence and intensity, gonadal condition, recruitment potential, and growth of oysters was examined monthly at five locations along the Caloosahatchee River estuary, Florida. Habitat suitability of oyster reefs for fishes and decapod crustaceans was examined at three of these sites. Higher temperatures and salinities favored the parasite *Perkinsus marinus,* and histological analyses revealed the presence of several additional parasitic or commensalistic organisms.

Comparison of mortality among sites indicated that juvenile oysters tolerated salinities of 15–38 ppt. Spat recruitment was higher at sudtidal (1–5 spat/shell) than at intertidal locations, where sparse oyster distribution and swift currents appeared to limit settlement success. The late peak in gametogenesis (August to September) observed at all sites may have resulted from reduced salinities during May to July or may imply that oysters spawn twice per season. Oyster-reef habitat supported a fish and decapod assemblage averaging 77 individuals m^{-2} or 14 individuals l^{-1} oyster cluster.

Reef-resident fishes included *Gobiesox strumosus, Chasmodes saburrae, Gobiosoma robustum,* and *Opsanus beta:* xanthid and porcellanid crabs represented the dominant crustaceans. Species diversity (H′) did not vary among sites; however, significant differences in density (individuals l^{-1} oyster cluster) were found in the fishes *G. strumosus* and *C. saburrae* and in the crabs *Panopeus herbstii* and *Petrolisthes armatus.* Overall, results suggest that periodic freshwater releases may benefit oysters by lowering the salinity and thus the intensity of parasite infection, *Perkinsus marinus.* It should be cautioned that the long-term effects of low salinity on oysters have not been investigated.

THE NUTRIENT VALUE OF SHELLFISH AND OTHER TRADITIONAL FOODS, THEIR PAST AND CURRENT CONTRIBUTION TO THE DIET OF FIRST NATIONS PEOPLE. Pamela Winquist, First Nations and Inuit Health Branch, Pacific Region, Health Canada. #540–757 West Hastings Street, Vancouver, BC V6C 3E6, Canada.

The nutrient value of shellfish and other foods traditionally used by First Nations people in British Columbia, Canada will be reviewed. Information on past and current consumption, and factors affecting use, will be discussed.

Shellfish and other traditional foods offer superior nutrient value compared to commercial alternatives. These foods have contributed significantly to the overall nutrient intake of First Nations people, in the past. Seafood and other traditional foods continue to contribute to the overall nutrient quality of the diet of First Nations people. Traditional foods provide nutrients that are often low in the commercial food diets of First Nations people, such as vitamin A, calcium, iron, polyunsaturated oils and omega-3 fatty acids and folic acid. When these foods are replaced by commercial alternatives, fat, sugar and salt intakes increase. Diets high in saturated fat, sugar and salt are one of the risk factors in the development of chronic diseases such as obesity, diabetes and coronary heart disease. Higher rates of these illnesses are seen in First Nations people, compared to the general population.

Factors influencing present use of traditional foods include access to a commercial food source, knowledge and skills of family members to fish, hunt and/or trap, amount of traditional food available, fish and wildlife regulations, contamination of traditional foods, and household income.

In conclusion, shellfish and other traditional foods are of high nutrient value. These foods should continue to be consumed as part of a nutritious diet, when they are available for safe harvest and preparation.

PREDATION OF JUVENILE SEA SCALLOPS (*PLACOPECTEN MAGELLANICUS*) DURING SEEDING TRIALS IN THE NORTHUMBERLAND STRAIT. Melisa C. Wong,[1] M. A. Barbeau,[1] L. A. Grecian,[1] L-A. Davidson,[2] M. Niles,[2] and Donna Murray,[3] [1]Department of Biology, University of New Brunswick, Fredericton, NB, E3B 6E1, Canada; [2]Department of Fisheries and Oceans, Gulf Fisheries Centre, Moncton, NB, E1C 9B6, Canada; [3]Botsford Professional Fishermen's Association Inc., 1696 Route 955, Little Shemogue, NB, E4M 3M6, Canada.

The Botsford Professional Fishermen's Association Inc. and the Department of Fisheries and Oceans (Moncton, NB) have conducted a scallop enhancement project in the Northumberland Strait since 1998. Predation of juvenile sea scallops by sea stars (*Asterias vulgaris*) and rock crabs (*Cancer irroratus*) is a concern in the Northumberland Strait. Our goal was to quantify predator-induced mortality of seeded scallops and to determine how quickly mortality occurs after seeding. We deployed assays (consisting of scallops tethered to lead-weighted lines) to monitor scallop mortality at seeded and non-seeded sites, after seedings in October 1999 and October 2000. In both years, shell remains on the tethered lines indicated the presence of both sea stars (empty intact shells) and rock crabs (shell fragments) at both sites. In October 1999, scallop mortality did not differ between the seeded site and the non-seeded site or show a significant change over time. In October 2000, scallop mortality did not differ between sites, while scallop mortality was significantly higher 10 days after seeding than 2 days after.

Journal of Shellfish Research, Vol. 21, No. 1, 321–328, 2002.

POPULATION AND BEHAVIORAL CHARACTERISTICS OF INTRODUCED OYSTER DRILLS, *CERATOSTOMA INORNATUM*, IN WILLAPA BAY.

Jeremy M. Breach and **Jennifer L. Ruesink**, Department of Zoology, University of Washington, Seattle, WA 98195-1800.

Japanese oyster drills in Willapa Bay were studied to discern population parameters including density, size-frequency distribution, food preference, and movement rates. Drills were collected during the summer of 2001 from 0.0625 and 1 m^2 quadrats near the Washington Department of Fish and Wildlife lab at Nahcotta, Washington. Drill density averaged 31 m^{-2}, and the size distribution included a peak of small individuals suggestive of this year's recruitment. Drills showed a preference for feeding on smaller oysters, and oysters appeared to escape drill predation at shell lengths exceeding 2 cm. Drills were labeled and released into three different habitats to study drill movement. Significant differences were found between movement rates on eelgrass, oyster bed, and mudflat, with drills traveling up to 1 m/day on mudflat and eelgrass until reaching small patches of oysters. Risks of drill impacts are highest for seed oysters placed on the bottom in infested areas, particularly if few oysters are currently present.

JUVENILE GROWTH STUDY ON THE GEODUCK CLAM, *PANOPEA ABRUPTA*.

Amilee Caffey, Washington Department of Fish & Wildlife, Point Whitney Laboratory, Brinnon, WA 98320; **Are Strom**, University of Washington, WA 98062.

The geoduck clam has proven to be a challenging species to culture in the hatchery setting. Water temperature, salinity, sunlight, food concentrations, and handling all affect levels of growth. The goal of this study was to determine what effect temperature and varying food concentration levels in the surrounding water had on the juvenile geoduck clam.

The statistical analysis method was a two-way ANOVA in which juvenile clams were introduced to four varying environments where temperature and food concentrations were aberrant. Clams were placed in 1-in. square, plastic trays, layered with permeable fabric and sand. The stocking density was 100 juveniles per tray. Smaller juveniles were chosen, ranging between 14 and 19 mm in shell length in order to determine rapid growth rates. Three identical trays were subjected to each of the four treatments, with a total of 12 trays. The first and second treatments were subjected to a higher temperature, between 15 and 16°C. The third and fourth treatments were at a lower temperature, 10–11°C. The first and fourth treatment were held at a higher concentration of food, 45 k/mL. The second and third treatments were held at a lower food concentration of 15 k/mL. Flow rate was 6 L/min.

Shell length did not vary significantly between treatments, however, juveniles exposed to higher temperature (15–16°C), at higher food concentration (45 k/mL algal cells), demonstrated the most growth.

EFFECT OF HIGH-PRESSURE PROCESSING ON *VIBRIO PARAHAEMOLYTICUS* STRAINS IN PURE CULTURE AND PACIFIC OYSTERS.

Hakan Calik, **Michael T. Morrissey**, **Paul W. Reno**, and **Haejung An**, Department of Food Science & Technology, Oregon State University Seafood Laboratory, 2001 Marine Drive, Room 253, Astoria, OR 97103.

Several cases of *Vibrio parahaemolyticus* (Vp)-induced gastroenteritis occurred in the Pacific Northwest due to consumption of raw oysters. High-pressure process (HPP) technology has shown good potential in reducing pathogens. Environmental and clinical strains of Vp in broth cultures and Vp-inoculated live Pacific oysters (*Crassostrea gigas*) were subjected to HPP at different treatment settings (1–10 min at 241 MPa; 1–5 min at 276 MPa; 30–120 s at 310 MPa; 10–90 s at 345 MPa). Results showed that Vp numbers were reduced by HPP in both pure culture and whole oysters. Vp inactivation was dependant on treatment time and pressure. Optimum conditions for reducing Vp in pure culture and oysters from 109 to 101 CFU/mL were achieved at 345 MPa for 30 and 90 s, respectively. Resistance variations were detected between Vp in pure culture and in oysters. Further high-pressure tests with clinical 03:K6 Vp strain isolated from an outbreak in Texas (1998) showed that 5 min at 310 MPa was necessary for complete elimination, making the isolate the most baro-resistant of all strains used in the study. HPP proved to be an efficient means of reducing Vp in oysters.

AGE DETERMINATION IN GEODUCK CLAMS (*PANOPEA ABRUPTA*) UTILIZING PATTERNS IN SHELL ANNULI.

Elyse K. Cronin and **Brent Vadopalas**, School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA 98105.

Geoducks (*Panopea abrupta*) are deep-burrowing bivalves distributed from Southeast Alaska to Baja, California. This extremely long-lived species supports a lucrative fishery in Washington state, yet little is known of geoduck population dynamics. Age data are being collected from various sites in Puget Sound to investigate both population dynamics and temporal genetic structure in geoducks, via collaborations between the Washington Department of Fish and Wildlife (WDFW), Washington Sea Grant, and the University of Washington School of Aquatic and Fishery Sciences.

To age geoducks, the hinge plate of the right valve was thin-sectioned using a diamond saw, polished, and finally etched with 1% HCl. Annual growth rings (annuli) were visualized via light microscopy, and two independent observer counts were made on three thin-sections for each clam. Annuli revealed year-specific width variation consistent across samples. These patterns may correlate with localized environmental factors or regional oceanographic conditions, and are used to establish year reference points in series of annuli.

Ages determined from 200 geoducks collected from a Hood Canal site sampled in 2000 ($N = 1010$) ranged from 5 to 136 y. When complete, this age data set will be used in analyses of genetic population structure and population dynamics of the species in Puget Sound.

CHARACTERIZATION OF PATHOGENIC AND NONPATHOGENIC BACTERIA ASSOCIATED WITH BIVALVE LARVAE AND SHELLFISH HATCHERIES.

Robyn M. Estes, Russell P. Herwig, School of Aquatic and Fishery Sciences, Box 355020, University of Washington, Seattle, WA 98195-5020; **Ralph A. Elston,** AquaTechniques/Pacific Shellfish Institute, P.O. Box 687, Carlsborg, WA 98324.

Bacterial diseases are a major cause of larval mortality in shellfish hatcheries. Even with proper sanitation measures, bacterial pathogens cannot be eliminated. The proper identification of pathogens and the application of probiotics may help control disease outbreaks.

More than 100 bacterial isolates were collected from larval Pacific oysters, larval geoducks, and locations within hatcheries in the Pacific Northwest and Hawaii. Isolates were characterized by whole cell analysis and restriction fragment length polymorphism (RFLP) of 16S rDNA using three restriction enzymes. Both of these methods show similar relationships between the isolates. Pathogenicity tests of isolates collected from Pacific oyster larvae from Washington and Oregon showed that 3 out of 33 isolates were highly pathogenic. These assays examined larval mortality and the ability of larvae to remain suspended in a water column. Pathogenic and nonpathogenic bacteria strains appear closely related to each other. These results could provide information for the development of probiotics in shellfish aquaculture.

Future research includes sequencing the 16S rDNA of pathogenic bacteria, declaring new species if they cannot be identified as known species, and developing polymerase chain reaction (PCR) primers for rapid detection of pathogenic bacteria. This will help in early detection of pathogenic bacteria and in determining the source and ecology of the pathogenic organisms in hatcheries.

OYSTER GROUNDS: A SUPERIOR HABITAT FOR SMALL, SEDIMENT-DWELLING INVERTEBRATES.

Steven P. Ferraro and **F. A. Cole,** U.S. Environmental Protection Agency, 2111 S.E. Marine Science Drive, Newport, OR 97365-5260.

As part of a programmatic effort to determine estuarine habitat values for ecological risk assessments, quantitative field studies of small, sediment-dwelling invertebrates were conducted in Willapa Bay, Washington, in July 1998 and Tillamook Bay, Oregon, in July 1999. The six habitats included in both studies were (1) "grow-out" (2–3 y old) oyster ground culture, (2) eelgrass, *Zostera marina*, (3) mudshrimp, *Upogebia pugettensis*, (4) ghost shrimp, *Neotrypaea californiensis*, (5) bare mud, and (6) subtidal, undredged. About fifteen 0.01 $m^2 \times 5$ cm deep, 0.5 mm mesh samples were collected randomly in each habitat throughout both estuaries.

Multivariate analyses of the data revealed that the invertebrate fauna on oyster grounds was much more similar to that in eelgrass and mud shrimp habitat than that in ghost shrimp, bare mud, and subtidal habitat. Among the six habitats studied, oyster grounds consistently ranked either first or second in terms of the number of species, abundance, and total biomass of invertebrates. Oyster grounds, which have high economic value in terms of oyster production, are also ecologically valuable because they provide a superior habitat for small invertebrates upon which many larger animals (e.g., fish, crabs, waterfowl) feed.

STATUS OF THE OLYMPIA OYSTER, *OSTREA CONCHAPHILA*, IN CANADA.

Graham E. Gillespie, Fisheries and Oceans Canada, Pacific Biological Station, Nanaimo, British Columbia, V9R 5K6.

The Olympia oyster, *Ostrea conchaphila*, is the only oyster native to the Canadian Pacific coast. Olympias supported commercial fisheries in British Columbia from the late 1800s to about 1930, when focus of the oyster industry shifted to Pacific oysters, *Crassostrea gigas*.

Olympia oyster distribution in British Columbia is limited by specialized habitat requirements, and relatively low fecundity and dispersal. Olympias are vulnerable to temperature extremes, and are not resistant to harvests on a commercial scale. Habitats that once supported large aggregations in Georgia Strait no longer do, in part because of historic overharvests and environmental stresses, and because development of large oyster reefs may require centuries without disturbance. Small relict populations survive at low tide levels and under floating structures. Olympias are locally common at sites on the west coast of Vancouver Island, and little information exists on populations in Johnstone Strait or in the Central Coast. They do not occur in the Queen Charlotte Islands.

Olympia oysters are not likely facing imminent danger of extinction or extirpation in Canada. Limiting factors have led to significant reductions to population levels in the past. From the limited data available, the Committee on the Status of Endangered Wildlife in Canada (COSEWIC) assigned a status of Special Concern in November 2000. Proposed federal legislation, the Species At Risk Act (SARA), will require development of an Olympia oyster management plan within 3 y.

OYSTER AQUACULTURE AS FISH HABITAT IN PACIFIC NORTHWEST COASTAL ESTUARIES. Geoff Hosack, David Armstrong, Bryce Semens, School of Aquatic and Fishery Sciences, Box 355020, University of Washington, Seattle, WA 98195; **Brett Dumbauld,** Washington State Department of Fish and Wildlife, Willapa Bay Field Station, P.O. Box 190, Ocean Park, WA 98640; **Steven Rumrill,** South Slough Estuarine Research Reserve, P.O. Box 5417, Charleston, OR 97420.

Increased pressure on traditionally managed stocks of marine and anadromous fish, calls for protection of essential fish habitat under the Magnuson-Stevens Act, and recent listings of several salmonid stocks under ESA, have brought aquaculture activities that take place in coastal estuaries under increased public scrutiny.

We initiated a study designed to examine the ecological role that oyster aquaculture plays as habitat in coastal estuaries of the Pacific Northwest. The goal of the project is to identify and quantify beneficial and adverse impacts of shellfish farming on eelgrass, juvenile salmonids, and other selected estuarine fauna and flora, and to develop farming practices and recommend management protocols that protect or enhance those resources. We present results of initial fish and invertebrate sampling in selected habitats from Willapa Bay during spring and summer 2001, and an experiment designed to examine the effects of oyster harvesting on eelgrass habitat. We make a plea to managers to consider oyster aquaculture areas as fish habitat on a broader estuarine scale.

SURVIVAL AND GROWTH EFFECTS ON YIELDS OF PACIFIC OYSTERS, *CRASSOSTREA GIGAS*. Chris Langdon, Ford Evans, John Brake, and **Sean Matson,** Coastal Oregon Marine Experiment Station and Department of Fisheries and Wildlife, Oregon State University, Newport, OR 97365.

In Spring 1999, 29 full-sib families derived from crossing nonselected "wild" oysters were planted at a subtidal site in Yaquina Bay, Oregon. In addition, in Fall 1999, 32 full-sib, families from crosses within two groups of six selected families were planted at a an intertidal site in Tomales Bay, California. After about 1 y of growth, each cohort was harvested and average yields, survival, and individual growth rates determined for each family. These parameters were adjusted for the effects of differences in average initial weights of planted spat per family if a significant ($P < 0.05$) effect was detected.

Adjusted survival explained 57% and 68%, and growth explained 25% and 21% of the variation in adjusted family yields at the Yaquina and Tomales sites, respectively. Furthermore, up to 79% of the variation in family yields at the Tomales site was explained by differences in survival among families, if survival was not adjusted for a significant (regression, $r^2 = 0.38$; $P < 0.0001$) positive effect of initial spat weight. These results indicate that both growth and, perhaps to a greater degree, survival should be considered when designing breeding programs to increase oyster yields.

RESEARCH TO EXAMINE USE OF HIGH HYDROSTATIC PRESSURE TO INACTIVATE HUMAN ENTERIC VIRUSES IN OYSTERS. Cynthia S. Marshall and **Russell P. Herwig,** School of Aquatic and Fishery Sciences, Box 355020, University of Washington, Seattle, WA 98195-5020.

The desire for safe shellfish products in the retail market and food service establishments is paramount to the success and growth of the shellfish industry. Unfortunately, bacterial and viral pathogenic organisms may be associated with fresh and processed shellfish. These organisms can lead to seafood-borne illness that may result in severe economic impacts on the shellfish industry, causing shellfish bed closures, product recalls, and lost consumer confidence. Human enteric viruses are the causative agents associated with a large, but poorly understood, number of seafood-borne illnesses per year. The principle viruses associated with seafood include hepatitis A, Norwalk virus, Norwalk-like viruses, and astrovirus. Viruses are typically not monitored in seafood products and in shellfish growing waters because of the difficulty and expense of quantifying active virus particles.

There is a large demand for raw oysters in the market. Depuration or relaying may be used to reduce the number of pathogenic organisms present in live shellfish before they are harvested. In recent years, high hydrostatic pressure (HHP) treatment has been shown to reduce or eliminate bacterial pathogens from shellfish while retaining sensory properties of the raw product. We are beginning a new research project that will examine the effects of HHP on human enteric viruses. Poliovirus will be used as a model virus in our experiments. This virus was chosen because it can be safely used in the laboratory and can be cultured using standard protocols. In laboratory experiments, we will vary hydrostatic pressure, time of exposure, pH, and temperature on preparations containing poliovirus.

PREDICTABILITY OF GROW-OUT PERFORMANCE FROM NURSERY PERFORMANCE OF PACIFIC OYSTER, *CRASSOSTREA GIGAS*. Sean E. Matson, Chris Langdon, Ford Evans, John Brake, and **Dave Jacobson,** Hatfield Marine Science Center, Oregon State University, 2030 S. Marine Science Dr. Newport, OR 97365-5296.

The predictability of Pacific oyster (*Crassostrea gigas*) grow-out performance from nursery performance was investigated by measuring yield, survival, and growth of pedigreed families of Pacific oysters, in the nursery and at a grow-out site in Totten Inlet, Washington. Early prediction of grow-out performance could significantly reduce labor, materials, and space required to select pedigreed families on the basis of performance in an oyster breeding program. This research was conducted as part of the Molluscan

Broodstock Program, a breeding program for the sustainable increase in Pacific oyster yields through genetic selection. Yield was measured as oyster bag weight in grams and is a function of both survival and growth.

Unadjusted yield, yield adjusted for initial size, and unadjusted individual growth of Pacific oyster seed in the nursery were used as predictors of unadjusted yield, yield adjusted for initial weight, and unadjusted individual growth in the field. Unadjusted nursery yield was found to be a significant predictor of unadjusted grow-out yield ($P = 0.0009$, $r^2 = 0.250$). Initial planting weight, however, was also a significant predictor of unadjusted grow-out yield ($P < 0.0001$, $r^2 = 0.283$). Similarly, initial nursery weight was a highly significant predictor of nursery yield ($P < 0.0001$, $r^2 = 0.703$). Thus, adjustments were employed to both nursery and grow-out yield, to remove the effect of initial weight. Adjusted nursery yield was not a significant predictor of adjusted grow-out yield ($P = 0.9975$, $r^2 = 2.475 \times 10^{-7}$). These data indicate that heavy spat grew into heavy oysters because they were planted as heavy spat. They also indicate that Pacific oyster families with high yields at grow-out (adjusted for initial weight) are not easily identified in the nursery using the methods described here.

THE EFFECTS OF CLAM AQUACULTURE ON INTERTIDAL ECOSYSTEM STRUCTURE AND FUNCTION.

Daphne M. Munroe and **Leah Bendell-Young,** Department of Environmental Science, Simon Fraser University, 8888 University Drive, Burnaby, BC V5A 1S6.

Quadrat and core sampling was carried out to gather baseline data regarding ecosystem structure and function from three beaches on Denman Island, British Columbia. Ecosystem structure was examined through biodiversity measures (species richness, evenness, and heterogeneity), community composition, and species distribution. Ecosystem function was evaluated using percent silt and percent organic matter from core samples. The three study sites experienced different levels of commercial aquaculture. One site was a recreational harvest beach and the other two were leased for commercial aquaculture: one was 75% covered with nets, the other was only 20% covered.

We observed differences in ecosystem structure and function among the three sites. First, species richness was higher on the beach where no commercial practices occurred. Second, there were higher numbers of organisms per quadrat in the upper areas of the recreational beach and considerably more surface species on that beach. Third, we saw that the distribution of the most abundant clam species was limited to the upper half of the beach where no commercial clam culture was conducted; however, on the other two beaches, the distribution of this clam species extended the length of the study area.

This research indicates a high probability that commercial clam culture causes changes in intertidal ecosystem structural and functional components. Further research is imperative to provide managers with the scientific information needed to develop sustainable and environmentally sound management protocols.

HABITAT VALUE OF COMMERCIAL OYSTER CULTURE GEAR.

Paul G. Olin, University of California Sea Grant, Davis, CA 95616; **Jim Hobbs,** University of California, Davis, CA 95616.

Oyster growers in Tomales Bay, California, produce deeply cupped single oysters for the half-shell market using plastic mesh socking attached to stakes, and plastic mesh bags on the bottom, on racks or floating attached to longlines. This oyster culture gear and the oysters that are grown form a complex three-dimensional habitat that interacts in a variety of ways with the biological and physical components of the estuarine ecosystem. This habitat is utilized by a myriad of fish and invertebrates, which are often prey for larger commercially important species such as halibut or dungeness crab.

To document the habitat value of cultured oysters and gear, fish and invertebrates from 36 culture bags were collected and all macroorganisms were enumerated and identified to species. Ten phyla and 11 taxonomic classes were represented by the 51 different species identified. One oyster culture grow-out bag held more than 5,000 organisms, although more typically between 600 and 1,000 individuals were found in each bag.

In Tomales Bay approximately 8% of the intertidal and subtidal bottom lands are leased for shellfish culture by the state. Of this 8%, around 2% is actively farmed. Although this represents a small portion of the Bay, it is highly productive and provides complex intertidal habitat that has been lost in many areas due to erosion and resulting sedimentation.

OVERVIEW, 22nd MILFORD AQUACULTURE SEMINAR.

Walter J. Blogoslawski, U.S. Department of Commerce, National Oceanic & Atmospheric Administration, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, 212 Rogers Ave., Milford, CT 06460.

With more than 193 registrants, the 22nd Annual Milford Aquaculture Seminar was our largest gathering of industry, research, and academic interests.

By blending both the theoretical and practical aspects of aquaculture, the meeting permitted attendees an exchange of technology in aquaculture methods outside their own expertise and provided a forum where the latest innovations were introduced and discussed.

Fifty formal papers and posters were presented by attendees from 10 U.S. coastal states and France. Meeting attendees represented 3 vocational aquaculture high schools, 16 universities, 6 marine labs, and several state and federal institutions involved in shellfish and finfish aquaculture. A highlight of the meeting was a set of papers reviewing the northeastern aquaculture pioneers, making us aware of the difficulties and successes of those who laid the foundation for our aquaculture ventures and studies. Other topics included information on new hatcheries, education, disease, nutrition, and culture techniques.

The seminar has developed a tradition of offering the latest information available in the field in an informal atmosphere. This has successfully promoted a free exchange among all with an interest in the success and future of aquaculture. This seminar continued that approach which allowed all attendees to enjoy and learn from the formal presentations, and afforded informal opportunities to discuss the latest developments pertinent to this important expanding field.

At this year's seminar, 45 separate aquaculture companies met in an evening session to discuss the feasibility of forming an industry group tentatively titled "The East Coast Shellfish Growers Association." The proposed Association's goals are to promote and protect association members' needs in state and regional contexts and involve all stakeholders in the task of enhancing the shellfish aquaculture industry. The main reason for joining together is to promote industry unity and to counteract recent anti-aquaculture litigation and publicity.

The meeting was sponsored by the National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, Connecticut.

INFLUENCE OF QUAHOG GROW-OUT NETS ON BENTHIC DIVERSITY IN WELLFLEET, MA.

Peter Adamik, Roxanna Andersen, Murray Crous, Graham Hains, Vicke Starczak, Isabelle Williams, Diane Murphy, and **Dale Leavitt,** SouthEastern Massachusetts Aquaculture Center, Massachusetts Maritime Academy, 101 Academy Dr., Buzzards Bay, MA 02532.

The question of environmental impacts from shellfish aquaculture has been posed recently both locally and at an international level. An often-used indicator of environmental health is the diversity of species within the ecosystem in question. The prevailing assumption is that a decrease in biodiversity suggests a decrease in the quality of the environment. To begin addressing the issue of environmental impacts of shellfish aquaculture on local intertidal flats, we initiated a study investigating benthic diversity associated with netted raceways used for quahog (*Mercenaria mercenaria*) grow-out as compared to uncovered, unimpacted intertidal flats. The specific question asked was, "Does the presence of aquaculture netting structures and high quahog planting densities in the intertidal marine habitat alter the diversity of macrobenthic species in proximity to the nets?"

The study plan was to visit two sites having a history of quahog aquaculture and collect replicated core samples within and outside of the netted raceway. The samples were preserved, stained, and returned to the laboratory. In the laboratory, the samples were sieved to 500 μm and all living tissue, as stained with rose bengal, was sorted and identified to the lowest taxonomic level possible.

A total of 39 macrobenthic species were identified in the core samples from sample site 1 (Town Landing, Wellfleet, MA) and 27 from site 2 (Old Wharf, Wellfleet, MA). The dominant species in all samples at Town Landing was the glassy tube worm, *Spiochaetopterus oculatus*; at Old Wharf, the dominant species were the capitellid worm, *Heteromastus filiformus* and the mud snail, *Ilyanassa obsoleta*. The impact of shellfish aquaculture on environmental quality was analyzed in terms of the species richness, species diversity, and distribution of dominant species between sites and treatments.

In general, there were minor or no differences between netted and nonnetted treatments at the two sites investigated. Many other factors can influence diversity, species richness, and evenness of the intertidal macrofauna, including hydrography and fluid interaction under the netted area, human activities related to shellfish farming, and the historical background of the netted site (long-term culture, mid-term culture, or short-term culture). It was concluded that further study was warranted to include a seasonal and long-term component to the study.

POSSIBLE LARVAL MYCOSIS AS A CAUSE OF BIVALVE SEED MORTALITY IN A PRODUCTION HATCHERY.

John Aldred, Town of East Hampton, Shellfish Hatchery, 159 Pantigo Road, East Hampton, NY 11937; **Inke Sunila,** State of Connecticut, Department of Agriculture, Bureau of Aquaculture, P.O. Box 97, Milford, CT 06460; **Christopher Martin,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460.

Since 1996, the shellfish hatchery at East Hampton has experienced sporadic unexplained mortalities in cultures of hard clams (*Mercenaria mercenaria*) and bay scallops (*Argopecten irradians irradians*). Typically, a population of larvae progressed normally through metamorphosis and then, early in the juvenile stage (post-set) stopped feeding. In such cultures, examination revealed many dead or dying individuals. Within 2–4 days of the first indication of the problem most animals were dead. Affected juveniles ranged in shell length from 0.2 to 1.5 mm. Eastern oysters (*Crassostrea virginica*) reared at the same hatchery have not been affected. Preventative measures have been unsuccessful. These included switching algal diets, careful monitoring of pH, changing water more frequently, and giving special attention to cleaning and disinfecting the system. On occasion, it has been possible to rescue some juveniles from affected cultures by moving them to a flowing water system, with clams surviving better than scallops.

During the 2001 growing season, similar mortalities were observed. Samples of juvenile clams (approximately 1.0 mm in shell length) from two cohorts were preserved in Davidson's fixative. Scallop juveniles also from two cohorts (ranging from approximately 0.2 to 0.5 mm in shell length) were similarly fixed. Following decalcification, the specimens were stabilized in agarose, embedded in paraffin, sectioned to 6 μm, and stained with hematoxylin-eosin according to standard histopathological procedures.

Microscopic examination revealed invasion of most tissues and the shell by fungal mycelia. Mycelia were detected in the gill filaments where they often completely obstructed the hemolymph canals. Fungal hyphae were observed within the mantle cavity, with invasion of all epithelia (mantle, gill, and foot). The hyphae appeared to have some affinity to mucus. Cilia were entrapped. All layers of shell were invaded, with penetration to the exterior. The hyphae stained dark blue with hematoxylin, measured approximately 2–3 μm in diameter, and were rarely branched and septate.

Evidence of starvation was apparent. In most instances, food particles were absent from the digestive system and adductor muscles were atrophied. In advanced stages of invasion, tissues were disintegrated, with complete loss of vesicular connective tissue in some specimens. We concluded that larval mycosis was the cause of the observed mortalities. The fungus appears to be an opportunistic pathogen causing significant morbidity and mortality when conditions are optimal for its pathogenic development. Bivalve cultures in hatcheries often collapse and new cultures are initiated. The cause or causes of mortality are rarely determined. We suggest that larval mycosis may be a common, underrecognized cause of such events.

NEW DEVELOPMENTS WITH NONNATIVE SHELLFISH SPECIES IN THE CHESAPEAKE BAY.

Standish K. Allen, Jr., Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

VIMS has been systematically examining the potential of several nonnative species to alleviate the serious decline of oyster stocks in the Virginia portion of the Chesapeake Bay. One that has emerged as quite promising is the Suminoe oyster, *Crassostrea ariakensis*. Field trials with sterile triploids have shown a general resistance to disease, rapid growth rate, and high survival. Formal and informal test marketing of the product has been similarly successful. As with any nonnative species, serious concerns exist about the long-term implications of introduction. Some of these issues are associated with simultaneous introduction of pests or pathogens, and some are associated with the ecological effects of sustained population growth in the Bay. By culturing this species in the hatchery, pest and pathogen issues are largely, but not wholly, addressed. Aquaculture of triploid-only individuals mitigates, but does not eliminate, most of the ecological concerns. Aquaculture of hatchery-raised sterile triploid seed represents an intermediate solution to assisting the industry between abandoning research on nonnative species and wholesale introduction of diploids. The industry potential is enormous, but there are lingering questions about how precisely this "revolution" will or won't proceed.

THE EFFECTS OF VARYING COLD WATER TEMPERATURES, SIZE AND POPULATION DENSITY ON THE GROWTH AND MORTALITY RATES OF BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*, IN AN UPWELLER.

Brian J. Ball, Stephanie T. Rutkowski, Emily T. Griffiths, Mattituck High School, 15125 Main Road, Mattituck, NY 11952; **Kim W. Tetrault,** Cornell Cooperative Extension—Suffolk County Marine Program, 3690 Cedar Beach Road, Southold, NY 11971.

The growth of scallops has been known to slow in cold temperatures. The objective of this experiment was to observe the growth and mortality rates of larger and smaller sized bay scallops sorted into silos of varying densities in an upweller with decreasing coldwater temperatures.

To set up the experiment, five silos were filled with smaller scallops (10–20 mm) and five silos were filled with larger scallops (21–30 mm). Each silo of larger and smaller scallops varied in population density. The five silos of smaller scallops had 300, 700, 800, 900, and 1,200 scallops per silo, respectively. The five silos of larger scallops had 150, 180, 250, 330, and 350 scallops per silo, respectively.

Once a week, data were collected from a sample size of 30 scallops from each silo. Using a caliper, the size of the scallops was recorded to observe any growth. Any mortality within the sample population was also noted. Eight weeks into the experiment, January 10, 2002, all of the scallops were counted in each silo and all of the deaths were recorded. Using the data, mortality ratios of the entire population for each silo were calculated. A total count was done to verify the accuracy of our sample populations. The scallops were then returned to the silos for further study.

The results of this experiment show that for the varying population densities that we measured, the larger scallops continued to grow and had a low mortality rate in coldwater temperatures ranging from 13.21 to 0.27°C. The population density of each silo for the larger scallops had little effect on the growth and mortality rates. The growth and mortality rates in the smaller scallops were greatly affected by the population densities in our experiment. The silos with the fewest scallops (296 and 659) showed the most growth, whereas the silos with the highest density of scallops (1,162 and 844) showed less growth. For the smaller scallops, the silos with the highest density had the greatest mortality rate. The silo containing 1,200 scallops had a mortality rate of 10.4%, whereas the mortality rates for the remaining smaller groups of scallops had a mortality rate of approximately 5%. Experimental testing will continue through April in order to reach valid conclusions from this study.

CATCH STATISTICS OF *HOMARUS AMERICANUS*, THE AMERICAN LOBSTER, FROM A 3-WK STUDY CONDUCTED BY STUDENTS FROM THE SOUND SCHOOL REGIONAL AQUACULTURE CENTER ABOARD A COMMERCIAL LOBSTER VESSEL IN THE WATERS OFF FISHERS ISLAND, NEW YORK.

Amber L. Beitler and **John J. Roy**, The Sound School, 60 South Water St., New Haven, CT 06519

During the summer of 2001, from July 9 to August 1, six students from the Sound School Regional Aquaculture Center kept catch statistics on *Homarus americanus*, the American lobster, while interning as deck hands aboard the *UP FOR GRABS*, a commercial lobster vessel berthed in Noank, Connecticut. The student time aboard the vessel was credited toward their Supervised Occupational Experience (SOE) compliance requirements. The *UP FOR GRABS* fishes out of Noank and possesses both a Connecticut and a New York State Commercial Lobstering License. Eighty-five percent of the gear was fished on grounds that lie between an east-west line that can be drawn through Ram Island and Sea Flower Reef on the northern (Connecticut) side and a line running east to west 0.5 miles north of Fishers Island on the southern (New York) side of Fishers Island Sound. The remaining 15% of the gear was fished in an area just north of Ram Island. No differentiation was made between the areas being fished. Trawls were at times moved within this zone from areas of low productivity to areas where the catch was found to be higher, during a given week.

The time of the students' internship corresponded with the peak season for lobster capture in that area. Traditionally termed "the run" in the commercial lobster community, the month of July is considered to be the peak month for lobstering in the entire year. Forty-seven pot trawls were fished each week. All of the pots that were fished were wire. An average of 10 trawls, or 70 traps, were hauled each day, 4 days each week. Each trawl was hauled once each week. The students recorded the catch statistics from the 280 traps as each trawl was landed. The data that were taken included: the number of legal lobsters that were caught in each trawl; the number of sub-legal lobsters (or shorts) that were returned to the water from each trawl; the number of male and female legal lobsters found in each trawl; the number of dead lobsters found in each trawl; and the number of lobsters that exhibited shell-rot disease in each trawl. All categories were totaled daily. The daily totals were then compiled by week for 4 wk. A total of 2,018 lobsters were caught during the study.

Forty-five percent of the lobsters (191) landed in the first week were of legal size. The number of legal lobsters (341) that was landed in the second week increased by 56%. The third week of the study had a 4% drop in the number of legal lobsters (322) taken. There was a 38% drop in the number of legal lobsters (201) landed in the final week of the study. The percentage of sub-legal lobsters varied between 44% and 54% of the total number of lobsters taken each week during the study. More legal male lobsters were caught in the first and second week, whereas legal female lobsters appeared in greater numbers during the final 2 wk of the program. The number of dead lobsters found in the trawls ranged from 0.65% to 1.44%. All deaths were attributed to cannibalism, predation, or physical impact of the trap or trap components. The number of lobsters exhibiting shell-rot disease was less than 1% throughout the entire study. However, because of the proximity to the molt, this percentage may become greater later in the season.

The students at the Sound School had first hand experience with the dramatic declines in the lobster populations in western Long Island Sound during the late 1990's. We believe that it is becoming increasingly important to monitor accurately the existing stocks of *Homarus americanus* at all levels of the fishery, as well as in the scientific community. A concerted effort will be required to ensure the survival of this important natural resource.

EFFECTS OF WATER VELOCITY ON CONDITIONING OF SUMMER FLOUNDER *PARALICHTHYS DENTATUS* FOR NET PENS.

David A. Bengtson, Stephen Willey, and **Erin McCaffrey**, Department of Fisheries, Animal and Veterinary Science, University of Rhode Island, Kingston, RI 02881; **David Alves**, Coastal Resources Management Council, Stedman Government Center, Wakefield, RI 02879.

Attempts in the late 1990s to rear summer flounder in net pens suffered from high mortality during the month after fish were transferred from the nursery facility to pens. As part of the University of New Hampshire's Open Ocean Aquaculture Demonstration Project (OOADP), we investigated whether exposing summer flounder to increased (and constant) current velocity in the nursery stage would condition them for better performance in cages placed in Narragansett Bay, Rhode Island (not the OOADP site).

Three experiments, two of 60-day duration and one of 30-day duration, were conducted with different water velocities in tanks, using fish of 124 ± 4 g (exposed to 0, 15, or 30 cm/sec for 60 days), 257 ± 12 g (exposed to 0, 20, or 40 cm/sec for 60 days), and 387 ± 13 g (exposed to 0, 15, or 30 cm/sec for 30 days), in a raceway system with adjustable paddlewheels. For all of the size groups of fish, survival was significantly reduced at the highest current velocity. For the 124-g fish, survival in high velocity (26 ± 1%) was significantly lower than that in medium velocity (57 ± 7%) and in low velocity (67 ± 6%). For the 257-g fish, survival in high velocity (35 ± 19%) was significantly lower than that in medium and low velocities (100% in both cases). For the 387-g fish, survival in high velocity (50 ± 11%) was significantly lower than that in medium velocity (98 ± 2%); all 387-g fish in the low-velocity treatment were lost due to a system malfunction. For both 124- and 257-g fish, growth in the medium-velocity treatment was significantly better than that in the low-velocity treatment, which in turn was better than that in the high velocity treatment. For 124-g fish, growth was 76 ± 12 g, 49 ± 8 g, and 39 ± 0 g in the medium, low, and high velocities, respectively. For 257-g fish, growth was 47 ± 10 g, 25 ± 4 g, and −7 ± 17 g (weight loss) in the medium, low, and high velocities, respectively. For 387-g fish, growth at medium velocity (26 ± 6 g) was significantly greater than that at high velocity (−22 ± 8 g). Food consumption data from the 257-g fish showed that the fish in medium velocity grew most because they consumed significantly more food during the experiment (1,622 ± 128 g per tank) than did fish in low velocity (915 ± 65 g), which in turn consumed significantly more than fish in high velocity (640 ± 90 g). Nevertheless, there was no significant difference in food conversion ratio (FCR) between fish at low velocity (1.54 ± 0.37) and those at medium velocity (1.37 ± 0.23).

At the end of the experiment with 124-g fish, fish from the low-velocity and medium-velocity treatments were moved to cages in Narragansett Bay, where currents of about 1 knot (approx. 55 cm/sec) are routine. After 3 wk in the cages, no significant differences in survival were observed (low velocity = 83% ± 12%; medium velocity = 81% ± 2%). Subsequent damage to some of the cages and escapement of the fish precluded further statistical analysis of survival, as well as any growth measurements. We conclude that current velocities of 15–20 cm/sec in the nursery improve growth of juvenile summer flounder, that current velocities of 30–40 cm/sec are excessive, but that increased current velocity in the nursery does not improve fish survival upon transfer to cages.

REMINISCENCES OF EARLY PIONEERS IN OYSTER CULTURE. **Luther Blount,** Blount Shipyards, Warren, RI 02885.

In the late 1920s and early 1930s, there were about six oyster companies in Warren, Rhode Island, which not only worked closely with the Connecticut oyster people but also had connections in the nearby Taunton River and Assonet Bay areas in Massachusetts, where there was always a good oyster set.

In those days, oyster fishermen in Rhode Island were really into summer clam bakes, where all the oystermen gathered. My uncle, Byron Blount, of E.B. Blount and Sons, often invited Dr. Paul Galtsoff there. In fact, Dr. Galtsoff would drive over from Woods Hole to talk oysters with my uncle. So I knew him as a white-haired scientist discussing good and bad oyster sets and this always was his primary subject. Dr. Victor Loosanoff of the Milford Laboratory, Milford, CT followed Dr. Galtsoff's visits to my uncle and I happened to be there the day he showed us a paper egg crate coated not only with cement, but also literally loaded with thousands of oyster set. For the past half century I found myself working with these shellfish pioneers and learning from them as I built Prudence Island Farms.

Because we had previously bought spat on scallop shells from Dr. George Matthiessen on Fishers Island and knew how he got them, we looked for a marine biologist to help us get a set from Green Hill Pond on the Rhode Island south shore. We hired a young man who just graduated from the University of Rhode Island, called him "John Oyster," and began to buy scallop shells and get rafts made, which are used today in my salt water oyster pond on Prudence Island.

"CRAB SIGHTINGS" IN LONG ISLAND SOUND DURING 2001. **Diane J. Brousseau,** Biology Department, Fairfield University, Fairfield, CT 06430; **Ronald Goldberg,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460.

During summer and fall of 2001, there were a number of inquiries to the Milford Laboratory about observations of crustaceans in Long Island Sound. In July, swarms of megalopae of the Asian shore crab, *Hemigrapsus sanguineus*, were seen both in the water column and rafting on floating rockweed near Charles Island in Milford, Connecticut. These larvae were likely the result of an early summer spawning. Recent increases in population size of *Hemigrapsus* may account for greater abundance of the larvae than in the past. In early fall, reports were again made of dense aggregations of small crabs swimming close to the surface. Initially mistaken for Asian shore crabs by many observers, they were later identified by Nizinski (pers. comm.) as sub-adult pinnotherids, *Pinnixa chaetopterana*. This small crab is often found living as a commensal within the tube of the polychaete worm *Chaetopterus*. *Pinnixa* sightings were widespread, occurring in the Thimble Islands, Milford Harbor, and Housatonic River in Connecticut, and near Orient Shoals off Long Island. Fall swarming of *Pinnixa* prior to settlement has been observed previously by Mroczka (pers. comm.), but the early life history of this species has not been described fully. In October, an adult male shame-faced crab, *Calappa flammea*, was collected in shallow water by a scuba diver in Stonington, Connecticut. *Calappa* is predominantly tropical to subtropical, but larvae can drift as far north as southern New England, accounting for occasional occurrence of adults in this region. This molluscivorous crab spends much of its time buried in the sand, making brief excursions to search for food. The observations described above are not unique, but may have been more apparent during 2001 because of interannual variability in climate or the population dynamics of the species involved.

SOME CLASSICAL PERSONALITIES IN THE SHELLFISH RESEARCH ARENA: ECLECTIC OBSERVATIONS OF AN ERSTWHILE OBSERVER. Walter J. Canzonier, M.R.O.C.F., P. O. Box 662, Port Norris, NJ 08349.

The personalities of many of the scientists associated in the past with the shellfish research and development community might be of general interest to those currently engaged in this field. The personalities of these individuals, other than making them colorful and intriguing characters, probably also had a considerable influence on the approaches they used in addressing problems requiring scientific or technological intervention. Ergo, to better appreciate the contributions of some of the members of the community involved with the recent, and not-so-recent evolution of shellfish research, it has been suggested that it might be both entertaining and educational to have a glimpse at their personae. Using a capsule review of some of the key players in the shellfish research and development saga, I will attempt to share with the more recent entrants in the game a few anecdotal sketches of some of those individuals with whom I have had contact in my 45 years of involvement with the academic and the industry elements of molluscadom on the East Coast. This informal documentary, as distorted as it might be as a result of the undoubtedly biased perspective of the reporter, is offered to the curious in hope that it will help them gain a better insight into the personalities of those whom they have encountered merely as names in the nondigitized literature. Some of those mentioned were colleagues, others mentors, still others known to me primarily through accounts by relatives or close associates. Interest in documentation of personalities was first stimulated by the efforts of Sewell Hopkins, who prepared a set of three unpublished but extremely interesting and informative memoirs, two of which (University of Illinois and Project Nine) present enlightening and amusing sketches of his teachers and colleagues.

In this rambling account of the members of the "Old Guard," I will attempt to reconstruct the images of some of the well-recognized, as well as the lesser-known individuals. Certainly the names of Julius Nelson (known to me through the stories from his son); Galtsoff and Loosanoff, who worked in this immediate area; T. C. Nelson; J. G. Mackin and Sammy Ray of dermo fame; J. D. Andrews; and H. H. Haskin will probably be familiar to many currently working in this field. Other, less commonly recognized names include W. F. Wells, known to me only from exchanges of vitriolic correspondence with T. C. Nelson; L. A. Stauber, a polyvalent researcher more noted in the field of parasites of vertebrates, but always available to his students and colleagues as a valid anchor in the basic principles of shellfish pathology and physiology; his students S. Y. Feng and M. R. Tripp, among others; Joe Glancy, who doggedly pursued development of commercial shellfish hatchery technology despite strident attempts to rectify his errant behavior by his neighbor across the Sound; Mike Castagna who pursued a similar course in more southern waters; and M. R. Carriker, Carl Shuster, Herb Hidu, Tom Cheng, and others who at some point in their careers had close ties with the Department of Oyster Culture of the New Jersey Agricultural Experiment Station.

If asked what might be a common trait of these individuals, my observations would lead me to conclude that it was a capacity to mobilize their imagination to devise a plan of action that efficaciously utilized the often very limited resources available to them—whether this be in the laboratory or in the field. This intrinsic ability to adapt their efforts to the resources at hand enabled them to make significant contributions in the realm of academia, and to cost-effectively assist the shellfish industry in its quest for more productive culture practices and strategies. For this vanishing breed, a lack of sophisticated facilities and equipment was never considered to be an insurmountable limitation, but merely a challenging impediment to be circumvented by innovative tactics.

MASSACHUSETTS OCEAN RESOURCE INFORMATION SYSTEM (MORIS). Diane Carle, Office of Coastal Zone Management, Executive Office of Environmental Affairs, 251 Causeway Street, Suite 900, Boston, MA 02114.

Massachusetts Coastal Zone Management (CZM) has embarked on a long-term project to develop the Massachusetts Ocean Resource Information System (MORIS). MORIS will be a comprehensive database and ArcView GIS extension providing access to the broad range of information necessary to carry out the CZM mission. The first phases of the MORIS project were completed in 2001 and focus on information and tools useful for screening for potential aquaculture sites.

CZM contracted EVS Environmental Consultants to conduct the initial data mining and GIS application development. CZM also teamed with NOAA's Coastal Services Center (CSC), Massachusetts Division of Marine Fisheries (DMF), and Massachusetts Department of Environmental Protection (DEP) to add a "georegulation" tool that allows users to query an area for aquaculture-related regulations. Users are presented with a list of relevant regulations and can view summaries as well as the actual legislation. Users can also view the web sites of the relevant regulatory agencies. The CSC is also creating new data layers for the project, including benthic maps of selected areas of the Massachusetts coast and maps of areas suitable for sustaining shellfish growth. CZM is completing maps of existing aquaculture leases in Massachusetts. Future phases of the project will develop new water quality data layers and enhance the applications' water quality mapping capabilities. CZM is also pursuing funding to create an Internet mapping site for the project.

The MORIS CD containing the ArcView extension and database is available at no cost from CZM.

HABITAT SUITABILITY ASCERTAINED BY GROWTH AND SURVIVAL OF BAY SCALLOPS IN TIERED CAGES.

Joseph Choromanski, Sheila Stiles, Mark Dixon, and **David Veilleux** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460; **Christopher Cooper,** Ocean Technology Foundation, UCONN-Avery Point Campus, Groton, CT 06340.

A laboratory-spawned line of bay scallops (*Argopecten irradians irradians*) was used to evaluate the effectiveness of commercial three-tier, rigid-mesh cages for growing scallops in two proximate but dynamically different sites in eastern Long Island Sound. With permission of the Groton Shellfish Commission and the State of Connecticut Aquaculture Division, we established comparative field sites on the western side of Ram Island (low dynamic, gentle tides), and the southern end of the island (high dynamic, tidal current of up to 2 knots).

The scallops were spawned in March and held in temperature-controlled tanks in the Milford Laboratory at 22°C until May when ambient seawater temperature reached about 15°C. The scallops were then acclimated to the lower temperature and distributed in outdoor raceway tanks using densities determined as optimal—5 L biomass per tank. In late July, scallops with a mean size of 25 mm were deployed at each site, with a starting biomass of 2 L (approximately 400 scallops) in the top tiers of a set of two cages at each site. The cages were made of plastic-coated wire with a 7.5-cm mesh. Each cage measured 56 × 56 × 94 cm and was divided horizontally into three sections or tiers. Two ballast areas below the bottom tier provided an offset from the sea floor of approximately 15 cm. Cage inserts of smaller mesh (10 and 17.5 mm) measuring 41 × 10 × 81 cm were used to hold the scallops. After 1 month, the scallops were divided into three densities of 50, 100, and greater than 150 scallops per tier in each of the cages. The cages were checked monthly to the end of the experiment to determine survival and growth, with the added attention to shell indentations that might indicate density problems, and to check and remove fouling organisms.

Results from the field experiment indicated that satisfactory growth of scallops occurred at both sites. The initial growth rate was rapid, but then leveled off as the water temperature decreased. Growth of scallops was slightly better at the western side of the island (mean size of 51 mm) than at the southern end (mean size of 48 mm). There was no difference in the mean size of scallops in the top and middle tiers, with 50 and 100 scallops, respectively. Bottom tiers of all cages, stocked with greater than 150 scallops, did show slightly slower growth and higher mortality. Scallops in the cages from the southern, high-dynamic area exhibited more shell indentations; this could be attributable to the strong currents pushing the scallops together for periods of time, thereby causing a temporary decrease in available cage area that may mimic effects of higher shelf densities. Further studies are warranted in similar habitats to corroborate these results.

HORSESHOE CRAB AQUACULTURE: PRELIMINARY RESULTS FROM HATCHING AND REARING STUDIES.

Carmela Cuomo, Yale University, New Haven, CT 06520 and University of New Haven, West Haven, CT 06516; **Paul R. Bartholomew,** SUPERB Technical & Environmental, Hamden, CT 06517; **Leslie Angelini, Brian King,** and **Jeffrey Byczko,** The Sound School, 60 South Water St., New Haven, CT 06519.

Previous studies undertaken by the two senior authors during the summer of 2000 at the National Marine Fisheries Laboratory in Milford, CT resulted in the successful spawning of captive adult horseshoe crabs, *Limulus polyphemus*. The fertilized eggs were allowed to develop under conditions approximating field conditions, although predators were kept to a minimum. The eggs had a hatching rate of 60% over an initial 2-mo period, followed by a 98% hatching rate over the course of 10 mo. Evaluation of the long-term survival (greater than 1 y) of *Limulus* was not completed successfully because of a malfunction in the rearing tanks.

This study was undertaken in an effort to evaluate the role of different food sources on the growth and survival of post-hatch horseshoe crabs. Approximately 4,500 eggs were kept in small, experimental bowls filled with Long Island Sound (LIS) seawater and aerated. Initial egg densities varied per bowl, with a maximum density of 1,500 and a minimum density of 50. All bowls were checked daily for hatchlings. Upon hatching, all hatchlings from an individual bowl were removed to a separate bowl, with no more than 50 per bowl. Hatchlings were kept in aerated LIS seawater and a series of behavioral observations were made on them. Hatchlings in bowls were checked daily for molting.

Molted individuals were removed from hatchling bowls and placed in individual bowls of aerated seawater. The number of post-hatch molted individuals per bowl ranged between 10 and 30. Horseshoe crabs at this stage were separated into three groups for preliminary experiments examining the role of diet on growth and survival. They were fed one of three food items: newly hatched brine shrimp, rotifers, or concentrated dried food flakes. The juveniles were checked every day and any secondary molts or deaths were noted. When an organism underwent a secondary molt, that organism was transferred to a new bowl and fed one of the three food choices. This same procedure was repeated for every new molt stage reached. At the conclusion of the experiment, all surviving post-hatch molts (second and upward) were removed and placed in aerated, 10-gal aquaria containing artificial seawater and a bottom covered with 3 cm of fine sand.

The results suggest that diet may play a supporting role in the growth and survival of post-hatch *Limulus* juveniles, although this factor needs further investigation. In general, all juveniles reached their first post-hatch molt between 5 and 12 days. The time to second post-hatch molt varied with diet. There was a slight difference in molt timing among the three test groups. Juveniles (first post-hatch molt) reared on a diet of rotifers underwent a second post-hatch molt within 7–12 days, and those reared on a diet of brine shrimp generally molted between 10 and 14 days. Juveniles reared on flaked food generally molted between 9 and 12 days. Of these juveniles, those fed on a diet of brine shrimp experienced a mortality rate of up to 5%, whereas those fed on rotifers or flaked food experienced a mortality rate of <1%. Time to third post-hatch molt varied, with juveniles reared on flaked food molting sooner than juveniles reared on either brine shrimp or rotifers. Those fed flaked food were significantly more likely to molt (>90%) and survive (>85%) than those fed either rotifers or brine shrimp.

The results from these initial studies suggest that food quality and type has only a slight effect on the two earliest post-hatch molt stages of *Limulus polyphemus* juveniles, but has a strong effect upon the third post-hatch molt. It appears likely that this effect is related not only to the food type, but also to the life habit of the horseshoe crab, and that any rearing plan for this species must include at least a two-phase food supply consisting initially of zooplankton, followed by food that is mixed in with the sediments. Research on the effects of food quality on the growth of *Limulus* juveniles continues at this time.

A COOPERATIVE STUDY ON THE AQUACULTURE OF *PORPHYRA LEUCOSTICTA* (RHODOPHYTA) FOR AN INTEGRATED FINFISH/SEAWEED RECIRCULATING AQUACULTURE SYSTEM IN AN URBAN APPLICATION.

John J. Curtis, Sherry W. Lonergan, and **Paul J. Trupp,** Bridgeport Regional Vocational Aquaculture School, Bridgeport, CT 06605; **Peimin He,** Shanghai Fisheries University, Shanghai, People's Republic of China; **Raquel Carmona** and **Charles Yarish,** University of Connecticut, Stamford, CT 06901; **George P. Kraemer,** State University of New York, Purchase, NY 10577; **Christopher D. Neefus,** University of New Hampshire, Durham, NH 03824; **Thierry Chopin,** University of New Brunswick, Saint, John, NB E2L 4L5; **George Nardi,** GreatBay Aquaculture LLC, Portsmouth, NH 03801.

Aquaculture represents an excellent opportunity to help rejuvenate blighted coastal urban areas on the Northeast coast. On land, aquaculture requires a relatively small amount of space; building space can often be acquired at reduced cost in ungentrified city areas and aquaculture can represent an attractive, environmentally benign form of commerce. However, finfish and shellfish aquaculture operations are a source of an effluent with high concentrations of dissolved inorganic nutrients (N, P). To prevent eutrophication, the EPA is developing stringent guidelines for the release of N and P into coastal waters. An integrated recirculating aquaculture system, coupling the growth of seaweed and fish, can solve these problems for urban aquaculture facilities. Not only is the effluent remediated (the seaweed requires for growth the waste products produced by the fish), but an additional multiproduct, high-value crop can be generated. Marine aquaculture in the Northeast consists primarily of coastal pen-based salmon production and shallow benthic production of shellfish (mussels, clams, and oysters). There are very few tank-based (on land) marine aquaculture operations in the Northeast. One operation is GreatBay Aquaculture LLC (Portsmouth, NH), a land-based hatchery and grow-out facility for summer flounder and cod, high-value fish that are being sold to the U.S. and Japanese sushi and sashimi markets and to "white tablecloth" restaurants.

Our work is part of a multi-university effort (University of Connecticut, State University of New York at Purchase, University of New Hampshire, University of New Brunswick, and Shanghai Fisheries University) with GreatBay Aquaculture LLC to develop an integrated finfish/seaweed recirculating aquaculture system (RAS) suitable for urban aquaculture. The unique aspect of our RAS system is that it will be integrating the culture of finfish (i.e., summer flounder) and native species of seaweed (i.e., *Porphyra*). The red alga, "*Porphyra*", is the most valuable maricultured seaweed in the world, with an annual value of more than $1.8 billion. *Porphyra* (nori) is primarily used for food as the wrapping around sushi rolls; it is a major dietary source of taurine (controls blood cholesterol levels) and is rich in proteins, vitamins, trace minerals, and dietary fiber. On a dry weight basis, *Porphyra* can be worth more as a source of biochemicals than as food. It is the preferred source of the pigment, r-phycoerythrin, utilized as a fluorescent tag for biotechnological applications. The United States is dependent primarily upon foreign sources (i.e., China, Japan, and Korea) for nori via coastal net culture. BRVAS students are working alongside undergraduate and graduate students in the construction and operation of these systems.

The life history of *Porphyra* includes a microscopic filamentous stage (the conchocelis stage) and the more conspicuous macroscopic blade stage that grows attached to intertidal and shallow subtidal substrate. There are at least seven recognized species of *Porphyra* in the Northeast. We have begun evaluating one of these native species (*P. leucosticta*) as a candidate for the integrated RAS, because it may be one of the best sources for the sushi food industry and for r-phycoerythrin. We are developing the mass culture techniques (in both free culture or attached to nets) for this native species of *Porphyra*. We will report on the mass seeding technologies that we have developed and the specific growth rates of *P. leucosticta* at the BRVAS culture facilities.

UPDATE ON SHELLFISH RESTORATION AND REVIEW OF LOCAL HATCHERIES IN NEW JERSEY.

Gef Flimlin, Rutgers Cooperative Extension, Toms River, NJ 08755.

Cooperation among several sectors that work with water and shellfishery issues has led to two new accomplishments that combine an interest in improving both the ecology of the waterways and the potential economy of the shellfish industry in New Jersey.

In the summer of 2001, 10,000 bushels of washed oyster shell were deposited to construct a new reef in a near shore area in Keyport Harbor in western Raritan Bay. The project was spearheaded by the New York/New Jersey Baykeeper, with assistance from the National Marine Fisheries Service, Rutgers Cooperative Extension, local shellfishermen, and the NJ Department of Environmental Protection's Bureau of Shellfisheries. In a community-supported effort, 10,000 oysters, which had been raised in Taylor Floats by volunteers from the area, were deposited on the reef to establish a community. This effort of growing oysters by the volunteers continues.

Later that year in the fall, with the support from the South Jersey Economic Development District, the last oyster boat on the New Jersey Atlantic Coast moved 2,000 bushels of oyster seed to an old bed at the mouth of the Mullica River. The Fitney Bit bed will have been closed by the Bureau of Shellfisheries for a year when it is opened for public harvest. Industry representatives and Rutgers Cooperative Extension, who acquired the funds to do this work, are presently looking for more funds to expand this work.

Shellfish hatcheries in New Jersey have been reevaluating their production in light of challenges from Brown Tide blooms and unexplained hatchery mortalities.

FLOW CYTOMETRY AS A TOOL TO QUANTIFY THE OYSTER PHAGOCYTOSIS, RESPIRATORY BURST, AND APOPTOSIS. **Michael J. Goedken** and **Sylvain De Guise**, Department of Pathobiology, University of Connecticut, 61 N Eagleville Road, U-89, Storrs, CT 06269.

Infectious diseases are a significant problem in oyster aquaculture and cause immense production losses. The protozoan parasites *Perkinsus marinus* and *Haplosporidium nelsoni* have generated losses estimated in the hundreds of millions of dollars over the last 35–45 y in the Middle Atlantic states.

The relationship between parasites and oyster defense mechanisms is unclear. A better understanding of the immunopathologic association may reduce these economic losses. Defense mechanisms of the eastern oyster (*Crassostrea virginica*) were quantified at the single-cell level utilizing flow cytometry. Phagocytosis was measured using fluorescent beads. Respiratory burst activity was quantified as the increase in dichlorofluorescein-associated fluorescence upon stimulation. Apoptosis was evaluated with TUNEL assay. Three subpopulations of hemocytes (granulocytes, hyalinocytes, and intermediate cells) were identified with unique functional characteristics. Granulocytes were most active at phagocytosis and peroxide production, whereas hyalinocytes were relatively inactive. TUNEL assay application allowed quantification of hemocyte programmed cell death with temperature-dependant changes. Flow cytometry can rapidly, accurately, and directly quantify the morphology and function of a large number of individual cells, and will lead to a better understanding of the bivalve immune system.

COBIA CULTURE. **Josh Goldman**, Fins Technology, Inc., 15 Industrial Rd., Turners Fall, MA 01376.

Cobia (*Rachycentron canadum*), is considered a prime candidate for culture, given its extremely fast growth rate and excellent flesh quality. Interest in cobia culture has grown substantially in the last 5 y, fueled by reported successes in extensive, net-pen operations in Taiwan, and as U.S. researchers have gained some familiarity with captive fish. Fins Technology, with support from NOAA's National Sea Grant, has investigated a variety of aspects of intensive cobia culture in an effort to develop protocols for commercial production. We have evaluated growth and feed conversion efficiency at 10, 20, and 50 ppt salinity in artificial seawater, and have instituted routine bacterial and histological monitoring of our populations to assess the risks and develop appropriate health management strategies needed to support commercial production. During the last 2 y, we and our collaborators hope to demonstrate commercial feasibility of this promising species.

CREATING OPPORTUNITIES FOR STUDENT AQUACULTURE PROJECTS. **Eric Goodman, Colleen Cook,** and **Michael Weiss,** Friends Academy, Duck Pond Rd., Locust Valley, NY 11560.

The goal of our ongoing project is to increase awareness and participation in shellfish biology, habitat preservation, and aquaculture techniques among our peers. This group currently includes seven students in Friends Academy, our high school, as well as five students from Locust Valley and Oyster Bay, two nearby public schools on the North Shore of Long Island. The project began with a program designed as a basic introduction to shellfish aquaculture for local educators to motivate them to start similar projects in their schools. We held a series of seminars for students who showed an interest in our work and who wished to design an aquaculture project of their own. The topics of these seminars included working in the lab with algae and constructing grow-out equipment. Our next initiative was to construct a facility that was open to the public to increase the number of educational and research opportunities in the community. This facility, which is under development, is a hands-on center that includes a classroom as well as a fully functioning shellfish hatchery. We will be growing the Atlantic bay scallop (*Argopecten irradians irradians*) as well as the eastern oyster (*Crassostrea virginica*). Lessons in hatchery operation and maintenance, shellfish life cycles and anatomy, and the use of a FLUPSY are also taught in the hatchery. We hope that through our work in the center, students will use the hatchery to conduct their research relating to shellfish life cycles during the school year.

AN EXPERIMENTAL INVESTIGATION OF DIETARY FATTY ACIDS AND STEROLS AND THE IMMUNOLOGY OF THE AMERICAN OYSTER, *CRASSOSTREA VIRGINICA*: A WELL-FED OYSTER IS A HEALTHY OYSTER, N'EST-ÇE PAS? **Hélène Hégaret,** École Nationale Supérieure Agronomique de Rennes, France; **Gary H. Wikfors,** NOAA Fisheries, NEFSC, Milford, CT 06460; **Philippe Soudant,** Universite de Brest, France; **Maryse Delaporte, Jeanne Moal,** and **Jean-François Samain,** Laboratoire de Physiologie des Invertébrés, IFREMER, Brest, France.

The lipid composition of the algae fed to oysters is very important because fatty acids and sterols in the membranes of oyster cells to some extent have a dietary origin. The fatty acid and sterol composition of hemocyte membranes is thought to affect immune function, thereby linking nutritional status with ability to respond to environmental and health stresses. To investigate this linkage, we designed an experiment in which two replicates of seven feeding treatments were applied to the oyster, *Crassostrea virginica*, and hemocyte function was evaluated before and after a subsequent high-temperature stress. Twelve oysters (ca. 50 mm) were put into each of 14 computer-controlled feeding chambers. Algal diets fed at 10% and 50% daily rations (dry wt/dry wt) were LB 1077/1B (*Skeletonema costatum*), PLY429 (*Tetraselmis chui*), and a 50/50 (dry wt) mix; we also included two unfed controls. These two algae have different lipids: LB1077/1B contains the fatty acids C20:5(n-3) and C22:6(n-3) and cholesterol; whereas, PLY429 contains C20:5(n-3), but no C22:6(n-3), and 24-methyl and 24-methylene cholesterol. After 5 wk of feeding at 20°C, we sampled half of the oysters for hemocyte analyses and gill-membrane lipid composition, subjected the remaining oysters to 1 wk of high-temperature (28°C) stress, and sampled as previously. Gill membrane lipids will be analyzed by GLC (work in progress). Hemocyte function was evaluated by five methods employing the FACSCAN flow cytometer: identification of hemocytes by SYBR green fluorescence, viability by propidium iodide fluorescence, adherence and aggregation by forward- and side-scatter, phagocytosis using fluorescent plastic beads, and respiratory burst by a newly modified method using Zymosan A as the activator. These response variables were tested statistically, first using a nested ANOVA model, with feeding ration and regime as independent variables, and in second way using discriminant analysis.

Individual hemocyte functions were not affected significantly by feeding ration or regime; however, a consistent trend relating the higher ration with enhanced hemocyte function was apparent. By contrast, differences between unfed and fed oysters were, in many cases, highly significant and appreciable, with unfed oysters showing decreased function in most subpopulations of hemocytes (granulocytes, hyalinocytes, and intermediate cells). Discriminant analysis, using data from multiple hemocyte measurements, was able to differentiate between high- and low-quantity feeding treatments, as well as between the different algal diets. These findings indicate that nutrition does affect immune function in oysters, thereby mediating their response to stress.

THE ROLE OF THREE BACTERIA IN SHELL DISEASE OF THE AMERICAN LOBSTER (*HOMARUS AMERICANUS*).

Andrea Hsu, Erin Summers, and **James Estrada,** Boston University Marine Program, Marine Biological Laboratory, 7 MBL St., Woods Hole, MA, 02543; **Roxanna Smolowitz,** Marine Biological Laboratory, 7 MBL St., Woods Hole, MA 02543.

Although typically infecting impounded lobsters, lobster shell disease is becoming increasingly more prevalent in wild populations throughout the New England region. This study utilizes scanning electron microscopy (SEM) and histological analyses to describe the morphology and prevalence of bacterial cells present on carapace samples taken from two wild-caught lobsters with shell disease and one lacking any noticeable infection. SEM analysis revealed and statistical tests verified three separate morphological types of bacteria present on both carapace samples and cultures taken from shell lesions. Results from bacterial identification suggest two bacteria to be of the genus *Vibrio*, whereas the third is a *Pasteurella*-like organism. Bacteria on infected carapace were seen to concentrate on intact epicuticle, the edge of lesions, microscopic cracks and holes, and setal pores. Halo-like holes surrounded all bacterial types, closely matching the shape of the bacteria, suggesting that each bacterium is boring into the epicuticle. Healthy carapace showed substantial bacterial concentrations present only around carapace setae. Several of these bacteria were seen with small-bore holes surrounding them, but active boring and degradation of the epicuticle was minimal in contrast to the infected carapace. Histological observations show that there is a difference between the breakdown of wild and impoundment lesions. Shell lesions of wild lobsters show lattice-like cuticular remnants attached to underlying less degraded cuticle in several eroded foci. This study documents not only the presence of three bacterial species in shell disease of wild-caught New England lobsters, but also illustrates their role in the degradation of the carapace. This is the first evidence of the mechanism that is used to break down the epicuticle of the lobster shell, and suggests that different organisms are involved in causing wild and impoundment shell disease.

DERMO INVESTIGATIONS, RAZOR CLAM NURSERY TRIALS, AND PRELIMINARY BAY SCALLOP ADHESION CULTURE EFFORTS.

Richard C. Karney and **Amandine Surier,** Martha's Vineyard Shellfish Group, Inc., Box 1552, Oak Bluffs, MA 02557; **David W. Grunden,** Town of Oak Bluffs, Box 1327, Oak Bluffs, MA 02557; **Thomas E. Berry,** Martha's Vineyard Shellfish, Box 1660, Edgartown, MA 02539.

To compare the infection patterns of dermo disease (*Perkinsus marinus*) in Edgartown Great Pond and Tisbury Great Pond, cages of wild and disease-free cultured oysters were deployed in both ponds on June 20 and 21 and sampled monthly for mortality and dermo infection progression. Man-made breaches of the salt ponds' barrier beaches allowed for some manipulation of water chemistry within the ponds. Edgartown Great Pond was managed to maximize its exchange with the sea to reduce eutrophic conditions believed to be stressing its oyster population. Management in Tisbury Great Pond sought to limit exchange with the ocean in hopes of achieving salinities unfavorable to the dermo parasite. By October, infection rates in both ponds for all of the wild and two of the three groups of cultured oysters were 100%. The infection rate of one group of the cultured oysters in Tisbury Great Pond did not rise above 76%. By November, cumulative mortality of the wild oysters was 19.8% in Tisbury Great Pond and 29.5% in

Edgartown Great Pond. Mortality of the cultured oysters was 4.4% in Edgartown. The mortalities of cultured oysters at two sites in Tisbury Great Pond were 5.5% and 3.4%. The variation in mortality of the cultured oysters appeared to correlate with the densities of natural oyster beds at the sites.

In late August, seed razor clams (*Ensis directus*) with an average length of 20.1 mm were planted at two densities (54.5/ft^2 and 163.5/ft^2) in four different nursery systems—a tidal upweller, mesh-covered bottom boxes, and mesh-covered and open floating sand boxes. Final growth measurements taken in early November were poorest for the high-density tidal upweller (28.8 mm) and best for the low-density open floating sandbox (54.1 mm). In November, clam survival in the sandbox nurseries was as follows: low density/no mesh 56%; high density/no mesh 50%; high density/mesh 48%; low density/mesh 39%.

Several adhesives have been tested in efforts to develop a culture technology based on gluing bay scallops to plastic nets. A suitable adhesive has yet to be located.

SOME CULTURE STRATEGIES FOR GROWING ROTIFERS (*BRACHIONUS PLICATILIS*) AS FEED FOR AQUACULTURE APPLICATIONS. Robin Katersky, Barry Smith, Dean Perry, and **David Nelson,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460.

Rotifers are provided as first feed to larval finfish when they are absorbing their yolk sacs and their digestive systems have developed sufficiently to consume food. Marine finfish aquaculture, therefore, requires them in large numbers at these times. Rotifers can be fed marine microalgae for growth and reproduction as well as for enrichment just before they are fed to the fish.

Rotifers typically are grown in large tanks with algal culture added to the volume to replace the algal biomass previously consumed by the rotifers. Culture water is usually changed by draining the tank (and remaining algae), catching the rotifers on a screen, and resuspending them in clean water. Rotifers can consume large quantities of algae. Finfish studies at the Milford Laboratory require production of millions of rotifers. The finfish are fed daily at a density of 10 rotifers/mL in 893-L tanks. With an algal supply of 1 × 10^6 cells/mL, how does one get enough algal biomass for maximal rotifer growth in an economical space and time? We investigated two culture methods to achieve our requirements.

The first culture method investigated was to concentrate the rotifer tank using a hollow-fiber filter to remove 40 L/day of water only. The rotifer tank then was refilled with algal culture. This procedure was repeated daily, providing an average feeding of 200,000 algal cells/mL in 200- to 240-L rotifer tanks. Rotifer tanks were started with 46 rotifers/mL and reached 233 rotifers/mL in 4.8 days.

The second culture method used a different strategy. Rotifers were introduced into a full tank volume of algal culture (150 L) at a density of ~300,000 cells/mL. The rotifers then were left to grow for 4 days with only experimental samples removed. Rotifer densities consistently went from 59/mL to 232/mL in 3 days.

In all cases algae was consumed to below countable levels. The second culture strategy was much less labor intensive than both the traditional and the first method. The second, or all-algae method, reduced labor by over 50% and required three culture vessels to meet demand. For the remainder of the larval rearing period (summer 2001), the all-algae system was used for rotifer production because of its reliability and ease of use. This system produced an average of 30 × 10^6 rotifers/day.

These experiments, together with past work, indicate that there is much more potential for optimizing the culture of rotifers.

ASSESSING HABITAT VALUE OF MODIFIED RACK AND BAG AQUACULTURE GEAR IN COMPARISON WITH SUBMERGED AQUATIC VEGETATION, IN PARTICULAR, AN EELGRASS (*ZOSTERA MARINA*) BED. Brian Kilpatrick, Joseph DeAlteris, and **Robert Rheault,** Department of Fisheries, Animal, and Veterinary Science, University of Rhode Island, Kingston, RI 02882.

Submerged aquatic vegetation (SAV) has attracted considerable attention in recent years because of its role as an essential fish habitat necessary for sustainable fish production. Recent regulations that protect SAV have been critical in conserving and restoring this resource. Current policies that serve to protect SAV have affected applications for construction, docks, dredging, and aquaculture. Opponents of shellfish aquaculture operations argue that the gear used for the grow-out phase of the shellfish reduces the potential for SAV restoration, and may negatively impact estuarine ecosystems.

This study was conducted to compare and contrast habitat value of modified rack and bag aquaculture gear (MRBAG), submerged aquatic vegetation (SAV), and a nonvegetated shallow seabed (NVSB). Habitat value is defined herein by descriptive species diversity statistics and each habitat's ability to support an abundance of organisms throughout the year. The study took place over the course of 1 y, in which each of the three habitats was studied at the end of each season (three replicate samples per habitat). Sampling was performed in Pt. Judith Pond, an estuarine pond in Rhode Island that discharges directly into Block Island Sound. Specially constructed lift nets were used to sample the aquaculture gear, whereas the remaining two habitats were sampled using a drop-net of identical size and a venturi-driven suction sampler. Organisms (>5 mm) in each sample were identified, enumerated, and measured to the nearest millimeter. Environmental data were collected at the time of each sampling period to discern similarities and/or differences among the three habitats. Biofouling organisms were measured in terms of percent cover, and an average surface area (square centimeters per square meter of seabed) of each biofouling phyla and/or class was estimated for each habitat and season. Structural components, in particular, emergent surface area, were measured to determine their role in providing habitat.

Environmental parameters (temperature, salinity, and dissolved oxygen) were not significant between habitats but were significantly different between seasons. Sediment type was primarily sand and was not found to be significantly different ($P > 0.05$) between habitats when the gravel size component (shell hash due to the aquaculture operation) was removed from the MRBAG habitat. The MRBAG habitat supports a significantly higher abundance of organisms per unit area (m^2) of seabed throughout the year. Total numbers of specimens collected are as follows: MRBAG, 6,777 individuals; SAV, 577 individuals; NVSB, 211 individuals. Species richness is consistently higher throughout the sampling periods in the MRBAG habitat as compared to the SAV and NVSB habitats. A two-way ANOVA using the richness estimates generated by the jackknife procedure using quadrat samples (Heltshe and Forrester 1983) indicated significant differences between all three habitats ($P < 0.001$). A Tukey HSD test indicated that MRBAG > SAV > NVSB in terms of species richness values. The species diversity of each habitat was computed using the Shannon-Weiner Index and showed a significant difference ($P < 0.001$) using a two-way ANOVA between habitats. A Tukey HSD test indicated that there were no differences between MRBAG and SAV habitats, but there were differences between MRBAG and NVSB habitats. The Smith and Wilson measure of evenness was used to describe how each habitat was organized in terms of species abundance proportions. MRBAG habitat had a consistently lower evenness value because the MRBAG habitat was dominated by a few species (*Neopanopeus sayi, Tautogolabrus adspersus, Mytilus edulis).* Habitat structural complexity was determined using emergent surface area of the structures found within each habitat. A two-way ANOVA indicated a significant difference ($P < 0.001$) between the MRBAG and SAV habitats in terms of surface area of structure (MRBAG or SAV) per square meter of seabed. These findings suggest that shellfish aquaculture gear provides habitat to many organisms throughout the year and may be ecologically beneficial to many native species of recreationally and commercially important fish and invertebrates, especially in the early life stages of these resources. This research is the first step in determining habitat value for shellfish aquaculture gear.

THE CULTURE OF BLACK PEARL OYSTERS ON SUBSURFACE LONGLINES IN SAVU SAVU, FIJI. **Gordon King,** Taylor Resources, Inc., 130 SE Lynch Rd., Shelton, WA 98584.

Continuing an informal company policy to diversify into new species and geographical areas, Taylor United, Inc., used family knowledge and contacts to develop a Black Pearl Oyster Farm in Savu Savu Bay on the Island of Vanua Levu in the island nation of Fiji.

The subsurface longline system as promoted by Dr. John Bonardelli was adapted for grow-out of the black pearl oyster, *Pinctada margaritifera.* The installation and development of the farm was complicated by political instability and an armed coup in Fiji. Despite these difficulties, the farm now has more than 30 longlines and 30,000 oysters, with several hundred pearls already harvested and several thousand due for harvest; many more are being implanted in 2002. Taylor Resources is employing a three-pronged approach for production of oysters for implantation: spat collection, buying mature oysters, and a joint-venture hatchery. It is believed that the farm will be a solid source of income for the company and is already providing important employment and revenue for the local Fijian population.

URBAN COMMUNITY MEETS AQUACULTURE: A CASE STUDY IN THE NORTHWEST. **Gordon King,** Taylor Resources, Inc., 130 SE Lynch Rd., Shelton, WA 98584.

Taylor United, Inc., an established shellfish farming company in Washington State, sought to expand their suspension mussel farming operation beginning in 1995. This led to a series of events including the formation of a local association to stop further aquaculture development; the production of a sophisticated anti-aquaculture propaganda video; many hundreds of protest letters to the local politicians, the press, and agencies; the requirement by Thurston County for Taylor United to complete an EIS; and a citizen law suit under the Clean Water Act claiming that the company should be required to get an NPDES permit.

Seven years and many tens of thousands of dollars later, the expansion is still on hold. The presentation documents this series of events and explores some of the various parties' attitudes, and asks how much of the friction is due to *bona fide* environmental concerns and how much is due to the gulf in knowledge and understanding between urban Americans and the industries that produce their food?

PROGRESS WITH CULTURING THE RAZOR CLAM (*ENSIS DIRECTUS*). **Dale Leavitt, William Burt, Diane Murphy,** and **Rebecca Hanson,** SouthEastern Massachusetts Aquaculture Center, Massachusetts Maritime Academy, Buzzards Bay, MA 02532.

As reported in 2001, SEMAC has embarked on a study to assess the feasibility of farming the razor clam (*Ensis directus*) in the northeast. Operating on research funds from the Northeast Regional Aquaculture Center (USDA-CSREES), we have contracted with a commercial shellfish hatchery (Aquaculture Research Corporation, Dennis, MA) to produce 1-cm seed razor clams for distribution to commercial shellfish growers throughout the northeast. The growers' role is to test existing or new technology for grow-out of a product for market. This presentation will provide an update of the results of this study after year 1.

Approximately 4 million razor clam larvae were spawned in the hatchery and reared through the nursery stage using conventional hatchery technology similar to that used for the surf clam (*Spisula solidissima*). Roughly 150,000 1-cm juveniles were delivered to SEMAC in July for distribution to the growers. Although the hatchery process needs refinement to increase the larval and early juvenile survival rate, we demonstrated that the hatchery stage of razor clam production is feasible and can potentially produce enough juveniles to sustain a commercial effort in razor clam farming. Adjustments to the hatchery procedures are currently being made as we enter our second year of hatchery production under this project.

The 2-cm juvenile razor clams were distributed to 10 commercial shellfish growers, ranging from New Jersey to Massachusetts, who had been selected through a competitive proposal process. Each grower received an allotment of seed with funds to construct their proposed culture system. Technology being tested ranges from conventional quahog culture techniques using netted raceways to floating culture trays and containment systems deployed on the bottom. The seed were distributed late in the growing season this year, but it allowed the growers to field test their proposed grow-out system for modification and improvement in anticipation of next year's larger scale seed distribution.

The two parameters of interest during this preliminary stage of the study were recovery of planted individuals and their growth as measured by a change in length. Recovery of juvenile razor clams using a variety of field grow-out technologies varied from very poor, where intensive digging within the grow-out area uncovered few individuals using a conventional quahog netted raceway, to very high, where two 4-in. cores produced more than 50 living individuals in a boarded and netted raceway. Growth rate also varied from very little increase in seed size during the 11-wk test period to significant growth where the 2-cm seed had grown to more than 5.4 cm in length. Given these preliminary results, the prospect of farming razor clams seems to be achievable and the improvement of hatchery and rearing technology will continue through the next growing season.

A COMPARISON OF SURVIVAL IN JUVENILE *ARGOPECTEN IRRADIANS IRRADIANS* USING VARIOUS CULTURE TECHNIQUES AT THE SOUND SCHOOL REGIONAL AQUACULTURE CENTER. **Kathryn R. Markey** and **John J. Roy,** The Sound School, 60 South Water St., New Haven, CT 06519.

Shellfish aquaculture is expanding in the northeastern United States. With the increased interest in commercial aquaculture has come the advancement of the techniques employed by the growers. As such, The Sound School Regional Aquaculture Center is rapidly expanding the portion of the school's curriculum that deals with shellfish aquaculture. We have successfully sought assistance from both commercial growers and scientists dedicated to the advancement of aquaculture. They have supported us in our endeavors to provide our students with a state-of-the-art education whenever possible. We have been involved in the culture of both oysters and hard clams for several years and are currently engaged in our second year of working with *Argopecten irradians irradians*, the bay scallop, at the school.

This year, in August, the National Marine Fisheries Service in Milford, Connecticut, donated approximately 3,000 *Argopecten irradians irradians* to the school. The Groton Shellfish Commission made arrangements with our students to over-winter 6,000 >20 mm and 26,000 10- to 15-mm bay scallops at the school. In addition, the Noank Aquaculture Cooperative made 20,000 4- to 6-mm bay scallops available to our program for a nominal charge. In our previous attempts to work with bay scallops, we concerned ourselves with monitoring growth as well as survival. We have learned, as have many in the industry, that when mortality in a scallop crop reaches 100%, most concerns with growth are unfounded. This year we have refocused our experimental regimes to deal with the issues of survival of the scallops over winter.

A variety of culture techniques have been employed to overwinter the juvenile bay scallops. Cages and ADPI bags, holding scallops at +25 mm in low densities, have been successful to date, with a 91% survival rate. Three upwellers have been designed. One is located on a fixed pier outside the school. The other two were built inside a wet lab in the school. All three upwellers have unique design modifications. The outside upweller holds approximately 1,200 +25-mm scallops and mortalities have been <3% of the total. More than 40,000 bay scallops of various sizes have been successfully held in the inside upwellers, where we attempt to maintain water temperature between 13 and 18°C and provide the juvenile bay scallops with supplemental feedings of microalgae. To date, mortalities in these systems have been <10%. Experience has shown that increased mortalities in the juvenile bay scallops are to be expected during the winter months. Complicating matters further are the issues that cold weather creates with the mechanical equipment. Pump failure or frozen pipes will dramatically increase mortality. However, there is no substitute for experience. With each setback, we learn, and each time we learn, we advance our techniques so that the next year's students have an increased likelihood of success.

SUSPENDED AQUACULTURE DEVELOPMENT IN CONNECTICUT. **Paul D. Maugle,** Mohegan Aquaculture LLC, 5 Crow Hill Road, Uncasville, CT 06382.

Aquaculture in Connecticut has for the last 150 y traditionally harvested native set shellfish from the bottom. Connecticut's oysters are the most valued oysters reared in the United States. Knowing that this approach is not inherently sustainable in eastern Connecticut waters, Mohegan Aquaculture LLC has chosen to have at its core the production of oysters in suspended longlines and floating cage systems (FADPI) culture systems.

It is not only necessary to treat the natural resource as a renewable resource, it is also necessary for the business to set up systems that can provide a sustained income. Traditional approaches to nursery rearing seed stock in the Long Island Sound, and in fact the approach taken along the entire east coast of the United States, is small scale. East coast floating upwelling systems (FLUPSY) development has been a bottleneck to furthering successful aquaculture of culchless oysters. In a FLUPSY, shellfish are nursery-reared from 1.5 to 25 mm. Current east coast FLUPSY technology produces about 800,000 to 1 million seed stock per FLUPSY and uses the labor of two personnel. West coast technology produces 8 to 12 million stockable seed per FLUPSY with two personnel.

The grow-out process plans will initially focus on producing hard clams for shellfish habitat restoration and individual culchless oysters. Hatchery-produced hard clams are reared in FLUPSY until they reach 8–12 mm, and are then seeded into our nursery areas. Oysters reared in the Stonington hatchery are transferred to the FLUPSY at 2.5–3 mm and reared until they reach 20–25 mm. Seed oysters are grown in floating cage systems or in trays along submerged longlines. Once the shellfish reach >50 mm, they are tumbled and transferred to suspended oyster rearing trays for rearing to market size.

To accommodate sail boating and other recreational activities, these tray units hang at regular intervals from a submerged longline 10 ft below the surface in waters that range from 18 to 28 ft at MLT.

Sustained rearing operation will enhance and sustain recreational shellfish activities because each spawn will bring new shellfish seed into the environment. These operations will increase essential fish nursery habitat, remove bacterial and nitrogen from coastal waters, mitigate coastal eutrophication, and serve as an environmental sentinel.

IT TAKES A COMMUNITY TO GROW A SCALLOP. Mary F. Morgan, Kathleen K. Becker, and **Kim Tetrault,** Cornell Cooperative Extension of Suffolk County, Marine Environmental Learning Center, Southold, NY 11791.

Cornell Cooperative Extension of Suffolk County, New York, is in the second year of an expansion of its Marine Program to include a community-based shellfish restoration model to foster stewardship of the marine environment. The project, called SPAT (Special Projects in Aquaculture Training) is based on the understanding that enhancement of shellfish beds contributes greatly to the health of estuarine ecosystems, and that local communities can play a significant role in stewardship and restoration. Bay scallops, *Argopecten irradians irradians*, hard clams, *Mercenaria mercenaria notata*, and eastern oysters, *Crassostrea virginica*, are commercially, recreationally, ecologically, and historically important species to the Peconic Estuary. However, currently the estuary supports only 1% of its historic oyster stocks and less than 1% of its historic scallop stocks, due in large part to the occurrence of brown tide algal blooms and its effects on habitat and shellfish health.

The SPAT project incorporates a community-based shellfish enhancement effort with intensive aquaculture training and information gathering. The active membership is currently 191 families from 41 different communities throughout Suffolk County. The families are currently in training to become Master Shellfish Gardeners, learning the process of growing local shellfish species in containment and collecting data on growth rates and survival. Each participant has been licensed by the NYS Department of Environmental Conservation and local townships to possess shellfish under a scientific collector's permit. In addition, more than 2000 volunteer hours have been donated to date to assist in culturing and planting millions of seed clams, oysters, and scallops in local waterways and select test plots. Dozens of participants assisted in a 250,000 bay scallop relay effort in March at Goose Creek, Southold. A planting of millions of seed clams took place with more than 30 community members at Cedar Beach Creek, in Southold, in August. Thousand of eastern oysters are being grown in containment to adult size in 48 local creeks and embayments. From June to December, two dozen participants have lent their time, effort, and expertise to build a community-operated shellfish hatchery on location, which will concentrate on the culture of bay scallops. The hands-on transfer of techniques that enable community participants, be they high school students, local business owners, or retired professionals, to restore locally important marine resources goes a long way toward raising awareness and developing a stewardship ethic within communities.

BAY SCALLOP (*ARGOPECTEN IRRADIANS IRRADIANS*) RESTORATION ON CAPE COD. Diane Murphy, Dale Leavitt, Bill Burt, and **Bill Clark,** Cape Cod Cooperative Extension, P.O. Box 367, Deeds & Probate Building, Barnstable, MA 02630.

The bay scallop (*Argopecten irradians irradians*) fishery has long held a historic supplemental niche for Cape Cod and southeastern Massachusetts fishermen. However, within the last 15–20 y, bay scallop populations have experienced a dramatic decline, with some localized extirpations. Some suggested causes for this decline include habitat degradation in the form of nutrient enrichment and loss of eelgrass beds as well as increased predation from introduced species such as green crabs (*Carcinus maenus*).

In 1999, in response to the diminished stocks of wild scallops on Cape Cod, a collaborative restoration effort was initiated between Cape Cod Cooperative Extension, SouthEastern Massachusetts Aquaculture Center (SEMAC), and selected Barnstable County municipalities. Why bay scallops? Rapid growth rate, high market value, unstable supply, coupled with the evidence of declining and/or absent natural populations from historically productive areas suggest that bay scallops would be viable candidates for enhancement purposes. Pursuant to an exhaustive review of current information available on the bay scallop, a regional workshop was held to design an effective restoration program. It was concluded that spawning sanctuaries would provide the best means of creating self-sustaining scallop stocks for commercial and recreational fishing purposes.

Now in its third year, the Barnstable County restoration program consists of purchasing small scallop seed derived from local broodstock in late summer to over-winter in off-bottom cages. These cages make optimal use of the water column for filter-feeding, as well as reducing predation and siltation. The following spring, scallop survival is assessed and scallops are redeployed into floating spawning sanctuaries sited in historically productive areas. Embayments are chosen with the greatest potential of larval entrainment—avoiding sites with extreme tidal fluxes to ensure localized settlement of seed. Optimal stocking densities also increase the likelihood of successful spawning. Spat bags are deployed in close proximity to the spawning sanctuaries in order to monitor recruitment. In addition, genetic fingerprinting (using RAPD-PCR) is being used to evaluate the success of the bay scallop restoration program.

EFFECTS OF *CRASSOSTREA VIRGINICA* POPULATIONS ON SEDIMENTATION, PHYTOPLANKTON SPECIES COMPOSITION, AND AMMONIA CYCLING IN EXPERIMENTAL MESOCOSMS.

Jennifer Mugg-Pietros and **Michael A. Rice,** Department of Fisheries, Animal and Veterinary Science, University of Rhode Island, Kingston, RI 02881.

To determine the effects of oyster populations on water quality, a mesocosm study was performed from June to October 2000. Mesocosms with a volume of 13,000 L were used, in which there were triplicate control tanks without oysters and triplicate experimental tanks each with 200 oysters (≈35 mm in valve height; nominally filtering about 55 L day^{-1} ind^{-1}). Experiments were run sequentially in time for 3-wk periods, with water exchange rates ranging from 0% to 100% per day (0–13,000 L day^{-1}). Several parameters were measured and compared between the control and experimental tanks, including chlorophyll-a, particulate organic and inorganic matter, sedimentation rates, nitrate, ammonia, phytoplankton species and numbers, and oyster growth rates. There were no significant ($P < 0.05$) differences between tanks for most parameters, with the exceptions of rates of sedimentation and species composition of phytoplankton in the water column. Diatoms of the genus *Nitzschia* were predominant in mesocosms with oysters; in control tanks, *Skeletonema* were dominant. Rates of ammonia excretion by oysters of various sizes were determined by the sensitive salicylate-hypochlorite method, allowing for rapid determination of excretion rates to minimize biases introduced by volatilization or transformation of the ammonia over time. The excretion of ammonia by oysters can be described by the allometric equation $E = 50.65w^{0.6992}$, when E is the excretion rate in μg NH_3-N hr^{-1} and w is the dry soft tissue weight in g. On the basis of these data, it would be expected in the 3-wk experimental period that an additional 470 μg L^{-1} ammonia above the average control concentrations of about 40 μg L^{-1} would be present in each mesocosm with oysters, but no significant difference was noted between the experimental and control tanks. This suggests that there is rapid cycling of ammonia, perhaps by uptake by the rapidly regenerating phytoplankton populations.

This is publication number 3910 of the College of the Environment and Life Sciences at the University of Rhode Island, with support from the RIAES under project number H-886.

A REVIEW OF DISEASES IN THE BAY SCALLOP (*ARGOPECTEN IRRADIANS IRRADIANS*) AND SOME OBSERVATIONS ON MORTALITIES AT THE MILFORD LABORATORY.

Steven Pitchford and **Richard Robohm,** USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460.

Various diseases and other causes of mortality in the bay scallop, *Argopecten irradians irradians*, will be reviewed, especially those that have been encountered historically and reported during hatchery and grow-out in the northeast Atlantic region. Unlike some of the other cultured bivalve species such as the eastern oyster, *Crassostrea virginica*, which is affected by MSX and dermo, the adult bay scallop does not appear to be susceptible to specific pathogenic agents that can cause widespread epizootics. Examples of infections in bay scallops to be discussed briefly include those caused by prokaryotes (rickettsia, chlamydia, *Vibrio* ssp.), protozoans, algae, and fungi.

As part of larger studies relating to immune system function and disease resistance in bay scallops, a program to screen for potential pathogenic targets was started in 1994. More than 70 bacterial isolates, the majority of which were *Vibrio* sp., were recovered from dead and moribund larval and adult bay scallops. High-concentration (approximately 10^6 bacteria/larvae) screening assays were conducted with 46 of the strains. Seven of these caused >80% mortality. Next, 1,000 2-day-old larvae/L were exposed in 48 h, using serial dilution challenges with the seven bacteria. Only two isolates were considered to be pathogenic for larvae, with median lethal concentrations (LC_{50}) of 8.65×10^2 and 1.98×10^3 colony forming units (cfu)/mL after 48 h. Following the crash of a bay scallop larval culture in 1998 at the Milford laboratory, monitoring of the cultures, the ambient seawater, and algal food sources for potential bacterial targets also was initiated.

Highlights of the monitoring program include consistent high counts of *Vibrio* sp. for 1 wk following periodic, hot, freshwater flushing of the seawater lines. These high bacterial loads may have resulted from the large amount of dissolved and undissolved organic matter that remained in the piping system. In addition, newly established mass algal cultures also would invariably show very high numbers of *Vibrio* sp. (>10^5 cfu/mL) soon after being started; however, the counts from these cultures would decrease to near 0 cfu/mL, usually after 4–8 wk.

Other occurrences of high mortality at the Milford laboratory also will be discussed; these include events with a possible infectious disease etiology and those where increased mortality resulted from biotic and abiotic causes, such as overcrowding and fouling. Several episodes of gas bubble trauma have resulted in mass mortalities, killing 75%–100% of adult scallops in very short periods. Over-wintering mortalities routinely reach 40% or even higher in cold winters, when water temperatures approach 0°C.

SHELLFISH AQUACULTURE'S EFFECT ON TOTAL ORGANIC CARBON (TOC) IN THE BENTHOS.

Perry Raso and **Michael A. Rice,** Department of Fisheries, Animal & Veterinary Science, University of Rhode Island, Kingston, RI 02881.

Rhode Island waters provide a suitable habitat for shellfish aquaculture. Rhode Island waters are also highly valued by both local residents and tourists. If shellfish aquaculture is going to expand as a successful industry in Rhode Island, it must progress in a manner that does not negatively affect the estuary or bay in which it is conducted. To examine the effects of shellfish aquaculture on the benthos, sediment samples were tested for total organic carbon (TOC). Fifteen 0.5-L sediment samples were taken at each of 14 different shellfish aquaculture leases in Rhode Island waters. Five samples were taken within the lease; five within 10 m of the lease, and five no less than 100 m from the lease in a similar water body (depth, flow, distance from shore). Results showed normal variance between TOC levels of samples taken within, around, and away from aquaculture leases. Mean TOC of all samples away from the lease was 1.48%, 1.49% near the lease, and 1.21% inside the lease, with confidence intervals overlapping. This study provides data showing that shellfish aquaculture, at the scale that it is currently practiced in Rhode Island, does not significantly affect TOC levels in the benthos.

This study is partially funded by RIAES project number H-886 and is publication number 3918 of CELS-URI.

INDUSTRIAL-SCALE SCALLOP CULTURE IN CHILE—THE C.M.I. EXPERIENCE.

Edwin Rhodes, Aquatecnics, LLC, Milford, CT 06460.

Cultivos Marinos Internacionales, S.A. (CMI) is the largest scallop aquaculture company in the world. CMI grows *Argopecten purpuratus*, native to Chile and Peru. Seed for the operation are primarily hatchery-produced, but seed collection is also employed. The original concept of producing 5-mm seed from a land-based hatchery and nursery did not work reliably, but settling hatchery-produced larvae on plastic mesh and putting them directly into the sea suspended from longlines proved to be successful. The scallops are subsequently grown in two pearl net stages, and three lantern net stages, all on longlines. CMI leases more than 1100 hectares of growing area, split about evenly between two bays about 300 miles apart, and uses a total of about 1,500 longlines, each 200 m long. Net changes to control fouling and to adjust scallop density are done on land in one bay, and from barges in the other. Scallops reach the market size of 80 mm shell height in 18 mo, and have an adductor muscle plus roe weight yield of 20 g each. CMI's production in the mid 1990s exceeded 5 million scallops/mo. Final product form is usually individually quick frozen (IQF), and virtually all of the scallops are exported from Chile to France.

THE DEVELOPMENT OF AN INSTRUCTIONAL SHELLFISH HATCHERY: A COLLABORATIVE EFFORT BETWEEN AEROS CULTURED OYSTER CO. AND THE SOUND SCHOOL REGIONAL AQUACULTURE CENTER.

Karen Rivara, Aeros Cultured Oyster Company, 100 Main St., Noank, CT 06340; **Amber L. Beitler** and **John J. Roy,** The Sound School, 60 South Water St., New Haven, CT 06519.

The Sound School Regional Aquaculture Center, in cooperation with Aeros Cultured Oyster Company, designed the Interdistrict Marine Educational Program's Instructional Shellfish Hatchery (IMEP/ISH). The Instructional Shellfish Hatchery program is an Interdistrict Cooperative Grant and is funded by the Office of Urban and Priority School Districts of the Connecticut State Department of Education. The IMEP/ISH project was formed to promote outcome-based learning between science classes from several coastal Connecticut high schools. The IMEP/ISH incorporates the vocational agriculture attitude of "learning through doing" as the method of education that best enables young researchers to conceptualize abstract points in their investigations as well as providing them with the techniques necessary to achieve the definable outcomes being sought.

The IMEP/ISH was constructed in the Purity Processed Seafood building at the Noank Shipyard in Noank, Connecticut. The program began on May 7 and finished on May 31, 2001. During that time period, Karen Rivara of Aeros, in conjunction with staff from The Sound School and instructors from the participating schools successfully implemented 10 laboratory lessons that had been designed for the IMEP/ISH curriculum. The laboratory lessons each considered an aspect of shellfish husbandry. The lessons included the following topics: water quality, shellfish biology, bivalve reproduction and spawning techniques, microalgae culture, hatchery technology, nursery systems, grow-out technology, shellfish health, harvest and handling methods, and depuration techniques.

The Sound School acted as host school for the project. Ella T. Grasso/Southeastern Vocational Technical School, Groton, Connecticut, functioned as a partner school in the program, providing the necessary benchtop space (in the school's BET lab facilities) for the shellfish dissection and the shellfish health laboratories. Students from Ledyard High School's aquaculture classes (VoAg Department) participated in the program as well. When the program was completed, 55 different students had participated in 199 student days of laboratory activities involving the major aspects of shellfish culture as practiced by professional aquaculturalists in Long Island Sound.

THE EAST COAST SHELLFISH GROWERS ASSOCIATION: A WORK IN PROGRESS.

Karen Rivara, East End Marine Farmers Association, Southold, NY 11971.

During the last 25 y, shellfish aquaculture has grown on the East Coast of the United States despite many obstacles. Newcomers in the industry come from many sectors of the economy, from retired schoolteachers and recent college graduates, to members of the traditional fisheries who look to aquaculture to maintain a sustainable living on the water. Established shellfish companies continue to use and improve various culture methods to meet the challenges of consistent production presented by losses due to disease and the loss of good cultivation areas.

Other stakeholders in the marine environment have challenged the growth of this industry. This impediment to the growth and survival of shellfish aquaculture stems predominantly from a lack of understanding regarding the actual impacts of the shellfish aquaculture industry. Those who are opposed to the growth of this industry overlook many of the benefits of shellfish aquaculture. In other cases, shellfish aquaculture is viewed as an impediment to the development of other industries in the marine environment. Unfortunately, those who are against the growth of the industry have in many cases taken their grievances to legislators and the press, further fostering a lack of understanding and animosity toward the industry. Too often aquaculturalists are put in the position of having to take time from growing their businesses to defend them against unreasonable public opposition.

The shellfish aquaculture industry clearly needs to become organized. We need to establish an East Coast Shellfish Growers Association (ECSGA) that will identify socio-political obstacles and work to remove them, will work in a proactive way with other stakeholders, and will develop a public outreach/public awareness protocol that will prevent the industry from constantly having to defend itself. The ECSGA would also take the lead to implement best management practices to guide individuals involved in shellfish cultivation as well as to inform legislators and other policy makers.

It is important that this association be industry-driven, but involve participation from related areas of the industry such as public shellfish aquaculture facilities, state extension programs, academia, government, and regulatory agencies. This year presents a unique opportunity to organize an East Coast Shellfish Growers Association. A roundtable discussion at the 22nd Milford Aquaculture Seminar will be devoted to the formulation of this association. We will discuss organizational considerations such as geographic scope, types of membership, mission statement, and the concerns of the industry that this association will address. In April, the National Shellfisheries Association annual meeting will be held in Mystic, Connecticut. This affords the shellfish aquaculture industry another opportunity to continue the process of forming an association. The goal of the ECSGA meeting at NSA in Mystic would be to continue discussion regarding the formation of the association and establish a committee of interested individuals that would also serve as the first Board of Directors. These individuals would complete the legal process of forming an association, establishing an office, setting meeting dates, and establishing membership.

There are many reasons why the East Coast shellfish aquaculture industry should begin to organize. We need to take advantage of the opportunity to do so this year.

HEAVY METAL SURVEY OF *FUCUS SPIRALIS* COLLECTED FROM SOUTHWESTERN LONG ISLAND SOUND.

René Sanz, Sherry Lonergan, Jennifer Sutorius, and **Dania Lieberthal,** Bridgeport Regional Vocational Aquaculture School, 60 St. Stephens Road, Bridgeport, CT 06605.

Fucus spiralis, commonly known as rockweed, is a brown alga found in the upper intertidal and midtidal zones of the North Atlantic. Similar to red algae, *Fucus spiralis* contains phycocolloids, which are valuable emulsifiers used in the manufacture of food, pharmaceutical, and healthcare products. In general, macroalgae take in heavy metals, some of which are beneficial for nutrition and others that are possibly harmful to algae and humans in high levels. These heavy metals accumulate in algae, which makes them useful in biomonitoring, marine pollution assessment, and phytoremediation. Because algae are becoming more popular for use in food, industry, and environmental applications, determining heavy metal concentrations is important to a wide range of audiences.

Samples from five sites known as, sites A, B, C, D, and E, located in southwestern Long Island Sound, were surveyed to determine the concentration of heavy metal intake by *Fucus spiralis*. The heavy metals being tested include: cadmium (Cd), chromium (Ca), copper (Cu), lead (Pb), and zinc (Zn). Samples were collected within 1 h of low tide. After samples were collected, the alga was washed, oven-dried, ground, and digested using a microwave lab station. Samples were then analyzed using atomic absorption spectroscopy. Some samples were analyzed in replicate to ensure quality control. Collection for test samples began on October 26, 2001, with the most current being December 19, 2001. Results of the sampling were as follows:

- Cadmium (Cd) at site A ranged from below detectable limits (n/d) to 0.04 μg/g; site B value was 0.04 μg/g; values at sites C and D were all n/d; and site E value ranged from n/d to 0.04 μg/g.
- Copper (Cu) at site A was 0.18 μg/g; site B value was 0.23 μg/g; site C values ranged from 0.036 to 0.0582 μg/g; site D values ranged from 0.048 to 0.1104 μg/g; and site E values ranged from 0.048 to 0.26 μg/g.
- Chromium (Ca) at site A was 0.02 μg/g; site B value was 0.03 μg/g; site E values ranged from n/d to 0.026 μg/g; site D values ranged from n/d to 0.082 μg/g; and site D values ranged from n/d to 0.083 μg/g.
- Lead (Pb) at site A was 0.48 μg/g; site B value was 0.5 μg/g; site C values ranged from n/d to 0.134 μg/g; site D values ranged from 0.022 to 0.14 μg/g; and site E values ranged from 0.02 to 0.51 μg/g.

- Zinc (Zn) at site A was 0.64 μg/g; site B value was 0.7 μg/g; site C values ranged from 0.1882 to 0.2332 μg/g; site D ranged from 0.06 to 0.214 μg/g; and site E ranged from 0.136 to 0.86 μg/g.

Analysis of these metals will continue at additional sites in Long Island Sound. Baseline data will be used in future comparative research of this and other algal species.

AQUACULTURE ACTIVITIES IN BROOKLYN, NEW YORK?

Martin P. Schreibman, Chester Zarnoch, John T. Tanacredi, Lucia Magliulo-Cepriano, Jacob Raz, and **Stefano Diomede,** Aquatic Research and Environmental Assessment Center (AREAC), Brooklyn College, 2900 Bedford Avenue, Brooklyn, NY 11210.

In Brooklyn College's Aquatic Research and Environmental Assessment Center (AREAC), state-of-the-art recirculating aquaculture systems (RAS) have been used to conduct a number of diverse aquaculture and environmental assessment/restoration programs. These projects include the following topics.

Finfish aquaculture: Our program consists of induction of spawning and/or grow-out of commercially important species. Our achievements include production of market-size walleye and tilapia, as well as the culture of winter and summer flounder.

Bivalve aquaculture: Recirculating systems for downwelling and broodstock conditioning were utilized in the culture of hard clams (*Mercenaria mercenaria*). Seawater used in the static algal and larval cultures was biologically and chemically treated and then reused. In its first season of operation, the hatchery produced 2 million hard clams; when 2.0 mm in shell length, they were moved out to a field site in Jamaica Bay, New York. An intensive study is underway to measure the survival and physiological condition of juvenile hard clams during the winter period. In addition, oyster seed were cultured in Taylor float systems at two sites in Jamaica Bay to monitor growth and water quality.

Ornamental and research aquaculture: AREAC has more than 600 aquaria dedicated to the culture of freshwater species for fish hobbyists and scientific research. Soft coral is also being propagated.

Captive breeding of horseshoe crabs: Adult horseshoe crabs were spawned in AREAC in July 2001. Developing animals were cultured to determine optimum temperature, medium, and nutritional parameters in recirculating systems. Currently, we have 2,500 horseshoe crabs with carapace widths ranging between 2 and 35 mm.

Environmental assessment and restoration: The impact of endocrine-disrupting chemical pollutants on freshwater and saltwater fishes has been studied for a number of years in AREAC. A program of field and laboratory experiments has begun to examine the effects of nonylphenols on winter flounder reproduction (in collaboration with Dr. Anne McElroy, SUNYSB). In another project, we have simulated the Hudson River by creating microcosms in our recirculating aquaculture systems in order to study the incidence of liver tumors and mortality in Atlantic tomcods.

Educational outreach programs: AREAC is developing curricula for pre-K–12th grade students, teachers, and their families to enhance their knowledge and teaching ability on issues relating to aquaculture and the environment.

Our programs have been funded by NPS, USACE, DEC, Con Edison, and CUNY.

SHELLFISH AQUACULTURE: GOOD FOR THE ECONOMY, GOOD FOR THE ENVIRONMENT, GOOD FOR YOU!

Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, 1080 Shennecossett Road, Groton, CT 06340.

The United States ranks 3rd worldwide in the consumption of seafood, yet it ranks 11th in aquaculture production, with just 1.1% of global production by weight. World production of bivalve mollusks has increased steadily over the past decade, and 80% of world bivalve production is cultured product. Oysters comprise 35% of that total; clams and arkshells combined constitute about 33%, with China producing approximately 64% of the world total. The United States ranks 3rd among bivalve-producing nations and only 19th in production via aquaculture. Possible reasons for these discrepancies and the benefits of shellfish aquaculture will be delineated and discussed.

HEALTH MANAGEMENT GUIDELINES FOR SHELLFISH CULTURE IN THE NORTHEASTERN UNITED STATES.

Roxanna Smolowitz, Marine Biological Laboratory, Woods Hole, MA 02543; **Susan Ford,** Rutgers University, Port Norris, NJ 08349; **Lisa Ragone-Calvo,** Virginia Institute of Marine Science, Gloucester Point, VA 23062.

Bivalve diseases can cause significant losses of both cultured and wild stocks. To prevent the spread of disease among populations, most states generally do not allow the importation of bivalve shellfish unless the animals are considered to be "disease free." As a result, examinations for disease have become a necessary prerequisite for determining health status. However, shellfish transfer regulations vary by state, often appear capricious, and complicate the sale and transport of commercially important seed. Furthermore, both regulators and producers have few guidelines that would help them respond to and manage disease outbreaks, when they occur. Lines of communication need to be developed between diverse but knowledgeable groups to produce a set of standardized monitoring/management guidelines for use by state regulators. We describe a project intended to provide a set of uniform, scientifically based recommendations for the health management of commercially important bivalve species in the northeastern United States.

The guidelines will be produced as a result of a series of workshops and meetings proposed for the next 2 y that will include scientists, industry, regulators, and extension agents in the northeastern United States. This interchange will first identify the strengths and weaknesses of, as well as alternatives to, current approaches to bivalve health management in the region, and investigate those in use or proposed by other states, by the federal government, and by other countries. The guidelines that follow from these discussions will be published in booklet form and will be posted on the Web.

In addition to the guidelines, the document will also contain sections pertaining to (1) concepts in disease spread, control, and diagnosis; (2) descriptions of standard diagnostic methods; (3) an examination of the potential application of novel molecular-based diagnostics, including an assessment of their accuracy and sensitivity, and how their outcome should be interpreted; (4) a fact sheet for each disease or disease agent; and (5) a glossary of general terms. The fact sheet will include the common and scientific names of the disease agent and its host or hosts, known geographic distribution, known environmental limitations, life cycle, method of transmission, recommended diagnostic procedures, and treatment or amelioration methods. Each disease agent will be classified according to its potential danger to bivalve stocks. Although the guidelines will have no force of law, we anticipate that the inclusion of all interested parties in their development should lead to their use by all northeastern states because the recommendations are reasonable, scientifically based, and because they will benefit the shellfish industries in the region.

PREVALENCE AND MORTALITY ASSOCIATED WITH SSO AND SSO-LIKE INFECTIONS OF *CRASSOSTREA VIRGINICA* IN THE NORTHEAST.

Roxanna Smolowitz, Marine Biological Laboratory, 7 MBL St., Woods Hole, MA 02543; **Inke Sunila,** State of Connecticut, Dept. of Agriculture, Milford, CT 06460; **Nancy Stokes** and **Lisa Ragone-Calvo,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Haplosporidium costale (seaside organism, SSO) was identified as a cause of mortality in the eastern oyster (*Crassostrea virginica*) on the Atlantic coast of Maryland and Virginia in 1962 and is now endemic there. Early (1962) investigations in Virginia showed mortality associated with SSO could reach 60% in some years. SSO plasmodia are first identified in tissue sections in early spring. Mortality resulting from synchronous sporulation in the connective tissues occurs in May–June each year. Until recently, post-sporulation SSO plasmodia have not been positively identified in oyster tissues until the following spring.

SSO-infected oysters have also been found along coastlines of the more northern states, but historically, SSO morbidity and mortality has not been considered significant. Northeast regulatory agencies do not restrict shipments of oysters on the basis of positive SSO findings. In late spring 1998, oyster culturists in Katama Bay, Martha's Vineyard, Massachusetts, observed 20%–70% mortality of cultured stocks. The cause was identified as SSO, thus indicating that SSO can cause significant mortalities in some years in the northeast. Notably, in 1998 in both Connecticut and Massachusetts, SSO-like sporulating plasmodia were noted in sections of oysters in the late fall of the year. Although no other cases have since been identified in Massachusetts, SSO-like, fall sporulating organisms continue to be identified in Connecticut.

Haplosporidium nelsoni (MSX) also produces plasmodia in oyster tissues and is a cause of significant mortality in mid-Atlantic and northeast oyster populations. It is difficult to differentiate *H. nelsoni* and *H. costale* plasmodia using traditional diagnostic methods, and it is possible that SSO and SSO-like plasmodia have been misidentified as MSX over the last several years, resulting in the confusion between mortality associated with MSX and SSO.

In this study, species-specific DNA-based diagnostic PCR methods and in situ hybridization (ISH) were employed in conjunction with traditional histological examination to differentiate *H. nelsoni* and *H. costale* infections in cultured oyster populations in Massachusetts and Connecticut, with the main objective of determining to what extent mortality is attributable to SSO and/or MSX. Additional objectives were to identify the SSO-like organism and to determine if fall and winter infection characteristics (i.e., prevalence, tissue forms, and locations) of SSO are of value in predicting SSO-related disease severity in the following spring.

Results indicate that pathologists cannot reliably differentiate MSX, SSO, and SSO-like plasmodia in traditionally stained tissue sections. Using species-specific DNA primers and probes, PCR and ISH methods can differentiate between these infections. In addition, ISH can help quantify the relative proportion of SSO and MSX plasmodia within tissue sections. Some plasmodia identified in oyster tissues collected in the fall, which might have been identified as MSX, are positive for SSO and SSO-like organisms. The relationship of SSO-like organisms to SSO and MSX plasmodia continues to be studied. Combining the history of oyster mortality in a specific location with results from various diagnostic tests is the best way to predict morbidity and mortality associated with these oyster diseases in any population.

This work is sponsored by a NOAA/Sea Grant Oyster Disease Research Award.

RHODE ISLAND'S SHELLFISH RESTORATION PROGRAM IN RESPONSE TO THE *NORTH CAPE* OIL SPILL.

Karin A. Tammi, Najih Lazar, and **Arthur Ganz,** Rhode Island Department of Environmental Management, Coastal Fisheries Laboratory, 1231 Succotash Road, Wakefield, RI 02879; **James G. Turek,** National Oceanic and Atmospheric Administration Restoration Center, 28 Tarzwell Drive, Narragansett, RI 02882; and **John G. Catena,** National Oceanic and Atmospheric Administration Restoration Center, One Blackburn Drive, Gloucester, MA 01930.

On the evening of January 19, 1996, the tank barge *North Cape* struck ground off Point Judith, Rhode Island, and began leaking oil in the vicinity of two National Wildlife Refuges, several salt ponds, and public and private beaches. Wind and wave action dispersed the oil into the atmosphere, throughout the water column, and into the benthic sediment. Approximately 828,000 gallons of heating oil were released into the surrounding offshore and inshore environment, affecting large numbers of crustaceans, mollusks, birds, amphipods, and fish. It was determined that the spill was responsible for the loss of about 150 million surfclams, *Spisula solidissima*, with a total biomass of 379,000 kg, for a value of $1.5 million. The spill resulted in the formation of a natural resource trustee group, composed of Rhode Island Department of Environmental Management, the National Oceanic and Atmospheric Administration, and the United States Fish and Wildlife Service, to evaluate the injury to the natural resources and to plan the resulting restoration activities. Because the surfclam population should recover to natural baseline levels within 3–5 y, a compensatory shellfish restoration program will be launched in Narragansett Bay and in the coastal salt ponds. Beginning in 2002, the trustees will initiate a multifaceted and multispecies approach to shellfish restoration with programs for the eastern oyster, *Crassostrea virginica*; Northern quahog, *Mercenaria mercenaria*, and the bay scallop, *Argopecten irradians irradians*. The shellfish restoration strategy will utilize many techniques, which include a remote setting program for *C. virgincia* and spawning sanctuaries and spat collection for bay scallops, *A. irradians irradians*. The shellfish restoration initiatives in response to the *North Cape* oil spill disaster offer tremendous opportunities for Rhode Island's shellfish resources.

SPAT (SPECIAL PROGRAMS IN AQUACULTURE TRAINING) UPDATE, 2002. ESTABLISHING A MODEL FOR COMMUNITY-BASED SHELLFISH CULTURE AND RESTORATION. Kim Tetrault, R. Michael Patricio, and Mary Morgan.

Cornell Cooperative Extension of Suffolk County, Marine Environmental Learning Center, Southold, NY 11971.

Cornell Cooperative Extension of Suffolk County, New York, has expanded a component of their marine program division to include a series of educational and training initiatives collectively referred to as SPAT (Special Programs in Aquaculture Training). The SPAT campaign is now 1 y old and has made tremendous progress. The active membership of SPAT Master Shellfish Gardeners is currently 191 families strong, with attendance at the monthly workshop series (11, 2-h lectures) consistently exceeding 100 participants. More than 2,000 h have been logged into the community hands-on training sessions held weekly throughout the year. SPAT members assisted in culturing and planting millions of seed clams, oysters, and scallops in local waterways and selected test plots, as well as maintaining personal "garden" stocks. A new web site (www.cce.cornell.edu/Suffolk/MARprograms/Aquacultruemain.htm) now allows members to record data that have been collected on a monthly basis for growth and survival of cultured oysters (*Crassostrea virginica*). A community-built and operated hatchery on location is expected to be operational for the 2002 growing season, which will concentrate on the culture of bay scallops (*Argopecten irradians irradians*).

Various projects are planned for the 2002 season. These include restoration work on two community spawner sanctuaries funded by NOAA (oysters) and 5-Star (clams/scallop) grants. Two additional spawner sanctuaries, one for oysters and another for scallops, have been designated by the town of Southold. All sanctuaries will be stocked and monitored by SPAT trainees. The focus will be on early field planting and predator control techniques for select species of clams, oyster bed preparation and reef building, and intensification of scallop deployment at multiple stages within healthy eelgrass beds. The community hatchery is expected to significantly increase the production of bay scallops with a target goal of 5–10 million post-set for the 2002 season. A grant to examine the sociological components of the SPAT initiative has been awarded by an anonymous foundation. Two pilot educational programs, one at the third-grade level and one at the teenage level, are actively in progress. New internships in community-based shellfish restoration activities are available.

It is the intention of the Cornell Cooperative Extension SPAT initiative to establish a model for community-supported shellfish restoration efforts through intensive training and active participation. The founding members of SPAT are excited and prepared to meet the challenges in the upcoming year.

A NEW CLAM FOR CONNECTICUT. John Wadsworth,

Niantic Bay Shellfish, LLC, 15 First Street, Waterford, CT 06385; **Tessa Simlick** and **Nancy Balcom**, Connecticut Sea Grant, University of Connecticut, 1084 Shennecossett Road, Groton, CT 06340.

The razor clam *Ensis directus*, is one of the few untapped resources in shellfish aquaculture in the northeastern United States. The market supply of razor clams is low and inconsistent, particularly because of the difficulty in harvesting these fast-digging shellfish. If razor clam production were to become economically feasible and less labor intensive, there would be great opportunity to expand this underutilized species to niche markets. The Northeastern Regional Aquaculture Center (NRAC) has provided funding for the aquaculture industry to test various clam grow-out methods in four states: Connecticut, Massachusetts, New York, and Rhode Island. In Connecticut, a project was initiated to investigate razor clam grow-out in cages. Seed clams were obtained from the Aquaculture Research Corporation (ARC) in Dennis, Massachusetts, in September 2001. The clams were held initially in upwellers and then transferred to cages for field experiments. The project consisted of two experiments, the first of which was designed to compare razor clam growth rates in cages lined with felt set at two different heights. Replicate cages were lined with felt to the top of the cages or, the high position (H1). The remaining cages were lined up to the level of the sediment, or low position (H2). The second experiment was designed to compare razor clam growth rates between two different growing areas, the Niantic River (NR) and the Niantic Bay (NB) in Waterford, Connecticut. The clams were divided among replicate cages and stocked at a density of one clam/2.5 cm^2 (one clam/in.^{2}). Monthly inventories to determine clam density and growth rate (length and width to ±0.01 mm) were performed beginning in September 2001. As of early February, preliminary results showed that there was no significant difference in growth rates between felt heights (H1 vs. H2) or growing area (NR vs. NB) (ANOVA, $P < 0.05$). The clams grew in length from 18.84 ± 2.22 mm to 34.71 ± 4.46 mm. High densities were observed in the NR cages (>90% of original stocking densities), however, the clams were present in very low densities in the NB cages.

LIFE IN A TRAILER—DEVELOPMENT OF A NEW SHELLFISH HATCHERY AT THE MASSACHUSETTS MARITIME ACADEMY. **Bethany A. Walton,** Aquaculture Laboratory, Massachusetts Maritime Academy, 101 Academy Drive, Buzzards Bay, MA 02532.

The Aquaculture Lab at the Massachusetts Maritime Academy (MMA) in Buzzards Bay, Massachusetts, officially opened its doors in April 2001. Located at the southern entrance to the Cape Cod Canal on Taylor's Point, the hatchery is a cooperative venture between MMA and Barnstable County; the SouthEastern Massachusetts Aquaculture Center (SEMAC) also provides technical support. This facility is not a production-scale shellfish hatchery, but rather, a "teaching hatchery." This teaching hatchery serves as an integral component of an introductory aquaculture course taught at MMA to provide "hands-on" training for students in shellfish biology, hatchery techniques, and intermediate culture.

The building (a refurbished trailer that measures approximately 1100 ft^2) consists of two primary areas, one devoted to algae production and the other to larval production. The greenhouse area holds twelve 250-L Kalwall tubes and has space for several 3-L carboys and 1-L jugs. Microalgae production consists primarily of batch culture of more than 10 species. The larval production area has a capacity to produce approximately 30–50 million 1-mm larvae and holds four 937.5-L larval tanks; there is also a small area devoted to setting animals and broodstock holding tanks. A limited amount of upweller space is also on site. Two innovative features of the hatchery are its seawater system and protected interior surfaces. The seawater system is a multiple pump system that feeds into a common manifold consisting of four titanium submersible pumps with a capacity of 50 gal/min. In addition, the interior surfaces of the facility are protected by a commercial polyurethane formulation (typically used for spray-on truck bed liners) applied to the floor and walls to seal them from corrosion and water damage.

Not only will we continue to use the hatchery as a teaching tool, we will also be coordinating our 2002 spawning activities with the Eastham Aquaculture Technology and Training Center to maximize shellfish propagation and enhancement efforts in the Cape Cod area. We plan to produce razor clams (*Ensis directus*), bay scallops (*Argopecten irradians irradians*), and eastern oyster (*Crassostrea virginica*) larvae for remote sets in various Cape Cod towns. Currently, we are culturing a small number of razor clam larvae.

THE NEW OYSTER WARS: POLICY PERSPECTIVES ON THE INTRODUCTION OF *CRASSOSTREA ARIAKENSIS* IN THE CHESAPEAKE BAY. **Donald Webster,** University of Maryland, Wye Research & Education Center, P.O. Box 169, Queenstown, MD 21658.

Oyster harvests in the Chesapeake Bay have declined more than 90% in the past 50 y, largely due to the influence of the oyster diseases *Haplosporidium nelsoni* and *Perkinsus marinus*. Recent studies regarding the potential of the species *Crassostrea ariakensis* have shown that this animal may provide beneficial attributes desirable both for reconstruction of the oyster fishery as well as for environmental management of the Bay. However, because it is a nonindigenous species, there are factors to be considered prior to any large-scale introduction. Variations in the current status of the *Crassostrea virginica* resource, as well as historical differences of management techniques inherent in the two states, have led to challenges regarding open-water introductions, as well as plans to increase stocks of the nonnative oyster in the future. This paper focuses on the policy differences between Maryland and Virginia and the attitudes of various user groups that are interested parties in the potential introduction of *C. ariakensis* in the Chesapeake Bay.

DEVELOPMENTS IN SOFTSHELL CLAM HATCHERY AND NURSERY PRODUCTION ON MASSACHUSETTS' NORTH SHORE. **Scott Weston, Mark Fregeau,** and **Joe Buttner,** Northeastern Massachusetts Aquaculture Center and Department of Biology, Salem State College, Salem, MA 01970.

A major goal of the Northeastern Massachusetts Aquaculture Center (NEMAC) focuses on nurturing a sustainable aquaculture industry on Massachusetts North Shore amenable to existing social, economic, and environmental conditions. Several North Shore communities are exploring aquaculture as a means to diversify and supplement their capture fisheries while restoring and enhancing endemic populations. Historically, the softshell clam (*Mya arenaria*) supported significant commercial and recreational harvests. Efforts initiated in the1990s to augment natural populations now involve a half dozen towns. Culture protocols adapted to local conditions have demonstrated the efficacy of stocking 10- to 15-mm spat in spring. Availability of suitable seed is limited and has impeded stocking efforts. With the encouragement and participation of local communities, NEMAC has targeted reliable and ultimately large-scale production of spat as a priority objective.

NEMAC's second year of operation (2001) started early as

200,000 juvenile clams were collected by local shellfishers from the Rowley River in November 2000 and successfully overwintered in the Cat Cove Marine Laboratory. Clam survival approached 100%, though growth at 15–17°C averaged ~0.5 mm/mo between 3 January and 7 May. Clams were returned to the Rowley community and released in early May 2001 at approved sites. Starting in early July 2001 and continuing to the present, NEMAC personnel and North Shore shellfishers have monitored sites in the Rowley River to ascertain water quality, clam abundance, and optimal release sites.

NEMAC personnel induced four spawns of local clams between early May and mid July. Inadequate setups for settling larvae diminished survival of initial spawns and polyspermy adversely impacted larval development during the fourth spawn. NEMAC produced 75,000 post-set spat, supplemented by 500,000 clams imported from the Beals Island Regional Shellfish Hatchery (BIRSH) in Maine. All clams were cultured in the laboratory on *Tetraselmis chuii* and T-ISO. As clams reached ~3.5 mm in length, they were transferred to screen-bottom trays at 10,000 clams/tray (~3,600 cm^2). Approximately 30 periwinkles (*Littorina* sp.) were added to each tray to crop macroalgae and other fouling organisms. The first tray was stocked in mid July and stocking continued throughout the summer. All trays were covered with white plastic, floated in Smith Pool, and exposed to tidal flush. Initial growth averaged 2.5–5 mm/mo. At 8–9 mm, growth of clams diminished, which is indicative of overcrowding. Approximately 70% of the clams stocked in upwellers survived. Clams are being overwintered, 250,000 (8–15 mm) in spat bags suspended in Smith Pool and 150,000 (3–8 mm) are distributed in trays stacked in a trough with a continuous flow of filtered seawater. Laboratory-housed clams are fed 1–2 times daily with a *Tetraselmis chuii* and T-ISO mix. The objective is to release 200,000 spat of suitable size onto approved tidal flats in spring 2002. It is hoped and anticipated that on-going, collaborative restoration/enhancement efforts will evolve into commercial enterprises conceived and pursued by local shellfishers.

RAPID GROWTH OF BAY SCALLOPS, *ARGOPECTEN IRRADIANS IRRADIANS*, IN LONG ISLAND SOUND. **James C. Widman, Jr.** and **David J. Veilleux**, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460.

Bay scallops, *Argopecten irradians irradians*, were held in pearl nets to evaluate the suitability of western Long Island Sound as a culture site for scallops. Scallops were deployed at six locations off the coast of Darien, Connecticut. Pearl nets were anchored with a cement block and vertical lift was provided by an attached subsurface buoy. Nets were deployed singularly or in groups of three. Thirty scallops were measured to the nearest 0.1 mm, placed in each of nine pearl nets, and transported to the site in coolers filled with ambient seawater. Initial deployment was on July 25, 2001, and the experiment ended on February 6, 2002.

Survival was high, although there was some initial mortality. Survival for the entire experiment averaged 71% and ranged from 53% to 83%. After the initial mortality, survival after September 11 averaged 93% and ranged from 79% to 100%. The increase in survival after the September 11 sampling period indicates that there may have been some handling/transport problems.

Scallops with initial mean shell heights ranging from 6.8 to 7.7 mm on July 24, 2001, grew to mean shell heights ranging from 45.4 to 50.6 mm by February 6, 2001. Growth rates were high from July 24 until October 16, when water temperatures began to decline below 15°C. Less than 1 mm of growth occurred after December 4, when water temperatures were low. Rapid growth rates ranging from 0.36 to 0.49 mm/day were observed during the period from September 11 to October 16, 2001, a period of declining water temperatures.

For the experimental regime, Western Long Island Sound appears to be a suitable site for culturing bay scallops.

LIVESTOCK DOMESTICATION IN THE THIRD MILLENNIUM: ALL WET? **Gary H. Wikfors**, USDOC, NOAA, National Marine Fisheries Service, Northeast Fisheries Science Center, Milford Laboratory, Milford, CT 06460.

The dictionary defines "domestic" animals as those "kept by and for the use of man." The first domestication of land animals (sheep in what is now Turkey) is thought to have occurred between 13,000 and 9,000 y ago during the Neolithic-to-Paleolithic transition in human history. Since that time, the trajectory of human food acquisition has been away from the hunter-gatherer mode to increasingly sophisticated husbandry of both plants and animals. The one exception to this historical paradigm has been seafood. It appears, however, that mankind now is entering a transition period from harvest of wild populations in the sea to domestication for the same reasons that drove land-animal domestication—rising demand and limited supply of wildlife for harvest. We have the benefit of about 10,000 y of human experience to guide decisions about marine plant and animal domestication—both successes and failures. There has, however, been limited effort to transfer the broad principles of animal husbandry downstream; therefore, the first objective of this presentation will be to advance this transfer.

At this early stage in the transition to aquaculture, the first few global, industrial-scale aquaculture products—salmon and shrimp—have reached a point of development to impact world seafood markets, as well as generate controversy about the future of aquaculture expansion on several fronts, chiefly economic and environmental. Unquestionably, mistakes have been made with shrimp and salmon, as they have with agricultural livestock production methods. What lessons can be learned from modern agriculture and our limited experience with industrial aquaculture and how can these be related to broad principles identified from the history of animal husbandry? These questions will be discussed comparatively.

BLUE MUSSEL AQUACULTURE IN LONG ISLAND SOUND. **Lawrence Williams,** Jessie D., Inc., 68 Anchorage Drive, Milford, CT 06460; and **Tessa Simlick,** Connecticut Sea Grant, University of Connecticut, 1084 Shennecossett Road, Groton, CT 06340.

A pilot-scale investigation into the longline culture of blue mussels *Mytilus edulis* in Long Island Sound has been initiated. The project, in progress since the spring of 2001, includes collecting and grading seed for grow-out on dynamic longlines at three sites in Long Island Sound and comparing production rates. A horizontal head rope (100 ft in length) was submerged 6 ft below the surface (at MLW) and anchored with concrete blocks (150 lb total weight). Vertical seed collecting lines (11 ft in length) were attached to the head rope at 3-ft intervals. Seed collectors were placed over submerged mussels beds in Branford, Milford, Fairfield, and Stonington, Connecticut, in late April 2001. A large seed-set appeared in Stonington in early June 2001, however, mussels were not visible on the collectors in western LIS until mid-July 2001. In late September 2001, a second set of seed attached to the seed collectors.

ARACHIDONIC ACID REQUIREMENTS IN LARVAL SUMMER FLOUNDER, *PARALICHTHYS DENTATUS*. **Stephen Willey** and **David A. Bengtson,** Department of Fisheries, Animal and Veterinary Science, University of Rhode Island, Kingston, RI 02881; **Moti Harel,** University of Maryland Center of Marine Biotechnology, 701 East Pratt Street, Baltimore, MD 21202.

Highly unsaturated fatty acids (HUFAs) have been identified as essential fatty acids in marine fish and the dietary requirements for the n-3 (omega-3) HUFAs eicosapentaenoic acid (20:5n-3, EPA) and docosahexaenoic acid (22:6n-3, DHA) have been well documented. Only recently has attention been given to HUFAs of the n-6 series, in particular arachidonic acid (20:4n-6, AA). The impetus for much of this attention is the fact that AA is highly conserved during periods of starvation and also serves as a precursor in the biosynthesis of eicosanoids, physiologically active compounds that aid in stress response, among other things.

The AA requirements of larval summer flounder were determined for the rotifer- and *Artemia*-feeding stages. Experimental emulsions contained adequate n-3 HUFA ratios and emulsion levels of AA were set at 0%, 3%, 6%, 9%, and 12% (AA0, AA3, AA6, A9, and AA12). Examination of fatty acid levels in live feeds and larval tissues confirmed the physiological incorporation of fatty acids relative to dietary levels. In the first experiment, survival, growth, and salinity tolerance (2 h in 70‰) were measured at 18 days after hatch (dah) after feeding the larvae the various levels of AA. Larvae fed AA6-enriched rotifers were better able to survive the salinity tolerance test. AA enrichment up to 12% had no effect on growth and survival. In the second experiment, larvae fed AA0- or AA6-enriched rotifers until 23 dah, followed by unenriched 24- and 48-h *Artemia* nauplii until 32 dah. These larvae were then subdivided and fed AA-enriched *Artemia* from 33 to 45 dah. At the end of this experiment, larvae fed AA6-enriched rotifers had higher survival, increased growth, and survived better in the salinity tolerance test (2 h in 80‰) than did those fed AA0 (unenriched) rotifers. The AA enrichment of *Artemia* did not have any significant effect on these variables. Thus, the provision of AA6-enriched rotifers early in larval development may serve to enhance larval stress tolerance at the rotifer stage, while also increasing larval survival, growth, and stress tolerance later in the *Artemia* stage.

Journal of Shellfish Research, Vol. 21, No. 21, 357–440, 2002.

ABSTRACTS OF TECHNICAL PAPERS

Presented at The 94th Annual Meeting

NATIONAL SHELLFISHERIES ASSOCIATION

Mystic, Connecticut

April 14–18, 2002

CONTENTS

PERKINSUS

George R. Abbe, Brian W. Albright, Carol B. McCollough, Christopher F. Dungan and Stephen J. Jordan
Environmental effects on *Perkinsus marinus* infection rates, growth and survival among Dermo-disease-free juvenile oysters planted at three salinity regimes in the Patuxent River, Maryland 371
Bassem Allam and Susan E. Ford
Transport of particles across epithelia from oyster mantle cavity: a model for *Perkinsus marinus* invasion 371
Louis E. Burnett and Christopher S. Milardo
Effects of oyster emersion on the growth and the metabolism of *Perkinsus marinus* 371
David Bushek, John Scarpa and Susan E. Laramore
Susceptibility of the Caribbean oyster *Crassostrea rhizophorae* to *Perkinsus marinus* 371
Fu-Lin E. Chu, Eric Lund and Ellen Harvey
Does the unique fatty acid synthetic capability of *Perkinsus marinus* have implication for virulence? 372
Lewis E. Deaton and Percy J. Jordan
Effect of *Perkinsus marinus* on phenoloxidase activity in bivalve hemolymph 372
Christopher F. Dungan, Rosalee M. Hamilton, Carol B. McCollough, Kimberly S. Reece and Karen L. Hudson
Epizootic diseases in Chesapeake Bay clams 372
Vincent G. Encomio, Shawn Stickler and Fu-Lin Chu
Evaluation of physiological condition in Dermo resistant oysters 373
Tarquin Dorrington, Marta Gómez-Chiarri and Lenore Martin
Evaluation of antimicrobial peptides for recombinant feed-based delivery in shellfish aquaculture 373
Julie D. Gauthier, Jerome F. La Peyre and Jill A. Jenkins
Flow cytometric analysis of lectin binding to *in vitro* cultured *Perkinsus marinus* surface carbohydrates 373
Eileen E. Hofmann, John M. Klinck, Eric N. Powell, Susan E. Ford, Stephen Jordan and Eugene Burreson
Climate variability and Dermo disease in Chesapeake Bay 374
Stephen L. Kaattari, E. Alanna MacIntyre and Christopher G. Earnhart
Modulation of *Perkinsus marinus* functions by host-derived products 374
Jerome F. La Peyre, Amy D. Nickens, Sandra M. Casas and Antonio Villalba
Viability and growth of *Perkinsus marinus* and *Perkinsus atlanticus* at three temperatures 374
Eric D. Lund, Fu-Lin E. Chu and Philippe Soudant
Is the temperature and salinity-dependent virulence of *Perkinsus marinus* associated with increased lipid metabolism? 374
Carol B. McCollough, Christopher F. Dungan, Stephen J. Jordan, George R. Abbe and Brian W. Albright
Perkinsus marinus infection rates in specific-pathogen-free juvenile oysters planted at three salinity regimes in the Patuxent River, Maryland 375
Kennedy T. Paynter, Tim Koles and Don Meritt
Perkinsus prevalence in oysters produced in the hatchery and planted in the field 375
Sammy M. Ray, Thomas M. Soniat, Enrique V. Kortright and Lance Robinson
Recent trends in levels of infection of *Perkinsus marinus* in oysters from Galveston Bay, Texas: results of the Dermowatch Monitoring Program 375
Kimberly S. Reece
Utilization of molecular genetic data for detecting, identifying and describing *Perkinsus* species 376
Pilar Muñoz Ruiz and Marta Gómez-Chiarri
Protease activity in the eastern oyster *Crassostrea virginica* after experimental infection with the protozoan parasite *Perkinsus marinus* 376
S. M. Stickler, V. G. Encomio, S. K. Allen, Jr., F-L. E. Chu and J. F. La Peyre
"Natural Dermo resistance" in eastern oyster stocks: Chesapeake studies and defense-related activities 376

THE BIOLOGY AND CONSERVATION OF FRESHWATER MUSSELS

Alan D. Christian, David J. Berg and B. Crump
Spatial and temporal analysis of ecosystem processing of freshwater mussels in two headwater streams 377
Susan Rogers, Richard Biggins and Steven Ahlstedt
Conservation activities for freshwater mussels by the United States Fish and Wildlife Service 377
William F. Henley and Richard J. Neves
Diet evaluation for the freshwater mussel *Elliptio complanata* (Bivalvia: Unionidae) 377

Curt L. Elderkin, David J. Berg, Janice L. Metcalfe-Smith, Caryn C. Vaughn, Alan D. Christian and Sheldon I. Guttman
Hierarchical analysis of MtDNA variation in *Amblema plicata*, a widespread mussel species 378

Jeffrey T. Garner and Thomas M. Haggerty
Gametogenesis, spawning, brooding and glochidial discharge in *Megalonaias nervosa* (Bivlavia: Unionidae) from the Tennessee River in Alabama 378

Catherine M. Gatenby, Daniel A. Kreeger, Robyn Reinmiller and Richard J. Neves
Clearance rate and filtration efficiency of *Elliptio complanata* (Bivalvia: Unionidae) exposed to different laboratory conditions 378

Daniel A. Kreeger, Catherine M. Gatenby and Deborah Raksany
Variability in condition index and tissue biochemistry of *Elliptio complanata* held in the field and laboratory 378

Richard J. Neves, Jess W. Jones and William F. Henley
Propagation of endangered freshwater mussels in recirculating culture systems 379

Daniel E. Spooner and Caryn C. Vaughn
Small-scale ecological function of freshwater mussels (Family: Unionidae) in the Kiamichi River, Oklahoma 379

Caryn C. Vaughn, Daniel E. Spooner, Melissa Moore and Keith B. Gido
Comparative and experimental evidence for the functional role of freshwater mussels in streams 379

W.-H. Wong, Jeffrey S. Levinton and Benjamin Twining
Assimilation of microzooplankton by zebra mussels: the benthic zooplankton loop 380

GENETICS AND MOLECULAR BIOLOGY

Charles L. Brockhouse and Gillian Richard
Unscrambling the lobster genome: complex heterozygosity in the American lobster? 380

Bruno Ernande, Joel Haure, Lionel Degrémont, Edouard Bédier and Pierre Boudry
Genetical basis of the plasticity of the resource allocation in the Pacific oyster *Crassostrea gigas* 380

Ximing Guo, Jian Wang, Brenda J. Landau, Li Li, Gregory A. DeBrosse and Krista D. Buono
The successful production of tetraploid eastern oyster, *Crassostrea virginica* Gmelin 380

Matthew P. Hare and Stephen R. Palumbi
Genetic distinctiveness of inshore and offshore *Spisula* clams 381

Dennis Hedgecock, Sophie Hubert, Gang Li and Katharine Bucklin
A genetic linkage map of 100 microsatellite markers for the Pacific oyster *Crassostrea gigas* 381

Gregg G. Hoffman, Ami E. Wilbur, Martin H. Posey and Troy D. Alphin
A single-step multiplex PCR identification assay to distinguish megalopae of *Callinectes sapidus* from *Callinectes similis* in plankton samples 381

Brenda J. Landau, Arnaud Tanguy and Ximing Guo
Searching for differentially expressed genes in diploid and triploid eastern oyster, *Crassostrea virginica* Gmelin 382

Zinin Yu and Ximing Guo
A basic AFLP linkage map for the eastern oyster, *Crassostrea virginica* Gmelin 382

Mingfang Zhou and Standish K. Allen, Jr.
Reversion revisited in *Crassostrea ariakensis:* chromosome set instability in field trials across salinity regimes 382

EAST COAST BIVALVE INDUSTRY SESSION

Standish K. Allen, Jr.
An overview of the potential for *Crassostrea ariakensis* in the Chesapeake Bay 382

Gregory A. DeBrosse, David R. Jones and Eric N. Powell
Surf clam (*Spisula solidissima*) culture in southern New Jersey: hatchery culture protocols and preliminary field grow out results 383

M. Richard DeVoe and G. Ross Nelson
Coastal states permitting procedures for deploying a tidal powered upwelling nursery system 383

George E. Flimlin, Jr.
Relevant issues for the east coast shellfish aquaculture industry: finding commonality to foster unity 383

Aman Luthra and William Walton
Stakeholders' perceptions and challenges to participatory management: the case of the soft-shell clam, *Mya arenaria* L., industry in Maine 384
Sandra Macfarlane
Embracing aquaculture BMP's: a concept whose time has come as a good neighbor or just one more thing to deal with? 384
Dana L. Morse and John Riley
Optimization of tidal upweller design: project wrap-up 384
Robert B. Rheault and Jeffrey T. Gardner
Growth and economics of shellfish nursery culture in a commercially available floating upweller 385
Leslie N. Sturmer, John E. Supan and Charles M. Adams
Enhancing seed availability for the hard clam aquaculture industry through application of remote setting techniques ... 385
William C. Walton
Using shellfish seed as a public enhancement tool: a review of its use and success in the northeast US 385
Christopher G. Warfel, P.E.
Growth and economic advantages of distributed powered upwellers: creating a new aquaculture niche 385
Donald Webster
The new oyster wars: policy perspectives in the introduction of *Crassostrea ariakensis* in the Chesapeake Bay 386

BIVALVE DISEASE STATUS AND TRENDS

Bruce J. Barber and Katherine J. Boettcher
Recent expansion of juvenile oyster disease (JOD) in Maine 386
David Bushek, Dwayne Porter, Loren D. Coen, M. Yvonne Bobo and Donnia L. Richardson
Status and trends of Dermo and MSX in South Carolina 386
Lisa M. Ragone Calvo and Eugene M. Burreson
A decade of disease: a report of oyster disease monitoring efforts in the lower Chesapeake Bay 1990–2000 387
Ryan B. Carnegie, Gary R. Meyer, Janice Blackbourn, Susan M. Bower and Nathalie Cochennec-Laureau
Development and application of a PCR for *Mikrocytos mackini*, the causative agent of Denman Island disease in oysters 387
Susan E. Ford
Development of high disease resistance in a wild oyster population 387
Stephen J. Jordan and Jessica Vanisko
The long-term role of parasitic diseases in oyster population dynamics 387
Dale Leavitt, D. Murphy, W. Burt, W. Clark, M. Hickey, J. Moles and R. Smolowitz
Cape Cod bivalve diseases monitoring program, Year 1 388
Karen L. Mareiro, Marta Gómez-Chiarri, Katherine Kerr, Emily Carrington and Arthur Ganz
Prevalence and intensity of parasitic diseases in bivalves from Rhode Island waters 388
Spencer Russell, Salvatore Frasca, Jr., Richard A. French and Inke Sunila
Modification and field trials of a multiplex PCR for the detection of three protozoan pathogens of the eastern oyster, *Crassostrea virginica*, Gmelin 1871 388
Thomas M. Soniat, Enrique V. Kortright and Sammy M. Ray
Dermowatch: a web-based approach for monitoring the oyster parasite *Perkinsus marinus* *(Dermocystidium marinum)* 389
Mary F. Stephenson, Sharon E. McGladdery and Nancy A. Stokes
Detection of a previously undescribed Haplosporidian-like infection of a blue mussel *(Mytilus edulis)* in Atlantic Canada 389
Inke Sunila
Monitoring bivalve health in Long Island Sound 389

DISEASES OF CRUSTACEA

Donald C. Behringer, Jr., Mark J. Butler, IV and Jeffrey D. Shields
Ecological ramifications of disease in the Caribbean spiny lobster, *Panulirus argus* 390

Kathleen Castro and Thomas Angell
Field observations on the development and progress of a shell disease episode for American lobster in Rhode Island: 1995–2001 390
Terry Glover, Lauren Bergey and Judith S. Weis
Effects of parasites on behavior of grass shrimp, *Palaemonetes pugio* 390
Barbara Horney, Andrea Battison and Allan MacKenzie
Cytocentrifuge preparations: an alternate method to examine the hemocytes of the American lobster *Homarus americanus* 391
Gretchen A. Messick and Tom F. Nalepa
Parasites in *Diporeia* spp. amphipods from Lakes Michigan and Huron 391
Jeffrey D. Shields
Pathological alterations in the eyes of the American lobster, *Homarus americanus*, infected with *Paramoeba* sp. 391
Jeffrey D. Shields, Donald C. Behringer, Jr. and Mark J. Butler, IV
A pathogenic herpes-like virus from the spiny lobster, *Panulirus argus* 391

BLUE MUSSEL BIOLOGY AND CULTURE

John Brake, Jeffrey Davidson and Jonathan Davis
Observations on growth, gametogenesis, and sex ratio of triploid and diploid *Mytilus edulis* 392
Jeff Davidson, Frank Baothroyd, Neil McNair and Thomas Landry
The distribution and biology of an invasive tunicate in Prince Edward Island, Canada 392
Ellen L. R. Kenchington, Kenneth R. Freeman, Benedikte M. Vercaemer and Barry W. MacDonald
A field study of settlement depths of *Mytilus edulis* and *M. trossulus* in Nova Scotia, Canada, 1998–2000 392
Angeline R. LeBlanc, Gilles Miron and Thomas Landry
Nutrient uptake and release from fouling organisms associated with cultured mussels in Tracadie Bay, PEI 393
Afton McGowen, Matthew Gordon and Paul D. Rawson
Species-specific settlement patterns of blue mussels in Cobscook Bay, Maine 393
Marcelo Miranda, David Innes and Raymond Thompson
Genetic aspects of the blue mussel (*Mytilus edulis* and *Mytilus trossulus*) hybrid zone in Atlantic Canada 393
Valérie Moreau, Edwin Bourget and Réjean Tremblay
Small scale distribution of *Mytilus edulis* and *M. trossulus* in the baie des Chaleurs and the Gaspé Peninsula 393
Randy W. Penney, M. J. Hart and N. Templeman
Mussel culture in a mixed species (*M. edulis* and *M. trossulus*) zone—some commercial implications 394
Paul D. Rawson
Cladistic analysis of genetic differentiation between populations of the blue mussel, *Mytilus trossulus* 394
Judith Senechal and Jon Grant
Behavior and growth of juvenile mussels (*Mytilus* spp.) in suspended culture socks 394
Benoit Thomas, Valérie Moreau and Réjean Tremblay
Update on the distribution of two mussels species (*Mytilus edulis* and *Mytilus trossulus*) in the Quebec maritime regions 394
Réjean Tremblay, Valérie Moreau, Thomas Landry, Bruno Myrand and Cyr Couturier
Performance of *Mytilus edulis* and *Mytilus trossulus* in the Gulf of St. Lawrence: a laboratory experiment 395
J. Evan Ward, Sandra E. Shumway and Jeffrey S. Levinton
Blue mussels as model systems to investigate pallial cavity function in bivalves 395

HARMFUL ALGAL BLOOMS

Marie-Claude Archambault, Jon Grant, Monica Bricelj and Don Anderson
Effects of clay, used to control harmful algal blooms, on juvenile hard clams, *Mercenaria mercenaria* 395
Rita A. Horner
History, some recent HAB events, and their impacts on shellfish and finfish in Washington State 396
Jay R. Leverone and Norman J. Blake
Effects of the toxic dinoflagellate, *Karenia brevis*, on larval mortality and juvenile feeding behavior in the bay scallop, *Argopecten irradians* 396

Gary H. Wikfors, Jennifer H. Alix, Roxanna M. Smolowitz, Lacey Wallace and Hélène Hégaret
Detrimental effects of a recent *Prymnesium* isolate from Boothbay Harbor, Maine (USA) upon juvenile bay scallops *Argopecten irradians* 397

SHELLFISH BIOLOGY

Richard R. Alexander and Robert M. Baron
Burrowing-induced internal fractures and external abrasion in shells of the hard clam *Mercenaria mercenaria* from Raritan Bay, New Jersey 397
Eleanor A. Bochenek, Eric N. Powell, John M. Klinck and Eileen E. Hofmann
Influence of environment and food supply on survival of *Crassostrea gigas* larvae: a modeling study 397
Andrew T. Cogswell and Samia Sarkis
Growth characteristics of *Argopecten gibbus* juveniles reared in two suspended culture systems 398
W. R. Congleton, Jr., B. R. Pearce and M. Parker
Growth and dispersal studies of *Mya arenaria* using a numerical flow model 398
Zaúl García-Esquivel, Marco A. González-Gómez and Francisco Ley-Lou
Estimation of ingestion and biodeposition rates of the Pacific oyster, *Crassostrea gigas*, in a coastal lagoon of NW Mexico 398
Laura E. Gómez, Ma. Teresa Viana, Zaúl García-Esquivel, Armando Shimada and Louis R. D'Abramo
Effect of dietary protein/energy ratio on growth and metabolism of juvenile green abalone *(Haliotis fulgens)* 399
John Kraeuter, Eric N. Powell, Eileen E. Hofmann, John M. Klinck, Ray Grizzle, Monica Bricelj and Stuart Buckner
Modeling the growth of the hard clam, *Mercenaria mercenaria* 399
Eric N. Powell, Eleanor A. Bochenek, John M. Klinck and Eileen Hofmann
Influence of short term variations in food supply and critical periods on survival of *Crassostrea gigas* larvae 399
Melissa J. Southworth, Juliana M. Harding and Roger Mann
Population structure of the hard clam, *Mercenaria mercenaria*, in Hampton Roads, Virginia 400
Helen Woods, Ken Moore and Carl Hershner
An examination of potential conflict between hard clam aquaculture and SAV in the lower Chesapeake Bay 400

SCALLOP BIOLOGY AND CULTURE

V. Monica Bricelj, Anne Veniot, Céline Barré and Peter Beninger
Postlarval development of the gills and implications for feeding in the sea scallop, *Placopecten magellanicus* 400
Maureen Davidson
The effects of stocking density in pearl nets on survival, growth, and reproductive potential of the bay scallop, *Argopecten irradians irradians* 401
Scott Feindel and Daniel Schick
Developing a coastal Maine sea scallop enhancement program 401
Brad Harris and Kevin Stokesbury
Growth and movement of sea scallops in the southern part of the Great South Channel on Georges Bank: a tagging study 401
Daniel L. Jackson, Barry W. MacDonald, Shaka James, Benedikte Vercaemer, Ellen L. Kenchington and Andre Mallet
Investigations with triploid Atlantic sea scallops, *Placopecten magellanicus* 401
Lisa M. Milke, V. Monica Bricelj and Christopher C. Parrish
A comparison of microalgal diets for enhanced production of *Placopecten magellanicus* postlarvae 402
Shawn M. C. Robinson, Jim D. Martin and Eddy J. Kennedy
Impacts and control of the spionid polychaete, *Polydora websteri* on the sea scallop, *Placopecten magellanicus* in midwater culture 402
Gregg E. Rosenkranz and Douglas Pengilly
Development of a stock assessment program for weathervane scallops in Alaska 402
Fabrice Pernet, Réjean Tremblay and Edwin Bourget
Biochemical indicator of giant scallop *Placopecten magellanicus* quality: larval growth, competency and settlement ... 403
Kevin D. E. Stokesbury and Brad Harris
Examination of sea scallop, *Placopecten magellanicus*, aggregations using a video survey in closed areas of Georges Bank 403

PARASITE AND HOST DEFENSES

Steven M. Allen and Louis Burnett
The effect of pH on the killing activity of hemocytes in the Pacific oyster, *Crassostrea gigas* 403

Robert S. Anderson, Brenda S. Krans, Sharon McGladdery and Roxanna Smolowitz
Mucoid secretions protect QPX from antimicrobial agents 404

Gwénaëlle Choquet, Philippe Soudant, Christophe Lambert, Christine Paillard and Jean-Louis Nicolas
Measurement of *Vibrio tapetis* cytotoxic activity on *Ruditapes philippinarum* hemocytes by flow cytometry 404

Christie-Sue Decker and Robert S. Anderson
Chemotaxis of hemocytes of the hard clam, *Mercenaria mercenaria,* to Quahog parasite unknown (QPX) and other microorganisms 404

Maryse Delaporte, Jeanne Moal, Jean-françois Samain, Philippe Soudant, Gwénaëlle Choquet, Christophe Lambert and Christine Paillard
Effect of dietary fatty acid composition on lipid profiles of haemocyte membranes in oysters and clams and its impact on immune functions 404

William S. Fisher and Leah M. Oliver
Activation of oyster defenses by environmental contaminants 405

Christophe Lambert, Christine Paillard and Jean-Louis Nicolas
Improvement by probiotics of *Pecten maximus* larvae defense capacity, measured by chemiluminescence 405

Christophe Lambert, Philippe Soudant, Gwénaëlle Choqnet and Christine Paillard
Development of a flow cytometric measurement of oxidative metabolism product formation by *Crassostrea gigas* hemocytes and application to evaluate pathogenic *Vibrio* inhibiting capacity 405

Ann C. Mountz and Robert S. Anderson
Purification of a novel antimicrobial peptide from the eastern oyster (*Crassostrea virginica*) 405

Christine Paillard, Gwénaëlla Choqnet, Christophe Lambert, Philippe Soudant, Helen Reid and Harry Birbeck
Temperature effect on immunocompetence of clam *R. philippinarum* and on *V. tapetis* cytotoxicity 406

Christine Paillard and Susan E. Ford
Repeated hemolymph sampling of individual clams: what does it tell us about sampling procedures? 406

Eric J. Schott, José A. F. Robledo, Wolf T. Pecher, Florence A. Okafor and Gerardo R. Vasta
The antioxidant system of the protistan parasite, *Perkinsus marinus* 406

Philippe Soudant, Gwénaëlle Choquet, Christophe Lambert, Alain Marhic and Christine Paillard
Seasonal and culture site effects on the physiological, immunological and Brown Ring disease status of the manila clam *Ruditapes philippinarum* 406

P. Soudant, C. Lambert, G. Choquet, S. Ford, C. Paillard, L. Degremont, M. Delaporte, J. Moal, P. Boudry, P. Soletchnick, J.-P. Joly, M. Ropert, E. Bédier, A. Huvet and J.-F. Samain
Relationships between summer mortalities and defence mechanisms in families of *Crassostrea gigas* reared in different environmental conditions 407

Qing-Gang Xne, Jerome F. La Peyre, Aswani K. Volety and Fu-Lin E. Chu
Purification and characterization of lysozyme from plasma of eastern oysters (*Crassostrea virginica*) 407

SEA URCHIN BIOLOGY, PATHOLOGY AND CULTURE

Ralph Elston
Sea urchin mortality in Maine, initial case report and overview 407

Eddy J. Kennedy, Shawn M. C. Robinson, John Castell and G. Jay Parsons
Importance of dietary minerals and pigments for increasing somatic growth of juvenile green sea urchins (*Strongylocentrotus droebachiensis*) 408

Gregory MacCallum, Shawn Robinson, Sharan McGladdery and Mary Stephenson
Sea urchin disease concerns in Atlantic Canada 408

Michelle Moody and Charles W. Walker
Photoperiod, urchin "eyes" and gametogenesis 408

Esther C. Peters
Abiotic and biotic threats to sea urchin health: what price culture? 409

Michael P. Russell
Growth response and acclimation of green sea urchins to fluctuating salinity 409
Paul Waterstrat and Ted Creaser
Urchin health issues in Maine 409

LOBSTER BIOLOGY AND FISHERIES

Kathleen M. Castro, J. Stanley Cobb, Richard Wahle and John Catena
The effects of habitat addition and stock enhancement for American lobsters, *Homarus americanus* on artificial reefs in Rhode Island 410
Andrei Y. Chistoserdov, Feliza Mirasol and Roxanna Smolowitz
Characterization of microbial assemblagies involved in the development of shell disease in the American lobster, *Homarus americanus* 410
J. S. Cobb and M. Clancy
Changes in lobster populations in Narragansett Bay, Rhode Island, 1959–2000 410
Cem Giray and Deborah A. Bouchard
The role of *Vibrio fluvialis* and other bacterial species in lobster mortalities in Maine 410
Diane Kapareiko, Richard A. Robohm, John J. Ziskowski, George R. Sennefelder and Anthony Calabrese
Shell disease prevalence and severity in offshore American lobster populations 411
Wendy Norden and J. Stanley Cobb
Depth-related predation pressure on larval lobsters (*Homarus americanus*) prior to settlement 411
Susan A. Little, Win Watson and Bonnie Spinazzola
The effect of temperature on sexual maturity in the female lobster, *Homarus americanus* 411
James Manning, Bonnie Spinazzola, Patrice Farrey, David Casoni and Clare Grindal
Environmental monitors on lobster traps 412
Roxanna Smolowitz, Andrea Hsu, Erin Summers and Andrei Christoserdov
Lesions associated with recent epizootic shell disease in *Homarus americanus* on the northeast coast 412
Barbara A. Somers, Kathleen M. Castro, John Sorlien and Tom Angell
What can data from industry conducted tag-recapture programs tell us? A study of the American lobster (*Homarus americanus*) 412

OYSTER REEFS AND RESTORATION

Elizabeth M. Flynn and Kennedy T. Paynter, Jr.
A characterization of ideal habitat structure for the striped blenny *Chasmodes bosquianus* 413
Raymond Grizzle, Larry Ward, Jamie Adams, Semme Dijkstra and John Nelson
A comparison of acoustic techniques, videography, and quadrat sampling for characterizing subtidal oyster reefs........ 413
Kimberly A. Hamilton, D. LaDon Swann and William Burkhardt, III
Prevalence of enteric microorganisms in the eastern oyster (*Crassostrea virginica*) and their overlying waters at representative sites of an oyster gardening program in Mobile Bay, Alabama 413
J. C. Issacs, W. R. Keithly and A. Diagne
Use and value of oyster reefs among recreational fishermen in Louisiana 414
Earl J. Melancon, Jr., Dale Diaz and Badiollah Asrabadi
Relaying as a method to remove hooked mussels from oysters prior to reharvest for sale........ 414
Roger I. E. Newell, Evamaria W. Koch, Melissa K. Wood, Ray E. Grizzle, and Raleigh R. Hood
Modeling the influence of filtration by oyster stocks on turbidity and seagrass growth........ 414
Stewart Harris and Kennedy T. Paynter
The effect of stocking density on benthic community development and shell height in the eastern oyster, *Crassostrea virginica* 415
Rachel E. Sackett, Russ Peterson, Ami E Wilbur and Jim Swartzenberg
Evaluating the contribution of commercial oyster aquaculture to recruitment........ 415
Lisa Wall, Linda Walters, Kevin Johnson, Neysa Martinez and Ray Grizzle
Recruitment of the oyster *Crassostrea virginica* on intertidal reefs in areas with intense boating activity in the Indian River Lagoon, Florida........ 415

OFFSHORE FISHERIES

Todd Gedamke and William DuPaul
Integrating vessel tracking, catch data, and depletion models to estimate commercial scallop dredge efficiency 416

Kevin D. Gaff, William D. DuPaul and David B. Rudders
The use of a 4-inch (101 mm) sea scallop (*Placopecten magellanicus*) ring dredges in the context of an area management strategy 416

Deborah Hart and Paul Rago
Rebuilding sea scallop (*Placopecten magellanicus*) stocks using area closures and rotational fishing 416

Paul J. Rago and Deborah R. Hart
Fleet dynamics of the Atlantic sea scallop fishery 416

Farhad Rajabipour
Population structure of the Indian squid, *Loligo duvaucelii* Orbigny, 1848, in Iranian waters of the Oman Sea 417

Anne Richards, Michael Fogarty, David Mountain and Mirta Teichberg
Recruitment dynamics of northern shrimp (*Pandalus borealis*) in the Gulf of Maine 417

James R. Weinberg and Charles Keith
Deep sea red crabs off southern New England: has there been a fishery impact on the population? 417

DISEASES OF SHELLFISH: CONTRIBUTED SESSION

B. K. Diggles, P. M. Hine, V. L. Webb, E. W. Maas, J. Nichol, S. Wakefield, R. Roberts, C. S. Friedman, N. Cochennec-Laureau, K. S. Reece and N. A. Stokes
Mortalities of cultured abalone, *Haliotis iris,* infected by a novel haplosporidian 418

Ralph Elston, Dan Cheney, Brian MacDonald and Andrew Suhrbier
Low salinity tolerance in Manila clams *Venerupis philippinarum* 418

Sean E. Matson and Christopher Langdon
A specific pathogen free culture system for *C. gigas* larvae and spat 418

Gary R. Meyer and Susan M. Bower
Intramitochondrial crystals within the haemocytes of mussels (*Mytilus edulis*) experiencing unexplained mortalities 419

James D. Moore and Carolyn S. Friedman
Environmental detection of the rickettsiales-like prokaryote causing withering syndrome in abalone 419

J.-L. Nicolas, M. Garnier, M. Gay and F. Leroux
Vibrio associated with juvenile oyster during summer mortality in France 419

Wolf T. Pecher, José A. F. Robledo, Cathleen A. Coss and Gerardo R. Vasta
Further molecular characterization of *Perkinsus andrewsi* and related isolates 420

José A. F. Robledo, Gerardo R. Vasta, Patrícia A. Nunes and M. Leonor Cancela
In vitro culture of *Perkinsus atlanticus* from clams *Tapes decussatus:* characterization of the rRNA gene 420

José A. F. Robledo, Eric. J. Schott, Adam G. Marsh and Gerardo R. Vasta
Gene discovery in *Perkinsus marinus* using expression sequence tags (EST) 420

José A. F. Robledo and Gerardo R. Vasta
The Nramp gene and competition for available iron between *Crassostrea virginica* and *Perkinsus marinus* 420

Arnaud Tanguy, Susan E. Ford and Ximing Guo
Characterisation of gene expression in response to *Perkinsus marinus* and *Haplosporidium nelsoni* infections in the eastern and Pacific oysters 421

BIVALVE HABITAT SUITABILITY AND THE ROLE OF BIVALVES IN ECOSYSTEMS

Loren D. Coen, Richard K. Wallace and Nancy Hadley
How community-based oyster restoration can enhance research efforts: examples from South Carolina and Alabama 421

William S. Fisher
Oyster habitat suitability as a component of resource management 421

Dana M. Frank and J. Evan Ward
Continuous monitoring of pumping pressure and valve gape in the oyster *Crassostrea virginica* in response to changes in environmental parameters 422

Raymond Grizzle, Jennifer Greene and Mark Luckenbach
A simplified seston uptake model for bivalves: preliminary field tests 422
Mark Luckenbach, Janet Nestlerode, Paige Ross, Jr. and Alan Birch
The influence of reef architecture and scale on success of oyster reef restoration 422
Jennifer Mugg Pietros and Michael A. Rice
Effects of *Crassostrea virginica* populations on sedimentation, phytoplankton species composition and ammonia cycling in experimental mesocosms 423
Thomas M. Soniat
A modified habitat suitability index for the eastern oyster, *Crassostrea virginica* 423
S. Gregory Tolley, Aswani K. Volety, Emily C. Lindland and James T. Winstead
Use of oyster habitat by reef-resident fishes and decapod crustaceans in the Caloosahatchee Estuary, Florida 423
Aswani K. Volety, S. Gregory Tolley and James T. Winstead
Effects of freshwater releases and season on oysters (*Crassostrea virginica*) in Caloosahatchee Estuary, Florida 424
James T. Winstead, Aswani K. Volety and S. Greg Talley
Parasitic and symbiotic fauna inhabiting oysters (*Crassostrea virginica*) and mud crabs (*Panopeus herbstii*) sampled from Caloosahatchee Estuary, Florida 424

POSTERS

Patrick Baker and Amy Benson
Habitat and ecology of green mussels, *Perna viridis*, in Florida 424
Shirley Baker, Ed Phlips, David Heuberger, Clay Montague and Leslie Sturmer
Introducing the CLAMMRS project: clam lease assessment, management and modeling using remote sensing 425
Andrea Battison, Barbara Horney, Richard Cawthorn and Allan MacKenzie
Hemocytes of *Homarus americanus* stained with a modified Wright-Giemsa stain: description and comparison to current classification schemes 425
Karine Bouilly, Alexandra Leitão, Helen McCombie and Sylvie Lapègue
Impact of atrazine on aneuploidy in the Pacific oyster, *Crassostrea gigas* 425
François Bourque, Bruno Myrand and Marcel Roussy
Status of the *Mytilus edulis* stock which supplies high-quality spat to mussel growers in Iles-de-la-Madeleine (Gulf of St. Lawrence) 425
Jason P. Breves and Andrew E. Tate
Predator induced phenotypic response by the common periwinkle (*Littorina littorea*) 426

PERKINSUS

ENVIRONMENTAL EFFECTS ON *PERKINSUS MARINUS* INFECTION RATES, GROWTH AND SURVIVAL AMONG DERMO-DISEASE-FREE JUVENILE OYSTERS PLANTED AT THREE SALINITY REGIMES IN THE PATUXENT RIVER, MARYLAND.

George R. Abbe* and **Brian W. Albright,** Academy of Natural Sciences Estuarine Research Center, St. Leonard, MD 20685; **Carol B. McCollough, Christopher F. Dungan,** and **Stephen J. Jordan,** Sarbanes Cooperative Oxford Laboratory, Oxford, MD 21654.

Specific pathogen-free (SPF) oysters were set on oyster shell and transplanted to three sites in the Patuxent River, Maryland along a salinity gradient to investigate environmental effects of *Perkinsus marinus* on infection rates, growth and survival. Oysters were held in trays on PVC structures 0.1 m off bottom on natural oyster bars. Several thousand spat were deployed at each site, and 100 oysters in a separate tray were followed for growth and mortality. From September 2000 to September 2001 salinities at Holland Point (HP, upper river), Gatton (GAT, mid) and Town Creek (TC, lower) averaged 11.1, 13.0 and 14.4, respectively. Oysters were examined monthly for growth and mortality and 30 were collected from each site for assay of *P. marinus* infections by whole body burden technique. This allowed determination of time to initial infection and subsequent progression of disease. An additional 30 from the natural population at each site were also examined monthly by rectal tissue assay. Oysters (initially 25 mm) at HP, GAT and TC grew 23, 34 and 27 mm, respectively, and survival was 95, 98 and 94% during the first 12 months. Mean intensity of dermo disease among feral populations (on a scale of 0–7) at HP, GAT and TC ranged from 1.1 to 4.2, 0.7 to 4.6 and 0.7 to 4.7, respectively, and averaged 2.51, 2.72 and 2.79. It appears that salinity had little effect on growth, survival and infection intensity during the first year; however, it is generally later that damage occurs. Preliminary data suggest that a mid-river site might be the best area to locate oysters, but additional data during subsequent years may dictate otherwise.

TRANSPORT OF PARTICLES ACROSS EPITHELIA FROM OYSTER MANTLE CAVITY: A MODEL FOR *PERKINSUS MARINUS* INVASION.

Bassem Allam and **Susan E. Ford,*** Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ 08349.

The digestive tract has long been considered the major portal of entry for the oyster parasite, *Perkinsus marinus*, but recent studies suggest that the mantle and gill may also be import invasion sites. We used 5-μm latex beads, placed in the mantle cavity, to determine whether *P. marinus* could be actively transported across mantle and gill epithelia. At intervals after incubation, oysters were processed for histological and cytological analysis. After 2 h, beads were observed in hemocytes at the epithelial surface and within the epithelium of the gill and mantle. After 6 to 16 h, beads were found within hemocytes in the underlying tissues. Sixteen hours following contact, only about 1% of hemocytes withdrawn from the adductor muscle contained beads, although most of those that did contained multiple beads. Over the next 96 h, the fraction of hemocytes with beads gradually declined. Meanwhile, tissue sections showed that beads were progressively transferred toward the digestive tract. These results emphasize the role of mantle and gill epithelia as portals of entry for *P. marinus* and other microorganisms, and suggest a role for hemocytes in their transport.

EFFECTS OF OYSTER EMERSION ON THE GROWTH AND THE METABOLISM OF *PERKINSUS MARINUS*.

Louis E. Burnett* and **Christopher S. Milardo,** Grice Marine Laboratory, University of Charleston, SC, 205 Fort Johnson, Charleston, SC 29412

We examined the effects of pH, oxygen, carbon dioxide, and temperature on the metabolism of the oyster parasite *Perkinsus marinus* simulating conditions that occur within the tissues of the Eastern oyster *Crassostrea virginica* during air exposure in the summer. *P. marinus* was cultured in a modified JL-ODRP medium in ambient air at high humidity. The culture medium was gassed with appropriate CO_2, N_2 and O_2 mixtures, and pH adjusted in order to simulate the conditions present in oyster hemolymph. Oxygen uptake of the parasite decreased proportionately with decreasing ambient oxygen, and decreasing pH increased *P. marinus* respiration under low CO_2 conditions ($p = 0.0006$); under 15 torr CO_2, there was no relationship between pH and oxygen uptake. Increased CO_2 levels (simulating conditions during oyster air exposure) significantly increased parasite O_2 uptake ($p < 0.0001$), as did increased temperature ($p < 0.0001$). Cycling temperature (at pH 6.3, 7.1 and 7.6) in 6-hour intervals from 25°C–35°C did not affect culture growth; however, when cycled from 25°C–40°C, cells showed a significant decrease in growth ($p < 0.0001$). Similarly, cells grown at 35°C and 15 torr ambient CO_2 showed decreased growth. These results suggest that summer environmental conditions in the intertidal zone and especially in the tissues of oysters play a role in keeping *P. marinus* infections of *C. virginica* at sub-lethal levels (SC Sea Grant R/ER-14).

SUSCEPTIBILITY OF THE CARIBBEAN OYSTER *CRASSOSTREA RHIZOPHORAE* TO *PERKINSUS MARINUS*.

David Bushek,* Baruch Marine Field Laboratory, PO Box 1630, University of South Carolina, Georgetown, SC 29442; **John Scarpa** and **Susan E. Laramore,** Harbor Branch Oceanographic Institution, Ft. Pierce, FL 34946.

The oyster pathogen *Perkinsus marinus* is a formidable problem for the American oyster, *Crassostrea virginica*. The Caribbean oyster *C. rhizophorae* is a closely related species of *C. virginica*.

but little is known of its resistance to *P. marinus* (Dermo). Therefore, Dermo resistance was compared between the Caribbean and American oyster.

Two Dermo-free families were produced and reared separately, under quarantine, for each species. Oysters from each family were challenged once via shell-cavity inoculations with either saline (control) or one of two genetically distinct isolates of *P. marinus:* ATCC 50762 from Fort Pierce, FL or ATCC 50783 from Cotuit Bay, MA. Parasite dosages were adjusted to 1×10^5 *P. marinus* per gram of wet tissue weight for each oyster. Oysters were fed phytoplankton twice a day and water was exchanged weekly for 16 wk. A natural infection study was also performed by placing oysters from each family in concrete tanks that received 7–10 L/min unfiltered seawater from the Indian River Lagoon and examining the oysters for infection over the course of 214 days. Infections in each experiment were determined using the whole-body burden method.

Fifteen America oysters and one Caribbean oyster died during the challenge experiment. Log10 transformed *P. marinus* burdens in surviving oysters were significantly heavier for Caribbean oysters (1.25 ± 0.08) compared to American oysters (0.72 ± 0.06). Control oysters did not develop infections (0.09 ± 0.01). In the natural infection study, parasites were detected in all groups after 103 days, but intensities were negligible and there was no difference in burdens between the two species. At the end of the study (day 214), most oysters had died (survival: 0 to 27%). *Perkinsus* prevalence was 100% in all surviving *C. virginica*, but 10% of the *C. rhizophorae* had escaped infection. There was no significant difference between species, however, in body burdens of survivors at the end of the natural exposure experiment. Results from the two studies indicate that Caribbean oysters are as susceptible to North American isolates of *Perkinsus*, but may be somewhat more tolerant of heavier parasite loads.

DOES THE UNIQUE FATTY ACID SYNTHETIC CAPABILITY OF *PERKINSUS MARINUS* HAVE IMPLICATION FOR VIRULENCE?

Fu-Lin E. Chu,* Eric Lund, and **Ellen Harvey,** Virginia Institute of Marine Science, the College of William and Mary, Gloucester Point, VA 23062; **Philippe Soudant,** Université de Bretagne Occidentale, Place Nicolas Copernic, 29280 Plouzané, France.

The fatty acid synthetic capability in all the studied parasitic protozoans are limited. *Perkinsus marinus* distinguishes itself from all of the other studied parasitic protozoans by its ability to synthesize a wide range of saturated and unsaturated fatty acids. Most interestingly, *P. marinus* utilizes a two carbon substrate (^{13}C-acetate) to synthesize the essential fatty acid, arachidonic acid (AA). The ability of *P. marinus* to synthesize AA is novel. No parasitic protozoan has been reported to be capable of synthesizing AA *de novo*. There is building evidence in the mammalian system that excess AA-derived eicosanoids (powerful intercellular signaling molecules) may be harmful to host defenses. Synthesis of AA increased dramatically from day 1 to day 3 in cultured *P. marinus* meronts. It has been suggested that AA metabolites may potentially affect the cellular immune function and the inflammatory response to infection. This research was funded by Metabolic Biochemistry Program, National Science Foundation (MCB9728284).

EFFECT OF *PERKINSUS MARINUS* ON PHENOLOXIDASE ACTIVITY IN BIVALVE HEMOLYMPH.

Lewis E. Deaton* and **Percy J. Jordan,** Biology Department, University of Louisiana at Lafayette, Lafayette, LA 70504.

Phenoloxidase has been implicated as a component of host defense in a variety of invertebrates, including molluscs. The enzyme is found in the hemolymph and hemocytes of bivalves. *Perkinsus marinus* is a protist that causes disease in oysters, but does not infect *G. demissa.* We collected hemolymph from the mussel *Geukensia demissa* and the oyster *Crassostrea virginica* and measured the phenoloxidase activity in the blood with a colorimetric assay. *Perkinsus marinus* was added to aliquots of hemolymph and the phenoloxidase activity compared to that in hemolymph not exposed to *P. marinus* at 1, 2, 4, and 6 hrs after addition of the protist. After 2 hours of incubation, the phenoloxidase activity in both *G. demissa* and *C. virginica* hemolymph mixed with *P. marinus* was significantly lowered. These results suggest that *P. marinus* may suppress some components of the host defense mechanisms of bivalves.

EPIZOOTIC DISEASES IN CHESAPEAKE BAY CLAMS.

Christopher F. Dungan,* Rosalee M. Hamilton, and **Carol B. McCollough,** Cooperative Oxford Laboratory, Oxford, MD 21654; **Kimberly S. Reece** and **Karen L. Hudson,** Virginia Institute of Marine Science, Gloucester Point, VA 23062.

Chesapeake Bay commercial clam landings have consistently declined to less than 2% of peak harvests during the past ten years, prompting Maryland DNR resource assessment surveys that included disease diagnostics. During 2000, ten sampled commercial clam populations (8 *Mya arenaria* softshell clams and 2 *Tagelus plebeius* razor clams) all showed *Perkinsus* sp. infections at prevalences of 30–100%. Seven of eight sampled *M. arenaria* populations also showed disseminated neoplasia (DN) prevalences of 3–37%, but neither sympatric *T. plebeius* sample was affected by DN disease. Depleted and diseased softshell clam populations, especially Eastern Bay stocks affected by both diseases, were projected to suffer heavy disease mortalities. Although both mesohaline commercial clam species were reported as *Perkinsus marinus* hosts in 1954, *Perkinsus* sp. infections in Maryland *M. arenaria* populations were not detected histologically in routine survey samples until 1990, the same year in which the current decline in landings began. Axenic in vitro *Perkinsus* sp. isolates were readily acquired from both clam hosts sampled during 2000, and from three additional clam species (*Macoma balthica, Mulinia lateralis, Rangia cuneata*) sampled during 2001. In vitro cell cycle and genetic characteristics of *Perkinsus* sp. isolates from Chesapeake Bay clams differ from those of *P. marinus* isolates from sympatric oyster hosts.

EVALUATION OF PHYSIOLOGICAL CONDITION IN DERMO RESISTANT OYSTERS.

Vincent G. Encomio,* Shawn Stickler, and **Fu-Lin Chu,** Virginia Institute of Marine Science School of Marine Sciences College of William and Mary Gloucester Point, VA 23062.

Distinct oyster stocks (F1 progeny) were grown in the field to compare resistance to Dermo. After two years, significant differences in mortality and growth were observed. To compare the effects of parasitic stress (*Perkinsus marinus*) on physiological condition and energy reserves between oyster stocks, energy reserves (glycogen, lipids, and total protein) were quantified and evaluated for their contribution to overall physiological condition. Biochemical indices were correlated with changes in shell height, condition index, and *P. marinus* infection. Total glycogen and protein contents increased with shell height. Results also indicate seasonal variation in condition index, which was highest in winter and decreased during the summer when infection levels were the highest. Glycogen also exhibited a similar trend. These trends were consistent between sites and over all oyster stocks, but variation between stocks was not significant, despite differences in infection intensities and mortalities. Although condition indices decreased as infections increased, data were not strongly correlated. This project was supported by ODRP, NOAA (Virginia Sea Grant # VA-OD-99-3).

EVALUATION OF ANTIMICROBIAL PEPTIDES FOR RECOMBINANT FEED-BASED DELIVERY IN SHELLFISH AQUACULTURE.

Tarquin Dorrington,* Graduate School of Oceanography, University of Rhode Island, Narragansett, RI 02882; **Marta Gómez-Chiarri,** Department of Fisheries, Animal and Veterinary Sciences, University of Rhode Island, Kingston, RI 02881; **Lenore Martin,** Department of Cellular and Molecular Biology, University of Rhode Island, Kingston, RI 02881.

The long-term goal of this research is to develop recombinant strains of microalgae expressing antimicrobial peptides (AMPs) that could be fed to bivalves for treatment of infectious diseases. We screened for candidate AMPs that are toxic against marine pathogens without inhibiting the growth of candidate hosts for eukaryotic expression. Pleurocidin (from the winter flounder *Pleuronectes americanus*) and tachyplesin (from the horseshoe crab *Tachypleus tridentatus*) were active against *Vibrio* spp. in the range of salinity, pH and protease concentrations found in the digestive system of oysters (Minimum Inhibitory Concentration MIC_{50} at 24 hours 6.25–25 μM). Tachyplesin and pleurocidin had no effect on the growth of *Perkinsus marinus*. The yeast strains *Pichia pastoris* and *Saccharomyces cerevisiae* were resistant to tachyplesin and pleurocidin activity ($MIC_{50} > 200\ \mu M$), whereas three algal strains (*Skeletonema costatum, Chlamydomonas reinhardtii* and *C. pulsatilla*) were sensitive ($MIC_{50} < 50\ \mu M$). While proteases from *P. marinus* significantly reduced the antimicrobial activity of pleurocidin, they did not affect the activity of tachyplesin. These results are consistent with the finding that the substrate specificity of *Perkinsus* proteases is similar to that of elastase. Oyster clearance rates of *C. reinhardtii, C. pulsatilla,* and *P. pastoris* were similar to those of *Tetraselmis lucia*, a commercially available alga used in aquaculture.

FLOW CYTOMETRIC ANALYSIS OF LECTIN BINDING TO *IN VITRO* CULTURED *PERKINSUS MARINUS* SURFACE CARBOHYDRATES.

Julie D. Gauthier,* Biology Department, Nicholls State University, Thibodaux, LA 70310; **Jerome F. La Peyre,** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803; **Jill A. Jenkins,** National Wetlands Research Center, U.S. Geological Survey, Lafayette, LA 70506.

Parasite surface glycoconjugates are frequently involved in cellular recognition and colonization of host. The present study identifies surface carbohydrates by flow cytometric analysis of fluorescein isothiocyanate-conjugated lectin binding. Lectin binding specificity was confirmed by sugar inhibition and Kolmogorov-Smirnov statistics. Clear, measurable separation between fluorescence peaks and no parasite autofluorescence were observed. Parasites (GTLA-5 & P-1 strains) harvested at log phase growth from a protein-free medium reacted strongly with wheat germ agglutinin (WGA) and concanavalin A (Con A), reflecting presence of N-acetyl-D-glucosamine and glucose/mannose moieties, respectively. Both strains also bound, although with lower intensity, *Maclura pomifera* agglutinin (MPA) and *Bauhinia purpurea* agglutinin (BPA) (N-acetyl-D-galactosamine specific lectins), peanut agglutinin (PNA) (terminal galactose specific), and *Griffonia simplicifolia* II (GSII) (N-acetyl-D-glucosamine specific). Background fluorescence levels were detected for *Ulex europaeus* agglutinin I (L-fucose specific) and *Limulus polyphemus* agglutinin (sialic acid specific). The order of lectin binding intensity differed between strains: GTLA-5 reacted with MPA>GSII>PNA>BPA, whereas P-1 reacted with PNA>MPA>BPA>GSII, which may result from differential expression of glycoconjugates throughout log phase growth. Fluorescence microscopy revealed that PNA bound with high intensity primarily to schizonts (dividing cells), whereas the other lectins bound with approximately equal intensity among parasite growth stages. Future efforts will determine if *P. marinus* rapid recognition and internalization involves a specific lectin-carbohydrate interaction.

CLIMATE VARIABILITY AND DERMO DISEASE IN CHESAPEAKE BAY.

Eileen E. Hofmann* and **John M. Klinck,** Center for Coastal Physical Oceanography, Old Dominion University, Norfolk, VA 23529; **Eric N. Powell** and **Susan E. Ford,** Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ 08349; **Stephen Jordan,** Sarbanes Cooperative Oxford Laboratory, 904 South Morris Street, Oxford, MD 21654; **Eugene Burreson,** Virginia Institute of Marine Science, P.O. Box 1346, College of William and Mary, Gloucester Point, VA 23062.

A mathematical model that includes biological and environmental processes that contribute to the observed annual cycles of intensity and prevalence of the disease, Dermo, has been used to determine the effect of predicted climate variations on Eastern oyster (*Crassostrea virginica*) populations in Chesapeake Bay. Simulations that use the salinity change predicted for Chesapeake Bay by the Hadley Center Climate model for conditions of doubled CO_2 suggest that the present pattern of Dermo disease in the Bay will be altered to the benefit of the oysters. The predicted salinity change in Chesapeake Bay for conditions of doubled CO_2 produces an overall decrease in Bay salinity, which results in a decrease in the prevalence and intensity of Dermo disease. However, for reduced salinity conditions, there is a trade-off between reduced disease levels and reduced reproductive capacity of the oysters. Also, conditions of increased food can offset the effects of either increased or decreased salinity on Dermo disease levels. The simulated total oyster biomass changes suggest that for conditions of doubled CO_2, northern Chesapeake Bay oyster populations may not be viable over the long term without external inputs of juveniles. However, oyster populations in the Rappahannock and York Rivers increase or have stable biomass over time for most climate change conditions. One implication of these results is that oyster populations in southern Chesapeake Bay may sustain the Bay-wide oyster fishery. These simulations provide a basis for suggesting management plans for diseased oyster populations under conditions of climate change.

MODULATION OF *PERKINSUS MARINUS* FUNCTIONS BY HOST-DERIVED PRODUCTS.

Stephen L. Kaattari,* **E. Alanna MacIntyre,** and **Christopher G. Earnhart,** Department of Environmental Sciences, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

In an attempt to induce physiological changes *in vitro* that would be comparable to those elicited by natural infection, we have co-incubated *P. marinus* cells with extracts of *Crassostrea* spp tissues and plasma. Co-incubation with these host-derived materials gave rise to a variety of complex effects including altered differentiation, protease expression, growth rates, infectivity, and *in vitro* parasite mortality. Preliminary evidence is suggestive that a suite of such functions could be employed as a prognostic tool for the selection of resistant oyster stocks. However, variations in the relative activity of these materials suggest that preparative procedures and/or conditions of storage could confound such analyses. Thus, while indicative of prognostic value, the precise mechanisms of these biological effects must be resolved.

VIABILITY AND GROWTH OF *PERKINSUS MARINUS* AND *PERKINSUS ATLANTICUS* AT THREE TEMPERATURES.

Jerome F. La Peyre* and **Amy D. Nickens,** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803; **Sandra M. Casas** and **Antonio Villalba,** Centro de Investigacións Mariñas, Xunta de Galicia, aptdo. 13, E-36620 Vilanova de Arousa, Spain.

The ability to culture several protozoan parasites of the genus *Perkinsus* allows comparison of their growth and tolerance given different environmental conditions. This information is important to understand the distribution of these molluscan parasites and can be used to predict zones for high risk of mortalities of host populations. The effects of temperature on *P. marinus* and *P. atlanticus* were determined because temperature is a major factor controlling the prevalence and intensity of infection in their respective host, the eastern oyster, *Crassostrea virginica,* and the carpet shell clam, *Tapes decussatus.* Three isolates of each species were added to 96-well plates at a seeding density of 10^5 cells/ml and incubated at 4°C, 15°C and 28°C for 15 days. The parasite density, viability, size and metabolic activity were measured every other day starting on day 2. Parasite density was measured with a hemacytometer. Parasite viability was determined by neutral red uptake. Parasite metabolic activity was assessed by measuring the cellular bioreduction of the fluorescent dye Alamar Blue. The most significant result was that all three isolates of *P. atlanticus* multiplied at 15°C whereas no increase in parasite number of any *P. marinus* isolates was detected at 15°C. The growth rate of *P. marinus* and *P. atlanticus* was comparable at 28°C and neither species grew at 4°C. While perkinsosis is generally considered a warm water disease, this study suggests there will be differences in the temperature at which different *Perkinsus* species kill their respective hosts.

IS THE TEMPERATURE AND SALINITY-DEPENDENT VIRULENCE OF *PERKINSUS MARINUS* ASSOCIATED WITH INCREASED LIPID METABOLISM?

Eric D. Lund* and **Fu-Lin E. Chu,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062; **Philippe Soudant,** Université de Bretagne Occidentale, Place Nicolas Copernic, 29280 Plouzané, France.

Temperature and salinity significantly affect the rate of proliferation and development of *Perkinsus marinus* and the progression of the disease in its host, the eastern oyster. To better understand how these environmental parameters affect the nutritional metabolism of this parasite, the effects of temperature and salinity on the lipid metabolism of *P. marinus* were investigated. Using axenic cultures grown at 3 temperatures and 2 salinities, the uptake, incorporation and metabolism of two fluorescent lipid analogues in meronts and the lipolytic activities of meronts and extracellular proteins (ECPs) were determined. Uptake and bioconversion of the lipid analogues were positively correlated to temperature. Salinity did not affect the uptake, but bioconversion of these two components was lower at low salinity. Triacylglycerol lipase activity of cell homogenates and ECPs were positively correlated to temperature. Phospholipase activity was not detectable in ECP. This research was supported by NSF (MCB9728284).

PERKINSUS MARINUS INFECTION RATES IN SPECIFIC-PATHOGEN-FREE JUVENILE OYSTERS PLANTED AT THREE SALINITY REGIMES IN THE PATUXENT RIVER, MARYLAND.

Carol B. McCollough,* Christopher F. Dungan, and **Stephen J. Jordan,** Sarbanes Cooperative Oxford Laboratory, Oxford, MD 21654; **George R. Abbe** and **Brian W. Albright,** Academy of Natural Sciences Estuarine Research Center, St. Leonard, MD 20685.

Specific-pathogen-free (SPF) seed oysters were set and reared in filtered and sterilized Patuxent River water. They were transferred to three natural oyster bars in the Patuxent River along a salinity gradient. Deployment sites were located at Town Creek (TC, down river), Gatton (GA, mid-river), and Holland Point (HP, upriver). Samples of 30 oysters were assayed at 2, 4, and 8 weeks post-deployment for infection by *Perkinsus marinus*, using an enhanced RFTM whole body burden technique. Assays continued at 4-week intervals until three consecutive samples from each area tested positive for presence of *P. marinus*. Three discrete spat sets and deployments were made: September 2000, June 2001, and August 2001. Animals at sites TC and GA September 2000 deployments acquired *P. marinus* infections within 2 weeks, with prevalences of 10% and 3% respectively. Positive results at low prevalences and intensities continued for 8 weeks. Sites TC and GA June 2001 deployment acquired infections within 2 weeks, with 10% and 13% prevalences respectively, and positive results continued for 8 weeks with increasing prevalences. Site HP acquired one infection (3%) between 2 and 4 weeks. Positive results continued through two additional 4-week sampling intervals, with increasing prevalences. All August 2001 deployments acquired infections within 2 weeks, with prevalences of 7% at TC, 87% at GA, and 3% at HP, and positive results continued for 8 weeks. Infection intensities among these samples ranged from 1–23 hypnospores per host animal. The GA deployment was 100% infected by 8 weeks post-deployment. These results show that juvenile oysters acquire *P. marinus* infections as early as 2 weeks after placement in dermo disease endemic areas, and that these infections persist in the planted populations over time.

PERKINSUS PREVALENCE IN OYSTERS PRODUCED IN THE HATCHERY AND PLANTED IN THE FIELD.

Kennedy T. Paynter* and **Tim Koles,** Department of Biology, University of Maryland, College Park, MD 20742; **Don Meritt,** Horn Point Laboratory, University of Maryland Center of Environmental Science, Cambridge, MD 21613.

Since 1995, millions of oyster spat have been produced by the Horn Point oyster hatchery. Most of those oysters have been planted on oyster bars in various locations in the Maryland portion of Chesapeake Bay in association with oyster restoration efforts. Oysters planted in most of these areas were tested for *P. marinus* prior to being planted and then regularly tested, in some cases for as many as five years, after planting. Salinity, temperature and dissolved oxygen data were also collected at most sites. Data were analyzed from all monitored sites planted with *Perkinsus*-free spat over the past 5 years. Analysis showed that very few oysters were infected with *P. marinus* during their first year. In fact, very few oysters were infected during their second and even third years. Of the nearly 2,000 oysters collected in 2001 that were planted on restoration sites in 1998, 1999 or 2000, only 44 were infected. In addition, infections appear to be more related to local infection foci than salinity. Infection rates in hatchery-produced oysters are lower than expected compared to the naturally set oysters transplanted by the State as part of the repletion program.

RECENT TRENDS IN LEVELS OF INFECTION OF *PERKINSUS MARINUS* IN OYSTERS FROM GALVESTON BAY, TEXAS: RESULTS OF THE DERMOWATCH MONITORING PROGRAM.

Sammy M. Ray,* Department of Marine Biology, Texas A&M University, Galveston, TX 77553; **Thomas M. Soniat,** Department of Biology, Nicholls State University, Thibodaux, LA 70310; **Enrique V. Kortright,** Kortright Corporation, 102 Allendale Dr., Thibodaux, LA 70301; **Lance Robinson,** Texas Parks & Wildlife Department, 1018 Todville Rd., Seabrook, TX 77586.

Since December 1998 oysters in Galveston Bay have been monitored for levels of the parasite *Perkinsus marinus* as part of the Dermo Watch Program. Monthly sampling of six reefs (Redfish, Hannah's, Frenchy's, Fisher's, Confederate and April Fool) and three leases provides good spatial coverage and adequate temporal resolution for management purposes. Each month oysters are collected, their length (L) measured, and checked for weighted incidence (WI) of infection; water temperature and salinity are also determined. Initial WI, T, S, and L are used by a model embedded in the DermoWatch web site (www.blueblee.com/dermo) to calculate a time to critical level of disease (t-crit). The t-crit is the number of days that it would take to reach a critical WI of 1.5 (assuming no change in T and S). Values of t-crit are low when T and S are high. The effects of drought conditions during 1999 and 2000 were reflected in higher WI and lower t-crit values throughout the Bay. Oyster growers and managers can use estimates of t-crit to manage disease. For example, heavily infected populations of oysters with t-crit values equal to or approaching zero can be moved to lower salinity sites or harvested before they die of disease.

UTILIZATION OF MOLECULAR GENETIC DATA FOR DETECTING, IDENTIFYING AND DESCRIBING *PERKINSUS* SPECIES. **Kimberly S. Reece,*** Virginia Institute of Marine Science, The College of William and Mary, Gloucester Point, VA 23062.

Morphological characters are unreliable for distinguishing among *Perkinsus* species. In addition, traditional detection methods for *Perkinsus* species such as histological analyses or the Ray's fluid thioglycollate assay do not differentiate among the species. Therefore, *Perkinsus* species designations are based largely on differences in hosts and/or geographic ranges. In recent years several species-specific molecular detection assays have been developed targeting DNA sequence differences among described species. DNA sequence data is also being used to support and validate descriptions of new *Perkinsus* species. Results from several molecular genetic studies indicate that caution must be employed, however, to ensure that adequate molecular data is available to appropriately develop molecular diagnostics and to discriminate among species. Intra-, as well as inter-specific sequence variation should be examined to confidently target a particular nucleic acid sequence in molecular diagnostic assays or to use DNA sequence data from a locus in phylogenetic analyses or for taxonomic discrimination. Data will be presented suggesting that genetic variation that was previously thought to represent sequence differences between two *Perkinsus* species is observed within the genome of a single *Perkinsus* species isolated from two different hosts. In another study, a comprehensive examination of sequence variation among *Perkinsus* species within the internal transcribed spacer region of the ribosomal RNA gene complex supports designation of a new *Perkinsus* species that is closely related to *P. atlanticus* and *P. olseni*. Currently, *P. atlanticus* and *P. olseni* cannot be distinguished based on available molecular sequence data suggesting that synonymization of these two species may be warranted pending results of more extensive and complete analyses.

PROTEASE ACTIVITY IN THE EASTERN OYSTER *CRASSOSTREA VIRGINICA* AFTER EXPERIMENTAL INFECTION WITH THE PROTOZOAN PARASITE *PERKINSUS MARINUS*. **Pilar Muñoz Ruiz** and **Marta Gómez-Chiarri,*** Department of Fisheries, Animal and Veterinary Sciences, University of Rhode Island, Kingston, RI 02881.

Perkinsus marinus, an endoparasitic protozoan parasite, has long been recognized as a serious oyster pathogen that is often blamed for widespread mortality of the Eastern oyster *Crassotrea virginica*. In order to investigate the molecular interactions between *P. marinus* and oyster hemocytes during early infection, *Perkinsus*-free Eastern oysters (Taylor Shellfish, Washington, USA), were inoculated either in the mantle cavity or the aductor muscle with cultured cells of *P. marinus*. Protease and antimicrobial activity were measured in filtered supernatants of hemolymph collected 4 hours, 24 hours, 4 days and 2 months after experimental infection. No antimicrobial activity was detected in hemolymph supernatants of parasitized or control oysters. Protease activity in hemolymph supernatants collected 4 h after experimental infection was significantly higher in parasitized oysters than in control oysters. There were no differences in secreted protease activity between control and parasitized oysters sampled 24 hours, 4 days and 2 months after experimental infection. Gelatin-gel electrophoresis (zymography) analysis showed the presence of 5 high molecular weight bands (60–220 KDa) with protease activity in both control and parasitized oysters. Large variations in both the amount of protease activity and the relative abundance of each protease were observed between individual oysters. The presence of low molecular weight proteases (35–50 KDa), corresponding to *P. marinus* serine proteases, was observed in hemolymph supernatants of a small proportion of experimentally infected oysters.

"NATURAL DERMO RESISTANCE" IN EASTERN OYSTER STOCKS: CHESAPEAKE STUDIES AND DEFENSE-RELATED ACTIVITIES. **S. M. Stickler,* V. G. Encomio, S. K. Allen, Jr.** and **F-L. E. Chu,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062; **J. F. La Peyre,** Louisiana State University, Baton Rouge, LA 70803.

The restoration of Eastern Oyster populations can be accelerated, in part, by using stocks of oysters resistant to the parasitic disease Dermo, caused by *Perkinsus marinus*. Similarly, identifying correlated defense activities will expedite the breeding process for disease resistance. We used putatively Dermo-resistant wild stocks from both the Gulf of Mexico and the Chesapeake Bay and a disease-resistant hatchery strain, and compared the resistance of their progeny to Dermo disease in a two-year common garden experiment at two Dermo-enzootic Chesapeake Bay sites. Using a modified body burden assay, we determined *Perkinsus* infection levels and Dermo-related mortality were considerably higher in Chesapeake stocks than in Louisiana stocks. Chesapeake stocks experienced wide variation in both disease infection levels and mortality. These results indicate a genetic basis for disease resistance, even within a single region. Monthly hemocyte counts and hemocyte and serum potential for killing *P. marinus*, and plasma protein, lysozyme, and protease inhibition levels were obtained for correlation with *Perkinsus* infection levels. This project was supported by ODRP, NOAA (Virginia Sea Grant # VA-OD-99-3).

THE BIOLOGY AND CONSERVATION OF FRESHWATER MUSSELS

SPATIAL AND TEMPORAL ANALYSIS OF ECOSYSTEM PROCESSING OF FRESHWATER MUSSELS IN TWO HEADWATER STREAMS. Alan D. Christian, Department of Zoology, Miami University, Oxford, OH 45056; **David J. Berg**, Department of Zoology, Miami University, 1601 Peck Blvd., Hamilton, OH 45011; **B. Crump**, Caddo Ranger District, Ouachita National Forest, 912 Smokey Bear Lane, Glenwood, AR 71943.

The objectives were to determine food resources, food resource nutrient composition, tissue nutrient composition and N and P excretion rates of two species of mussels from two Little Darby Creek, OH and two Ouachita River, AR headwater sites. Seston stable isotope analysis revealed no differences in $\delta^{15}N$ values between sites within a streams or seasons, however, summer $\delta^{13}C$ values were significantly different than spring and fall $\delta^{13}C$ and $\delta^{15}N$ values. No differences in mussel $\delta^{15}N$ values were observed between sites within a stream, but were significantly different seasonally and different regionally. Seston nutrient concentrations were similar between sites within a stream and among seasons. No significant differences in nutrient tissue concentrations were observed between species within a stream, sites, or seasons. Excretion rates of N and P were lowest in spring and highest in fall for all species. Average N:P ratios were below 16:1 for some species and above 16:1 for other species. Nutrient limitation experiments may have indicated N and P limitation in the fall. Isotope values were regionally different, locally similar, temporally variable and suggest mussels utilize a subset of the seston, possibly bacteria. Mussels may be providing an important ecosystem role by providing limiting nutrients to primary producers.

CONSERVATION ACTIVITIES FOR FRESHWATER MUSSELS BY THE UNITED STATES FISH AND WILDLIFE SERVICE. Susan Rogers,* US Fish and Wildlife Service, Conway, AK 72032; **Richard Biggins**, US Fish and Wildlife Service, Asheville, NC 28801; **Steven Ahlstedt**, US Geological Survey, Knoxville, TN 37828.

The Fish and Wildlife Service (FWS) is active in freshwater mussel conservation through several approaches: habitat restoration, propagation and reintroduction of juveniles, collaboration with partners, and conservation research. The FWS is involved in conserving both federally listed and unlisted species. Before any recovery program can be successful, however, habitat must be restored and protected. A program such as that enacted in partnership with The Nature Conservancy on the Clinch River can be particularly successful in reaching this goal. Partnerships are integral to the FWS's freshwater mussel recovery programs. For example, the Tennessee Valley Authority and the Army Corps of Engineers also have worked with the FWS on mussel conservation in relation to their water resource projects. In addition to habitat restoration, propagation efforts have been ongoing for approximately 10–15 y, and endangered mussel populations throughout the country are being augmented with propagated juveniles. Finally research is being conducted to determine the causes of the bottleneck in survival that juvenile mussels experience around 60 d of age. Further information needs that would aid the FWS's conservation efforts include quantification of the impacts of sedimentation from dredging and navigation projects on mussel populations, and the impacts of pesticides on glochidial transformation success.

DIET EVALUATION FOR THE FRESHWATER MUSSEL *ELLIPTIO COMPLANATA* (BIVALVIA: UNIONIDAE). William F. Henley* and **Richard J. Neves**, Virginia Cooperative Fish and Wildlife Research Unit, Department of Fisheries and Wildlife Sciences, Virginia Tech, Blacksburg, VA 24061.

To determine the effects of holding conditions and different algal diets on freshwater mussels, the tissues of adult eastern elliptio freshwater mussels, *Elliptio complanata* (56–106 mm) were tested for physiological and gametogenic condition over 8 sampling events. Treatments included a reference group from the source population, the Nottoway River, Virginia (NR), and 3 captive treatments. Captive treatments were mussels fed *Scenedesmus quadricauda* (S), *Neochloris oleoabundans* (N), and a no feed treatment (NF). Patterns in levels of soluble protein, glycogen, and percentages of moisture differed over the course of the experiment ($p < 0.01$). Production of ripe and developing gametes did not differ in the treatments ($p = 0.22$), but the NF mussels ceased gametogenesis in spring. Carbohydrate levels of the N and S animals did not differ from those of the NF mussels ($p = 0.99$). Soluble protein levels of the N and S mussels remained relatively high throughout the experiment, those of the NF animals declined, and those of the NR varied. Percent moisture in tissues of the treatments differed over time ($p < 0.001$). Levels of total lipids in the mantle tissues of the treatment groups, as well as muscle fiber diameters in the foot, provided useful complimentary data for assessing body condition.

HIERARCHICAL ANALYSIS OF MTDNA VARIATION IN *AMBLEMA PLICATA*, A WIDESPREAD MUSSEL SPECIES.

Curt L. Elderkin,* Dept. of Zoology, Miami University, Oxford, OH 45056; **David J. Berg,** Dept. of Zoology, Miami University, Hamilton, OH 45011; **Janice L. Metcalfe-Smith,** National Water Research Institute, Burlington, ON, Canada L7R 4A6; **Caryn C. Vaughn,** Dept. of Zoology and Oklahoma Biological Survey, University of Oklahoma, Norman, OK 73019; **Alan D. Christian,** Dept. of Zoology, Miami University, Oxford, OH 45056; **Sheldon I. Guttman,** Dept. of Zoology, Miami University, Oxford, OH 45056.

Knowledge of genetic structure of target species is essential for the development of effective conservation plans. *Amblema plicata* is a common, widespread freshwater mussel species. Six or seven individuals from six populations of *Amblema plicata* within the Lake Erie and Ohio River drainages were analyzed by sequencing restriction fragments from a 652-base portion of the mitochondrial cytochrome oxidase I (COI) gene and a 530-base portion of the nuclear internally transcribed spacer (ITS-1) gene. Percent sequence divergence was determined and the results were analyzed by calculating Tamura-Nei distances between individuals and then constructing neighbor-joining trees from the distance matrix. Two haplotypes were identified for the COI gene and all populations shared these haplotypes. Greater diversity was found for the ITS-1 gene, with a total of six haplotypes, although each population had only one or two haplotypes. Cluster analysis revealed no real geographic structuring for either gene. These preliminary results are in striking contrast to those we have found using allozymes. The latter group of loci showed significant differentiation between the Ohio River and Lake Erie basins. Further investigation is required in order to explain this apparent contradiction.

GAMETOGENESIS, SPAWNING, BROODING AND GLOCHIDIAL DISCHARGE IN *MEGALONAIAS NERVOSA* (BIVALVIA: UNIONIDAE) FROM THE TENNESSEE RIVER IN ALABAMA.

Jeffrey T. Garner,* Alabama Division of Wildlife and Freshwater Fisheries, 350 Co. Rd. 275, Florence, AL 35633; **Thomas M. Haggerty,** Department of Biology, University of North Alabama, Florence, AL 35632, Rebekah L. Rogers, Bradshaw High School, Florence, AL 35630.

The annual gametogenic cycle of *Megalonaias nervosa* was monitored over a two-year period by observing temporal changes in histological preparations of gonadal tissues. In male specimens, temporal changes in cell numbers and relative abundance were evaluated by counting different germ cell types along transects through gonadal acini. Temporal changes in female specimens were quantified by measuring diameters of oocytes and counting the numbers of oocytes per acinus. The cycles observed in both male and female *M. nervosa* differed from those observed in other members of the Ambleminae. Little activity was observed through most of the year, culminating in a flurry of activity in late summer and early autumn. In male specimens, acini filled with spermatozoa in July and August and all were released in September. In female specimens, oocytes developed and grew quickly during the period in which spermatogenesis occurred in males and all oocytes were released to the marsupia over a short period, showing a high degree of spawning synchronicity with the males. Glochidia quickly matured and were present in both inner and outer gill demibranchs until December.

CLEARANCE RATE AND FILTRATION EFFICIENCY OF *ELLIPTIO COMPLANATA* (BIVALVIA: UNIONIDAE) EXPOSED TO DIFFERENT LABORATORY CONDITIONS.

Catherine M. Gatenby,* Daniel A. Kreeger and **Robyn Reinmiller,** Patrick Center for Environmental Research, Academy of Natural Sciences, Philadelphia, PA 19103; **Richard J. Neves,** Virginal Cooperative Fish And Wildlife Research Unit, Department of Fisheries and Wildlife Sciences, Virginia Tech, Blacksburg, VA 24061-0321.

As part of an ongoing research program improve laboratory culture protocols for native freshwater mussels, we quantified and compared feeding rates and particle size preferences of mussels, *Elliptio complanata*, that were exposed to different holding conditions in the laboratory. Two culture parameters were examined: the importance of a burrowing substrate (sand) and the effect of food quality (natural seston vs. lab-cultured microalgae). A Multi-Sizer was used to measure and compare clearance rates for the whole diet (2–63 μm diameter), specific size fractions of the diet (e.g., 2–3 μm), and for various sized carboxylate microspheres. By comparing clearance rates for different sized particles, we calculated their relative filtration efficiency, which tended to be greatest for moderately large sized particles averaging 7–10 μm in diameter. Both clearance rate and filtration efficiency varied considerably between sediment/no sediment conditions, and among dietary treatments of different quality. These parameters were also monitored for periods of up to 60 d to determine whether *E. complanata* adjust either feeding rates or particle size preferences as an adaptive response to differences in physical (e.g. sediment) or nutritional conditions.

VARIABILITY IN CONDITION INDEX AND TISSUE BIOCHEMISTRY OF *ELLIPTIO COMPLANATA* HELD IN THE FIELD AND LABORATORY.

Daniel A. Kreeger,* Catherine M. Gatenby and **Deborah Raksany,** Patrick Center for Environmental Research, Academy of Natural Sciences, Philadelphia, PA 19103.

Like their marine counterparts, native freshwater mussels can be sufficiently abundant to affect key ecological functions (e.g., energy, biogeochemical cycles) and perform important ecosystem services (e.g., removal of suspended particulate matter, use as bioindicators). The effectiveness of freshwater mussels depends in part on their physiological rate functions, which may vary with their physiological condition. Our goal was to determine the level of variability in physiological condition of *Elliptio complanata*, a common unionid in the Atlantic drainage. Adults were subjected to a variety of laboratory and field conditions. In the lab mussels were held in continuous flow chambers with or without sediment and fed isocaloric rations of either natural seston or lab-cultured microalgae. Field populations were caged and transplanted to waters of varying quality. Condition index and proximate tissue biochemistry (protein, lipid, carbohydrate, ash) were monitored for 6 weeks in the lab and 1 year in the field. Both condition and tissue biochemistry of wild mussels varied seasonally, as expected for adults undergoing reproductive cycling. However, irrespective of these normal seasonal patterns, condition and tissue biochemistry also varied among all experimental comparisons; food quality (seston > algal diets), sediment conditions (sediment > no sediment) and environmental conditions (field site differences). Although *E. complanata* is considered to be one of the more hardy unionids, these results indicate that its physiological condition is sensitive to nutritional and environmental cues. Therefore, physiological fitness measures for *E. complanata* should prove useful as bioindicators, and studies of ecological processing by these animals should quantify physiological rate functions under a variety of conditions.

PROPAGATION OF ENDANGERED FRESHWATER MUSSELS IN RECIRCULATING CULTURE SYSTEMS. **Richard J. Neves,* Jess W. Jones** and **William F. Henley**, Virginia Cooperative Fish and Wildlife Research Unit, Department of Fisheries and Wildlife Sciences, Virginia Tech, Blacksburg, VA 24061.

A propagation facility for the production, culture, and release of endangered juvenile mussels has been established at Virginia Tech, to address the conservation needs of 70 federally listed mussel species in the United States. After years of research on species' life histories, substratum and food requirements, and efficacy of culture systems, the facility has been successful in culturing juvenile mussels for release to natal rivers. Nine species have been cultured thus far, and over 250,000 juveniles have been released to 3 rivers in Tennessee and 2 streams in Virginia. These culture systems are seemingly suitable for holding and conditioning adult mussels for spawning, and graduate student experiments are ongoing to test the range of applications to mussel conservation. A recent grant from the National Fish and Wildlife Foundation has allowed construction of a new facility to test the recirculating culture systems on a larger production scale, to begin in 2002. The new facility, coupled with an adjacent pond, will provide additional research opportunities and conditions for long-term rearing of juvenile and adult mussels.

SMALL-SCALE ECOLOGICAL FUNCTION OF FRESHWATER MUSSELS (FAMILY: UNIONIDAE) IN THE KIAMICHI RIVER, OKLAHOMA. **Daniel E. Spooner*** and **Caryn C. Vaughn**, Oklahoma Biological Survey and Department of Zoology, University of Oklahoma, Norman, OK 73019.

Freshwater mussel (Family Unionidae) biomass and species diversity is declining as a result of recent and historic anthropogenic impacts. Despite this marked trend, very little is known concerning the ecology of unionids with respect to stream ecosystem function and local macroinvertebrate assemblages. We performed a 12-month field enclosure experiment to examine the role of unionids in streams and document their associated sediment and epilithic communities. Treatments were two mussel species, *Actinonaias ligamentina* and *Amblema plicata*, shell treatment, and a non-mussel sediment treatment. We observed colonization of algae, ash-free dry mass and invertebrates in the sediment and on the shells over three time periods: 1 month, 3 months, and 12 months. Chlorophyll a, AFDM and invertebrate abundance were higher in treatments containing live mussels. This trend was significant for months where stream flows were low, but non-significant during periods of high flow. However, there were no significant differences between species despite observed trends. This study indicates that freshwater mussels have the capacity to impact local algae, invertebrate and organic matter dynamics. However this relationship appears to be context dependent and may be overridden by advective forces such as flow.

COMPARATIVE AND EXPERIMENTAL EVIDENCE FOR THE FUNCTIONAL ROLE OF FRESHWATER MUSSELS IN STREAMS. **Caryn C. Vaughn,* Daniel E. Spooner, Melissa Moore** and **Keith B. Gido**. Oklahoma Biological Survey and Department of Zoology, University of Oklahoma, Norman, OK 73019.

Both the overall abundance and species richness of freshwater mussels are declining at an alarming rate. If mussels play critical roles in the functioning of river ecosystems, this significant loss of benthic biomass may result in alterations of ecosystem processes and functions, and also may impact other stream organisms that have co-evolved with mussel assemblages. We used a comparative field study and laboratory experiments to investigate the functional role of unionids in streams. From 1999–2001, we sampled benthic macroinvertebrates, meiofauna and fishes living in and around mussel beds in nine rivers of the Quachita Uplands of Oklahoma and Arkansas. Data analyzed to date indicate that densities of some benthic groups, notably oligochaetes and filtering caddisflies, are significantly related to unionid density. Laboratory experiments compared community respiration rates, water column nutrient concentrations, algal clearance rates, excretion rates, and biodeposition rates of *Actinonaias ligamentina* and *Amblema plicata*. Both species exhibited a strong, linear relationship between biomass and most ecosystem processes at small spatial scales. However, there were only subtle differences between species in their effects. Our results indicate that unionids can have strong effects on ecosystem processes when biomass is high, but that these effects are context dependent and can be overridden by physical forces.

ASSIMILATION OF MICROZOOPLANKTON BY ZEBRA MUSSELS: THE BENTHIC ZOOPLANKTON LOOP. W.-H. Wong* and Jeffrey S. Levinton, Department of Ecology and Evolution, State University of New York, Stony Brook, NY 11794-5245; Benjamin Twining, Marine Sciences Research Center, State University of New York, Stony Brook, NY 11794-5000.

Bivalves living at high densities exert strong effects on the water column. Following their invasion of North American rivers and lakes, zebra mussels (*Dreissena polymorpha*) caused major declines in both phytoplankton and microzooplankton. We tested the hypothesis that the microzooplankton are a potential food source for zebra mussels, and by extension, other bivalves. We labeled phytoplankton with ^{14}C and fed them to two species of rotifers found abundantly in the Hudson River, which had declined following the zebra mussel invasion. The labeled rotifers were fed to zebra mussels and we estimated clearance rates and assimilation of carbon. For both species of rotifers the assimilation efficiency was 40–50%. Before zebra mussels dominated the Hudson River in 1992, the assimilation from rotifers was about 2 to 3 times higher than its routine metabolic rate and also contributed about 0.349 (J/h) to 0.662 (J/h) to mussels growth and reproduction, conferring a positive scope for growth. Since the zebra mussels became abundant, the assimilation is still sufficient to explain about 16.4% to 23.1% of the mussels routine metabolic rate. Therefore, rotifers play a conceivably large role in the zebra mussels energy budget whether at high rotifer concentrations (before the invasion) or at low rotifer concentrations (after the invasion).

GENETICS AND MOLECULAR BIOLOGY

UNSCRAMBLING THE LOBSTER GENOME: COMPLEX HETEROZYGOSITY IN THE AMERICAN LOBSTER? Charles L. Brockhouse* and Gillian Richard, Marine Aquatic Genetics, Biological Sciences, U. South Alabama, Mobile, AL 36688.

The American Lobster, *Homarus americanus* Edwards, is both a highly important economic species and a model for invertebrate physiology. In spite of this, remarkably little is known about any aspect of the genetics of this species. In view of the long breeding cycle, genomics approaches are clearly preferable to classical breeding genetics. As a prelude to a genomics program, we have undertaken genome size and meiotic studies. Using Feulgen staining densitometry, we determined the *H. americanus* genome size to be approximately 2.7×10^9 base pairs. Confocal microscopy was used to study meiosis in male lobsters. The chromosome number was found to be $n = 108$, in approximate agreement with previous studies. Large numbers of univalents with chiasma to multiple other univalents were observed at metaphase I. Most or all of the chromosomes were observed in these conformations. This is strongly indicative of heterozygous interchanges among the chromosomes, a condition which has the genetic effect of linking many chromosomes into a single linkage group.

GENETICAL BASIS OF THE PLASTICITY OF RESOURCE ALLOCATION IN THE PACIFIC OYSTER *CRASSOSTREA GIGAS*. Bruno Ernande, CNRS-CREMA, 17137 L'Houmeau, France; Joel Haure, IFREMER-LCPL 85230 Bouin, France; Lionel Degrémont, Edouard Bédier and Pierre Boudry* IFREMER-LGP, 17390 La Tremblade, France.

Phenotypic and genetic correlations between fitness-related life-history traits—such as survival, growth and reproductive allocation—have to be considered to better understand selective processes, both in the wild and in breeding programs. Quantitative genetic experiments, based on nested half-sib mating designs, were performed in the Pacific oyster *C. gigas* (1) to estimate genetic variance and the response to selection and (2) to document phenotypic and genetic trade-offs between life history traits. Physiological trade-offs, *i.e.* plastcity of resource allocation, were shown to vary among genotypes. Genetic polymorphism was primarily observed for the plasticity of reproductive effort. In addition, the degree of plasticity in reproductive effort appeared to be genetically correlated with mean survival. The signs of some significant genetic correlations were found to reverse accross environments. These results could explain the maintenance of genetic polymorphism for the studied traits. These may help us to better understand the causes of summer mortalities in *C. gigas* juveniles, on which a national program recently started in France.

THE SUCCESSFUL PRODUCTION OF TETRAPLOID EASTERN OYSTER, *CRASSOSTREA VIRGINICA* GMELIN. Ximing Guo,* Jian Wang, Brenda J. Landau, Li Li, Gregory A. DeBrosse and Krista D. Buono, Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

Triploid eastern oyster grow 30–40% faster than normal diploids. Fast growth reduces not only culture duration and cost, but also losses from diseases inflicted mortality, which represents a serious problem in the eastern oyster. The ideal way to produce triploids is through diploid x tetraploid mating. Triploid production from tetraploid is as simple as producing normal diploids, 100% effective and free from genetic defects caused by polar body inhibition. Tetraploid Pacific oysters have been successfully produced and commercialized. A small number of tetraploid eastern oysters were previously produced but lost. Here we reported the production of a large number of tetraploid eastern oysters. The tetraploids were produced using the Guo-Allen method—inhibiting polar body I in eggs from triploids fertilized with normal sperm. Triploid females were individually confirmed by flow cytometry before use. Fertilized eggs were treated with 0.5 mg/L cytochalasin B from about 10 to 30 min post-fertilization (PF). Thirteen replicates were made, and eight produced significant numbers of spats (>100). Ploidy analysis at two months PF found tetraploid spat in all replicates, ranging from 10 to 100%. Over 4000 tetraploid spats were produced from the eight surviving replicates. Tetraploids were larger than triploids and diploids within groups. At five months PF, about 10% of the tetraploids changed to primarily triploid/tetraploid mosaics. The tetraploids were made from a Rutgers disease-resistant stock, which demonstrated strong resistance to MSX, a parasitic disease. The combination of superior growth and disease-resistance may make triploid eastern oysters extremely valuable for aquaculture production.

GENETIC DISTINCTIVENESS OF INSHORE AND OFFSHORE *SPISULA* CLAMS.

Matthew P. Hare,* Biology Department, University of Maryland, College Park, MD 20742; **Stephen R. Palumbi,** Center for Conservation and Evolutionary Genetics, 16 Divinity Ave., Cambridge, MA 02138

Spisula solidissima is restricted to the western North Atlantic where it is commercially harvested by dredge from shelf waters between Georges Bank and Cape Hatteras. A closely related taxon, *S. solidissima similis*, inhabits the Gulf of Mexico and shallow coastal waters along the Eastern Seaboard. Although studies of the population biology and demography of *Spisula* clams have been productive because of the ability to age cohorts from annular growth rings, few data have been published on range distributions and patterns of genetic variation. The mitochondrial and nuclear DNA sequences presented here represent a preliminary effort to describe the phylogeny and biogeography of *Spisula* clams and relatives in the North Atlantic. Mitochondrial cytochrome oxidase I and nuclear calmodulin intron sequence data show the southern/inshore subspecies is genetically very distinct from *Spisula solidissima* populations from the Gulf of St. Lawrence (Canada), Georges Bank and offshore from Ocean City, Maryland. Despite the restricted inshore habitat of *S.s. similis*, genetic variation within this taxon is exceptionally high, suggesting a large effective population size or population substructure among coastal populations.

A GENETIC LINKAGE MAP OF 100 MICROSATELLITE MARKERS FOR THE PACIFIC OYSTER *CRASSOSTREA GIGAS.*

Dennis Hedgecock,* Sophie Hubert, Gang Li, and **Katharine Bucklin,** University of California, Davis, Bodega Marine Laboratory, Bodega Bay, CA 94923-0247.

A genetic linkage map will be an important tool for improving the Pacific oyster *Crassostrea gigas*, the most farmed aquatic species in the world. Combining 91 newly cloned and 23 previously published microsatellite DNA markers, we obtained 114 microsatellite DNA markers for testing on three outbred families, using 11-day-old larvae, to reduce segregation distortion caused by recessive deleterious mutations (Launey & Hedgecock 2001 Genetics 159:255). Of the 102 markers that are informative in at least one family, 98 are placed on a consensus map comprising 10 linkage groups and 880 centimorgans (cM; *cf.* karyotype of 10 chromosome pairs with an estimated length of 600–1000 cM based on chiasma frequency). Map distances and, occasionally, marker order differ between parents and among families. Of the 79 new microsatellites tested on four other *Crassostrea* species, 76 may be amplified from *C. angulata*, 65, from *C. sikamea*, 30, from *C. ariakensis*, and 8, from *C. virginica*. Decline in ability to amplify these markers across congeneric species, together with a high frequency of null alleles within *C. gigas* (40% of the loci are segregating for a null allele in at least one family), suggests that primer-target DNA sequences are rapidly evolving in oysters.

A SINGLE-STEP MULTIPLEX PCR IDENTIFICATION ASSAY TO DISTINGUISH MEGALOPAE OF *CALLINECTES SAPIDUS* FROM *CALLINECTES SIMILIS* IN PLANKTON SAMPLES.

Gregg G. Hoffman,* Ami E. Wilbur, Martin H. Posey, and **Troy D. Alphin,** Department of Biological Sciences and the Center for Marine Science, 5600 Marvin K. Moss Lane, University of North Carolina at Wilmington, Wilmington, NC 28409.

Understanding recruitment variation in economically important species such as the blue crab, *Callinectes sapidus*, requires the collection, processing, and identification of large numbers of larval animals. The identification process typically involves sorting of specimens based on morphological characters under a microscope, and subsequent enumeration of the species of interest. For some species combinations, morphological identification is complicated by a paucity of clear diagnostic features that reliably survive the collection process. In southeastern estuaries, the study of the recruitment dynamics of *Callinectes sapidus* is complicated by the co-occurrence of its congener, *C. similis*. We have developed a multiplexed PCR technique that efficiently and accurately distinguish *C. sapidus* and *C. similis* larvae. This assay relies on the use of species specific primers to amplify distinctly sized PCR (polymerase chain reaction) products and targets a portion of the mitochondrial cytochrome oxidase I gene. We have applied this technique to larval samples (megalopae) collected on settlement traps deployed during the 2000 and 2001 season in the Cape Fear estuary (North Carolina) to discern temporal and spatial patterns in larval abundance.

SEARCHING FOR DIFFERENTIALLY EXPRESSED GENES IN DIPLOID AND TRIPLOID EASTERN OYSTER, *CRASSOSTREA VIRGINICA* GMELIN.

Brenda J. Landau,* Arnaud Tanguy, and **Ximing Guo,** Haskin Shellfish Research Laboratory, Institute of Coastal and Marine Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

Triploid shellfish are useful for aquaculture because of their sterility, superior growth and improved meat quality. Triploids also provide a unique model system for analysis of certain biological processes. Triploids grow faster than diploids in most bivalves studied so far including oysters. This phenomenon has been referred to as triploid gigantism. Although several hypotheses have been proposed to explain triploid gigantism, we know little about changes in gene expression in triploid oysters. The identification of unique expression profiles in triploids may enhance our understanding of basic mechanisms of growth regulation. Because triploids are sterile, comparison of expression profiles during gametogenesis between diploid and triploid oysters may lead us to genes involved in sexual maturation and meiosis. We have begun a study searching for differentially expressed genes in triploid eastern oyster in the aim to better understand the physiological processes involved in growth and reproductive differences between diploids and triploids. Subtractive libraries were made to identify differentially expressed genes in both diploid and triploid oysters. Selected clones from these libraries are being sequenced. Results from the sequence analysis will be presented at the meeting.

A BASIC AFLP LINKAGE MAP FOR THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA* GMELIN.

Ziniu Yu* and **Ximing Guo,** Haskin Shellfish Research Laboratory, Institute of Coastal and Marine Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

Genetic markers and maps are needed to map and improve economically important traits in oysters. Amplified fragment length polymorphisms (AFLPs) are popular markers for linkage mapping in many agricultural species because of the relative ease of developing a large number of reliable markers at low cost. We tested AFLP markers for linkage mapping in the eastern oyster, *Crassostrea virginica* Gmelin. Selective amplification primers were labeled with fluorescent dyes, and amplified fragments were detected with the ABI 310 genetic analyzer and analyzed with the GenScan software. Forty primer combinations were screened, and ten of them were selected for linkage analysis of 81 progenies from a reference family derived from a Rutgers disease-resistant stock. The 10 primer pairs produced 212 polymorphic markers in the reference family; and 150 of them were informative or segregating in one of the parents. Chi-square analysis indicated that 136 (91%) markers segregated in Mendelian ratio, while the other 14 (9%) showed significant segregation distortion ($p < 0.05$). A basic linkage map was constructed with 84 segregating markers from the male parent. The markers formed 10 linkage groups, corresponding to the haploid number of 10 chromosomes in this species. The map covered a total of 439 cM, with average interval of 5.2 cM per marker. Additional markers including microsatellites are being added to this first linkage map of the eastern oyster.

REVERSION REVISITED IN *CRASSOSTREA ARIAKENSIS:* CHROMOSOME SET INSTABILITY IN FIELD TRIALS ACROSS SALINITY REGIMES.

Mingfang Zhou* and **Standish K. Allen, Jr.,** Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

VIMS has been systematically examining the potential of several non-native species for their potential in alleviating the serious decline of oyster stocks in the Virginia portion of Chesapeake Bay. One that has emerged as quite promising is the Suminoe oyster, *Crassostrea ariakensis*. We were interested in determining the stability of triploids from the period of seed to harvest (about 18 months). About 150 individually marked triploid *C. ariakensis* and 100 triploid *C. virginica* were deployed at each of seven sites in Virginia and North Carolina. Every three months, all triploid *C. ariakensis* were biopsied for hemolymph to determine the occurrence and extent of reversion (development of diploid cells within a triploid) by flow cytometry. As in other studies, *C. ariakensis* outgrew *C. virginica* at all sites. Overall, 26 mosaics were found among 919 individuals tested. The highest incidence of reversion was uncovered in medium salinity (average: ~5%) with high and low salinities 2% or less. Frequency of diploid cells within individual mosaics was generally less than 10% although we observed several "streakers" that obtained 65%, 46% and 28% diploid cells by study's end. These results demonstrate that the "risk of reversion" in commercial aquaculture of triploid *C. ariakensis* will likely be very low, but emphasizes that reversion is an inherent quality of autopolyploid oysters in the *Crassostrea* genus and persists through time. Therefore, the principal risk for recovery of reproductive potential among triploids seems to reside in unharvested and "lost" oysters that remain in the Bay for long periods of time.

EAST COAST BIVALVE INDUSTRY SESSION

AN OVERVIEW OF THE POTENTIAL FOR *CRASSOSTREA ARIAKENSIS* IN THE CHESAPEAKE BAY.

Standish K. Allen, Jr., Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

VIMS has been systematically examining the potential of several non-native species for their potential in alleviating the serious decline of oyster stocks in the Virginia portion of Chesapeake Bay.

One that has emerged as quite promising is the Suminoe oyster, *Crassostrea arkiakensis*. Field trials with sterile triploids have shown a general resistance to disease, rapid growth rate, and high survival. Formal and informal test marketing of the product has been similarly successful. As with any non-native species, serious concerns exist over the long-term implications of introduction. Some of these issues are associated with simultaneous introduction of pests or pathogens and some with the ecological effects of sustained population growth in the Bay. By culturing this species in the hatchery, pest and pathogen issues are largely, but not wholly, addressed. Aquaculture of triploid-only individuals mitigates, but does not eliminate, most of the ecological concerns. Aquaculture of hatchery raised sterile triploid seed represents an intermediate solution to assisting the industry between abandoning non-native research and wholesale introduction of diploids. The industry potential is enormous, but there are lingering questions about how precisely this "revolution" will proceed.

SURF CLAM (*SPISULA SOLIDISSIMA*) CULTURE IN SOUTHERN NEW JERSEY: HATCHERY CULTURE PROTOCOLS AND PRELIMINARY FIELD GROW OUT RESULTS. Gregory A. DeBrosse,* David R. Jones, and **Eric N. Powell,** Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

The state of New Jersey harvests over 90% of the worlds surf clams, *Spisula solidissima* (Dillwyn, 1817), with an annual value exceeding $30 million. The commercial fishing industry targets large clams, typically those larger than 80 mm shell length. These clams are used primarily for clam strips and chowders. Clams smaller than 70 mm cannot be fished economically, even though their per bushel value may be high. The raw and steamed clam trade uses primarily soft-shell clams (*Mya arenaria*) and hard clams (*Mercenaria mercenaria*). In the case of *Mercenaria*, the majority of clams utilized are produced by aquaculture, and this industry in New Jersey alone produced approximately $6 million worth of clams in 1998. The surf clam grows well in New Jersey, at about twice the rate of hard clams. Cultured yearling surf clams compare favorably with hard and soft-shell clams in a variety of product forms; steamed, fried, and on the half-shell, and therefore represent another potential species for these markets. A key to *Spisula* aquaculture success is to grow clams to marketable size (~50–55mm) in one year. To do this requires spawning and rearing animals out of season (e.g., during fall, winter, and early spring). This requires conditioning of brood stock in the hatchery, and defining the parameters of successful larval and juvenile culture. The specific parameters of brood stock conditioning, larval and juvenile culture, and preliminary field grow out data will be described in the presentation.

COASTAL STATES PERMITTING PROCEDURES FOR DEPLOYING A TIDAL POWERED UPWELLING NURSERY SYSTEM. M. Richard DeVoe,* South Carolina Sea Grant Consortium, 287 Meeting Street, Charleston, SC 29401; **G. Ross Nelson,** General Engineering Laboratories, 2040 Savage Road, Charleston, SC 29407.

Shellfish aquaculture is a growing segment of the U.S. aquaculture industry. Several nursery techniques have been developed for nursery growout of oysters from seed produced by hatcheries, including land-based runway systems and upwellers, and both bottom and off-bottom nurseries. The Tidal-Powered Upwelling Nursery System (TPU) was developed as a low cost alternative to these traditional nursery methods. The TPU has the advantage of being a floating structure using tidal power to upwell water into bins that house oyster seed.

A questionnaire was sent to coastal state permitting contacts during the year 2000 to determine if the TPU is a viable nursery option for oyster growout for culturists in their states, to determine the permits that would be necessary to deploy the TPU, and to estimate the costs associated with these permits. From this initial survey, four states were selected for a more complete analysis of the permits necessary to operate the TPU—Massachusetts, South Carolina, Washington, and Alaska. The permitting processes in these states were analyzed to compare and contrast the regulatory structures among these four states and with the results of the initial survey.

RELEVANT ISSUES FOR THE EAST COAST SHELLFISH AQUACULTURE INDUSTRY: FINDING COMMONALITY TO FOSTER UNITY. George E. Flimlin, Jr.,* Rutgers Cooperative Extension, 1623 Whitesville Rd., Toms River, NJ 08755.

Hatchery supported shellfish aquaculture on the East Coast of the United States has been growing since the 1970s. Once practically obscure, growers are now in every state bordering the Atlantic with over 60 hatcheries or seed nurseries scattered among the coastal states. Some of the newer states involved in hard clam, *Mercenaria mercenaria*, or American oyster, *Crassostrea virginica*, culture have shown very quick industry growth while places where shellfish aquaculture took hold over 25 years ago have practically slowed to a stand-still. With growth however comes scrutiny by governmental agencies, both state and federal, increased regulations, competition for space, environmental issues, disease concerns, and other challenges. Presently individual states have associations which can address concerns as they arise but there is no cohesive organization which can represent the common problems, as well as, promote pro-active activities for the growers throughout the region. This discussion will review the industry priorities respective to the social, political and scientific or technological problems that face the shellfish growers. A survey of growers, associations, hatchery/nursery operators, and extension personnel provides the input. A compilation of these issues will serve as a basis for the formation of a shellfish aquaculture industry group on the East Coast.

STAKEHOLDERS' PERCEPTIONS AND CHALLENGES TO PARTICIPATORY MANAGEMENT: THE CASE OF THE SOFT-SHELL CLAM, *MYA ARENARIA* L., INDUSTRY IN MAINE. **Aman Luthra*** and **William Walton,** University of Maine at Machias, Machias, ME 04654.

Local management of the soft-shell clam (*Mya arenaria*, L.) fishery in Maine involves the interaction of several different communities including commercial harvesters, shellfish committee personnel, scientists and the state, who share a common interest of increasing the productivity of their mudflats. Efficient management is hindered due to a lack of communication between these different communities. In 2000–2001, we surveyed 26 municipal shellfish committee chairs (7 in eastern, 8 in mid-coast and 11 in southern region) and interviewed 41 commercial harvesters (11 in eastern, 14 in mid-coast and 16 in southern region) to identify the knowledge gaps that exist between these 2 groups and across the 3 regions. Responding towns differed significantly in the number of commercial licenses issued and the price of recreational and commercial licenses across the 3 regions. Interviewed harvesters differed regionally in the number of active clamming months per year and in the number of commercial licenses held by each harvester. Both harvesters and chairs identified pollution, predation and overfishing as the factors that most severely limited the number of harvestable clams on the flats. Both groups identified a diverse array of predators with seagulls (*Larus* spp.) and green crabs (*Carcinus maenas*) topping their list. Harvesters identified raccoons (*Procyon lotor*) as the third most damaging predator while only one chair mentioned it. Stock enhancement is being pursued at different intensities and with different foci among the responding towns in the three regions. While most towns in mid-coast (57%) and eastern region (71%) are transplanting wild seed as a stock enhancement strategy, only responding towns from mid-coast (50%) and southern Maine (33%) are planting hatchery-reared seed. Both harvesters and chairs were opposed to reducing the two-inch minimum as well as leasing of intertidal flats. The survey and interviews identified areas of agreement and disagreement among these communities involved in the management of soft-shell clams, and these results can be used to guide both research and improved management.

EMBRACING AQUACULTURE BMP'S: A CONCEPT WHOSE TIME HAS COME AS A GOOD NEIGHBOR OR JUST ONE MORE THING TO DEAL WITH? **Sandra Macfarlane,*** Coastal Resources Specialists, Orleans, MA 02653.

In a labor intensive, high risk and competitive industry frought with uncertainty and reliance on natural conditions for growing food, initial efforts to foster an industry-wide or area-wide agreement on the most environmentally sound and "good neighbor" approach to the business have received a luke-warm reception at best from many growers. However, misinformation is rampant outside the industry from stakeholders who also have a vested interest in the manner in which the aquaculture is conducted in their back yard. In order for aquaculture to be sustainable, issues such as water quality, disease prevention and control, and care and maintenance of gear as well as animals is essential. Other stakeholders must be convinced that the aquaculture operation is conducting itself in the most prudent of manner on these issues and adopting BMP's or a Code of Practice is an effective mechanism to project a positive image. However, bringing all the voices to the table and bridging gaps in understanding among stakeholders is a crucial element in developing effective BMP's.

OPTIMIZATION OF TIDAL UPWELLER DESIGN: PROJECT WRAP-UP. **Dana L. Morse*** and **John Riley,** Maine Sea Grant Program/UMaine Cooperative Extension, Darling Marine Center, Walpole, ME 04573.

A fifth-scale model of a commonly-used tidal upweller design was built, and tested in the tow tank at the University of Maine, in Orono. The goal was to better understand the effects of design components on overall flow through the system, thus allowing future construction to be maximally efficient, and therefore profitable.

Three engineering considerations were tested at different speeds in the laboratory: scoop size, silo outlet opening size, and reduction of mooring line forces. Site visits were also made to local shellfish hatcheries, to examine the effects of shellfish seed size, bed depth, and shellfish species, on frictional flow loss in an upweller silo.

Results indicate that it is critical that the upweller platform maintains a level profile, as changes in horizontal aspect have adverse effects on flow and growth. Silo outlets should be made as non-restrictive as possible, by increasing the diameter of the outlet holes, submergence of the outlets, or by removing the upper portion of the silo wall entirely, and protecting against shellfish loss with plastic netting. Enlarging the scoop area over the initial design size has a limited effect on increasing flow through the upweller. Smaller shellfish seed tended to create stronger frictional head losses than the larger seed. Lastly, placement of an escape vent in the rear of the upweller can help to maintain a level profile for the platform.

In general, the original Mook design was well thought out. Though some modifications have resulted in performance improvements, the approach is sound and to the extent possible, makes use of the potentials afforded by tidal action.

GROWTH AND ECONOMICS OF SHELLFISH NURSERY CULTURE IN A COMMERCIALLY AVAILABLE FLOATING UPWELLER.

Robert B. Rheault,* Moonstone Oysters, 1121 Mooresfield Rd., Wakefield, RI 02879; **Jeffrey T. Gardner,** 227 Shore Rd., Westerly, RI 02891.

A small, commercially-available, floating upweller that serves as a dual-use dock and work platform has been deployed in several sites on the east coast. Five seasons of testing and development have led to production of a unit that is durable, functional, economical to operate and easy to maintain. Several producers claim that the device has resulted in substantial improvements in their production economics by accelerating growth, reducing variation in growth rates and cutting labor costs.

Growth and economic data from several Coastal Aquacultural Supply floating upwellers are compared with other conventional nursery culture methods such as a "Taylor float" and rack and bag systems. Capitol costs, labor costs, maintenance and operational expenses are described as well as siting and permitting considerations.

ENHANCING SEED AVAILABILITY FOR THE HARD CLAM AQUACULTURE INDUSTRY THROUGH APPLICATION OF REMOTE SETTING TECHNIQUES.

Leslie N. Sturmer,* Cooperative Extension Service, University of Florida, Cedar Key, FL 32625; **John E. Supan,** Office of Sea Grant Development, Louisiana State University, Baton Rouge, LA 70803; **Charles M. Adams,** Food and Resource Economics Department, University of Florida, Gainesville, FL 32611.

Hard clam, *Mercenaria mercenaria,* aquaculture has developed rapidly in the southeastern United States. Adequate seed availability is a major industry concern and has recently faced critical shortages. Technical procedures were developed and demonstrated to determine the economic feasibility of transferring remote setting technology from the Pacific Northwest molluscan shellfish industry to the hard clam culture industry. Competent pediveliger larvae obtained from commercial hatcheries were refrigerated, stored overnight and delivered chilled to remote set locations for evaluation of technique, site and season. Participating land-based nurseries were modified to incorporate mechanical filtration of water supply, remote setting tanks and downwellers. Management regimes evaluated over 4 trials included: 1) supplemental feeding with a commercial algal paste versus none, and 2) duration of shipping. Biological features documented included survival and time to reach a 1 mm seed, the minimum size presently obtained by nurseries. Results will provide for operational procedures and guidelines for remote setting of hard clam seed. The economic characteristics associated with the remote setting system will be described. Costs associated with producing the seed, including the original larvae cost, will be compared with the current market price for 1 mm seed. Remote setting of hard clam seed would allow nursery operators to become less dependent upon traditional seed sources and ensure a reliable supply of seed to growers.

USING SHELLFISH SEED AS A PUBLIC ENHANCEMENT TOOL: A REVIEW OF ITS USE AND SUCCESS IN THE NORTHEAST US.

William C. Walton, Wellfleet Shellfish Department, 300 Main Street, Wellfleet, MA 02667.

In response to dwindling stocks of shellfish (hard clams, *Mercenaria mercenaria,* oysters, *Crassostrea virginica,* soft shell clams, *Mya arenaria,* etc.) and increased fishing pressure, fisheries managers are implementing a variety of restrictive and proactive measures. One proactive strategy available to resource managers is to supplement the existing wild stock with hatchery-reared juvenile 'seed' supplied by commercial and public shellfish hatcheries. Planting seed on public grounds may enhance the fishery directly, by introducing shellfish that survive and grow to a legally harvestable size, and indirectly by increasing larval supply and subsequent year classes. This technique has been widely adopted in southern New England for hard clams and in northern New England for soft shell clams. Despite such implementation, quantitative assessments are rare. Here I review 1) local managers' perceptions of the success of such programs based on interviews and surveys, 2) quantitative and experimental studies of the survival of shellfish seed, and 3) known limiting factors. Although perceived and actual survival rates span the spectrum, this variation can largely be attributed to predation, which is a function of seed size at least in hard clams. Unlike private aquaculture, however, the scale of public seeding generally prohibits the use of nets to protect the seed. To illustrate the choices faced by public managers, I will present a case study of potential public seeding strategies of hard clams in Wellfleet, Massachusetts, highlighting the costs, risks and benefits.

GROWTH AND ECONOMIC ADVANTAGES OF DISTRIBUTED POWERED UPWELLERS: CREATING A NEW AQUACULTURE NICHE.

Christopher G. Warfel, P.E.,* ENTECH Engineering, PO Box 871, Block Island, RI 02807, with support from the Rhode Island Slater Office of Technology.

Distributed powered upwellers, (also known as grid-isolated, or renewable energy based upwellers) allow upweller technology to be used in areas where traditional sources of electrical/mechanical energy are not possible or desirable. The author presents the growth and cost performance findings from two years of research in the development of distributed generation upwellers utilizing solar energy. The design and prototypes went through several changes during the two years to facilitate its operability in a harsh environment. The present configuration has proved to have high reliability, provided for good growth, low mortality, and good ergonomics. Growth of *Crassostrea virginica* averaged 320% over base case for a relatively short four month growing seasons. The major benefits of this technology is the use of upwelling technology in areas that are not conducive to traditional utility powered upwellers, allowing for the benefits of upwellers to be realized in locations traditionally thought not to be ammenable to such technology.

THE NEW OYSTER WARS: POLICY PERSPECTIVES ON THE INTRODUCTION OF *CRASSOSTREA ARIAKENSIS* IN THE CHESAPEAKE BAY.

Donald Webster, University of Maryland, Wye Research & Education Center, P.O. Box 169, Queenstown, MD 21658.

Oyster harvests in the Chesapeake Bay have declined over ninety percent in the past fifty years due largely to the influence of *Haplosporidium nelsoni* and *Perkinsus marinus*. Recent studies regarding the potential of the species *Crassostrea ariakensis* have shown that this animal may provide many features desirable in the reconstruction of the oyster fishery as well as environmental management of the Bay. However, since it is a non-indigenous species, there are many factors to be considered in its introduction. Variations in the current status of the *C. virginia* resource, as well as historical differences of management techniques inherent in the two states have led to challenges regarding open-water introductions as well as plans to increase stocks of the non-native oyster in the future. This paper focuses on the policy differences between Maryland and Virginia and the attitudes of various user groups that are interested parties in the potential introduction of *C. ariakensis* in the Chesapeake Bay.

BIVALVE DISEASE STATUS AND TRENDS

RECENT EXPANSION OF JUVENILE OYSTER DISEASE (JOD) IN MAINE.

Bruce J. Barber,* School of Marine Sciences, University of Maine, Orono, ME 04469; **Katherine J. Boettcher,** Dept. of Biochemistry, Microbiology and Molecular Biology, University of Maine, Orono, ME 04469.

Juvenile oyster syndrome has caused mortalities of cultured Eastern oysters, *Crassostrea virginica*, in Maine since 1988. We have identified a likely etiological agent, a novel taxa in the *Roseobacter* clade of the marine alpha-proteobacteria. In oysters exhibiting signs of the disease (reduced growth and uneven valve growth), this bacterium comprises 40–95% of the total bacteria colonizing gill and mantle surfaces. Until recently, all documented outbreaks in Maine have occurred in the Damariscotta River. One strategy employed by oyster growers to avoid JOD mortality has been to use nursery sites outside the Damariscotta River. In the summer of 2000, however, mortalities of 70% in the New Meadows River and 20% in Maquoit Bay were reported by growers. In 2001, mortalities of 40% and 50% occurred in the New Meadows River and Sheepscot River, respectively. Thus in the last two years, JOD mortalities occurred in three additional locations, and in all cases, animals were heavily colonized by the same species of *Roseobacter*. The potential for utilizing genetic signatures of this bacterium for epidemiology will be discussed.

STATUS AND TRENDS OF DERMO AND MSX IN SOUTH CAROLINA.

David Bushek* and **Dwayne Porter,** Baruch Institute, University of South Carolina, PO Box 1630, Georgetown, SC 29442; **Loren D. Coen, M. Yvonne Bobo,** and **Donnia L. Richardson,** Marine Resources Research Institute, SCDNR, 217 Fort Johnson Rd., Charleston, SC 29412.

South Carolina has a relatively abundant and extensive population of oysters throughout the state. Dermo (*Perkinsus marinus*) and MSX (*Haplosporidium nelsoni*) are both present, but they do not cause widespread oyster mortality as reported in other regions. Surprisingly, little attention has been paid to understand why this difference exists. In South Carolina, virtually all oysters inhabit high salinity (20–35 ppt) estuaries where they form extensive fringing and mounding reefs in the 1.5 to 2 m intertidal zone. Their intertidal existence exposes them to daily temperature fluctuations that often exceed 30°C, with winter extremes below freezing and summer extremes that can exceed 50°C.

Since 1972, SCDNR's Marine Resources Research Institute (MRRI) has been documenting the occurrence of Dermo throughout the state. MSX has been documented since at least 1986 and monitored since 1994. In addition, the NOAA-funded Urbanization of Southeastern Estuarine Systems (USES) project has monitored these diseases in pristine and developed areas to identify potential relationships with different land-use patterns and landscapes. The data indicate that *P. marinus* is ubiquitous and abundant throughout the state. Prevalence and intensity peak from late summer to early winter, but unlike populations in the northeast, the parasite remains prevalent throughout the year. By comparison, *H. nelsoni* is relatively rare or altogether absent with mean prevalence generally below 20%. *Haplosporidium nelsoni* is known to be very sensitive to low salinities (10ppt or less). Low salinity is also often invoked as a major control that reduces prevalence and intensity of *P. marinus*. In South Carolina, most sites where oysters thrive rarely encounter such low salinities for more than a few hours. Furthermore, lowest salinities occur during low tide when the oysters are exposed. Instead, elevated temperatures may exceed the thermal tolerances of the parasites just long enough to shift the host-parasite dynamic in favor of the host. In this talk, we summarize recent findings and discuss implications for intertidal oysters along the southeast Atlantic coast of the United States.

A DECADE OF DISEASE: A REPORT OF OYSTER DISEASE MONITORING EFFORTS IN THE LOWER CHESAPEAKE BAY 1990–2000. **Lisa M. Ragone Calvo*** and **Eugene M. Burreson,** Virginia Institute of Marine Science, School of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

In the late 1980s oyster populations in the Virginia portion of the Chesapeake Bay were significantly impacted by epizootics of the oyster parasites *Perkinsus marinus* and *Haplosporidium nelsoni* as a consequence of dry and warm climatic conditions. The distributions of both parasites were widespread and the range of *P. marinus* was extended into upper tributary areas that had historically been disease free. Since that time VIMS has been extensively monitoring lower bay oyster populations for the presence of the pathogens via annual fall surveys of 30–40 lower bay oyster populations, monthly surveys of four oyster reefs in upper James River, and monthly summer surveys of naïve sentinel oyster that are transplanted to a site in the lower York River in May of each year. *Perkinus marinus* continues to persist in upper tributary areas, despite the occurrence of several years that were relatively wet and cold. Record high prevalences and intensities of *P. marinus* were observed in 1999 and 2000, and the parasite was found in all areas where significant oyster stocks remain. *Haplosporidium nesloni* prevalences were generally low in 1990, 1993, and 1998; however, record high levels were observed in 1999. In 1999, epizootics of the parasite were extensive and caused severe oyster losses in many areas. Clearly, both pathogens continue to be a significant threat to lower Cheaspeake Bay oysters. The correlation of disease patterns and environmental conditions will be discussed.

DEVELOPMENT AND APPLICATION OF A PCR FOR *MIKROCYTOS MACKINI*, THE CAUSATIVE AGENT OF DENMAN ISLAND DISEASE IN OYSTERS. **Ryan B. Carnegie,* Gary R. Meyer, Janice Blackbourn,** and **Susan M. Bower,** Fisheries and Oceans, Science Branch, Pacific Biological Station, Nanaimo, British Columbia, Canada V9R 5K6; **Nathalie Cochennec-Laureau,** IFREMER, Laboratoraire de Génétique, Aquaculture et Pathologie, BP 133, Ronce les Bains, F-17390 La Tremblade, France.

Mikrocytos mackini has caused Denman Island disease of *Crassostrea gigas* and *Ostrea edulis* in British Columbia, Canada since at least 1960. A small protistan parasite, *M. mackini* is commonly observed with standard histopathological techniques around the green pustules characteristic of Denman Island disease. In oysters with subclinical infections, however, *M. mackini* is not easily detected, and it is rarely observed before March and after June. Its mode of transmission, life cycle, and taxonomic affinities are unknown.

Our objectives were to design and validate molecular assays for *M. mackini* and to use these tools to re-examine the seasonal prevalence of *M. mackini* infections. We sequenced 1457 base pairs of *M. mackini* SSU rDNA and developed a PCR specific for this gene. We used this PCR to screen palp DNA samples from cultured *C. gigas* from Henry Bay, Denman Island, BC monthly (N = 100/month) from January to December 2001. PCR detected *M. mackini* more sensitively than did standard histopathology. PCR-based *M. mackini* prevalence estimates met or exceeded histopathology-based estimates in every month, and only two oysters *M. mackini*-positive by histopathology were misdiagnosed as negative by PCR. PCR confirmed a trend in seasonal *M. mackini* prevalence identified earlier by histopathology. Prevalence peaked in April and particularly May, when 22% of lower intertidal *C. gigas* were *M. mackini*-positive by PCR (12% by histopathology). However, PCR also detected *M. mackini* in the palps of apparently healthy *C. gigas* in every month of the year (through September 2001), a first indication that *M. mackini* may persist subclinically in oyster populations year round.

DEVELOPMENT OF HIGH DISEASE RESISTANCE IN A WILD OYSTER POPULATION. **Susan E. Ford,** Haskin Shellfish Research Laboratory, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

In 1957–1959, the introduced parasite, *Haplosporidium nelsoni*, killed 90–95% of the oysters (*Crassostrea virginica*) in lower Delaware Bay and about half of those in the upper Bay. Shortly thereafter, *H. nelsoni*-caused mortalities in the native population declined, equalling that of first-generation selectively bred oysters. For two decades, no further change in the wild population occurred, although steady improvement was achieved by continued selective breeding. Survival of the wild population is though to have plateaued because most oysters inhabited the upper bay and were protected from *H. nelsoni* by low salinity. From 1957 through 1989, *H. nelsoni* prevalence was cyclic, but overall high (annual maxima of 50 to 90%). After 1989, however, prevalence in wild oysters rarely exceeded 30% even though unselected oysters continued to become heavily infected, and molecular detection indicated that infective stages were present throughout the Bay. This apparent "second step" in the development of resistance in the native oysters occurred after the incursion of *H. nelsoni* into the upper bay in the mid 1980s, with widespread and heavy oyster mortalities occurring for the first time since the 1957–59 epizootic.

THE LONG-TERM ROLE OF PARASITIC DISEASES IN OYSTER POPULATION DYNAMICS. **Stephen J. Jordan** and **Jessica Vanisko.** Sarbanes Cooperative Oxford Laboratory, 904 S. Morris St., Oxford, MD 21654.

Populations of the Eastern oyster, *Crassostrea virginica*, suffer high rates of mortality from Dermo, MSX, or both diseases throughout most of the range of the species. The principal effect of high mortality rates on population structure is truncation of the size distribution, skewing the populations toward smaller oysters. Secondary effects include reductions in population biomass, harvests, and spawning potential, although there does not appear to be a strong effect on recruitment of juveniles. In Chesapeake Bay, the diseases, in combination, have had their most negative effects since the late 1980s, when Dermo spread throughout the population. Over the past decade, disease intensity and oyster mortality rates have been strongly dependent on salinity, intensifying in drought years, moderating during wet periods, and affecting most severely sub-populations in higher salinity regions. Time series of oyster population data from Maryland have been used to construct a model that simulates trends in the population at various rates of disease mortality, fishing mortality and recruitment. Current rates of total mortality appear not to be sustainable without significant management intervention.

CAPE COD BIVALVE DISEASE MONITORING PROGRAM, YEAR I.

Dale Leavitt,* **D. Murphy**, **W. Burt**, and **W. Clark**, Cape Cod Cooperative Extension, Barnstable, MA 02630; **M. Hickey** and **J. Moles**, Department of Marine Fisheries, Pocassett, MA 02559; **R. Smolowitz**, Marine Biological Laboratory, Woods Hole, MA 02543.

The effect of disease on bivalve populations is an important factor in determining management methods for the culture, harvest and movement of bivalves. In order to provide the information needed by extension and regulatory agencies and the aquaculturists, to effectively manage these populations on Cape Cod, MA, a monitoring program has been established as a cooperative project between Cape Cod Cooperative Extension Agency and the MA Department of Marine Fisheries. Hard clams, Eastern oysters and soft shell clams will be monitored over the course of each year. It is anticipated that the monitoring program will become a routine method for disease information gathering in MA.

Oysters and hard clams were collected in the fall of 2001. Twenty-five oysters from each site underwent testing for *Perkinsus marinus* using Thioglyocollate culture methods. Samples were also evaluated histologically for MSX and SSO. Sixty hard clams from each selected site were examined grossly for QPX. Twenty-five of these were examined histologically. In 2002, twenty five soft shell clams from several sites will monitored. Results of the first year of monitoring will be presented at this session.

PREVALENCE AND INTENSITY OF PARASITIC DISEASES IN BIVALVES FROM RHODE ISLAND WATERS.

Karen L. Mareiro,* and **Marta Gómez-Chiarri**, Fisheries, Animal, and Veterinary Science, University of Rhode Island, Kingston, RI 02881; **Katherine Kerr** and **Emily Carrington**, Department of Biological Sciences, University of Rhode Island; **Arthur Ganz**, Division of Fish and Wildlife, Department of Environmental Management, Wakefield, RI 02879.

The goal of this Shellfish Disease Survey is to assess disease prevalence and intensity in Rhode Island bivalves. Eastern oysters (*Crassostrea virginica*) were collected from several wild populations and local farms in August and November 1998–2001. Hard clams (*Mercenaria mercenaria*) were collected from selected locations in 1998, 2000 and 2001. Dermo disease (caused by *Perkinsus marinus*) is widespread in Rhode Island oysters, while prevalence of Multinucleated Sphere X (caused by *Haplosporidium nelsoni*) and Seaside Organism (caused by *Haplosporidium costale*) is low and restricted to a few locations. Prevalence of Dermo disease ranged from 0–100%, remaining low in oysters from aquaculture leases and a few wild locations. Intensity of Dermo disease has remained unchanged or increased since 1998. Several factors could be responsible for differences in prevalence of Dermo disease, including genetic factors, lack of infective particles and differences in environmental conditions. Trematode infections were common in Rhode Island oysters, but high prevalences of heavy infections were found only in wild oysters from Point Judith Pond and Block Island. Wild oysters from Pawcatuck River showed a high prevalence of the apicomplexan parasite *Nematopsis ostrearum.* No Quahog Parasite Unknown (QPX) was detected in Rhode Island hard clams.

MODIFICATION AND FIELD TRIALS OF A MULTIPLEX PCR FOR THE DETECTION OF THREE PROTOZOAN PATHOGENS OF THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*, GMELIN 1871.

Spencer Russell,* **Salvatore Frasca, Jr.**, and **Richard A. French**, Department of Pathobiology and Veterinary Science, University of Connecticut, Storrs, CT 06269; **Inke Sunila**, Bureau of Aquaculture, Department of Agriculture, Department of Agriculture, State of CT, Milford, CT 06460.

Populations of eastern oysters (*Crassostrea virginica*) along the eastern coast of North America have repeatedly experienced outbreaks of epizootic disease and mass mortality due to infections by protozoal parasites. As polymerase chain reaction (PCR) methodologies become routine laboratory procedures and diagnostic tools of choice, it is imperative to incorporate PCR quality controls to avoid false positive and negative results. In this study we describe the modification of a previously developed multiplex PCR (MPCR) for the detection of the eastern oyster parasites *Haplosporidium nelsoni, Haplosporidium costale* and *Perkinsus marinus* by incorporation of a quality control extraction and amplification PCR product from primers directed against an 805 base-pair (bp) sequence of the 28S SSU rRNA sequence of *Crassostrea virginica.* The modified MPCR simultaneously amplified 805bp, 564bp, 301bp and 151bp fragments of the SSU rRNA of *C. virginica, H. nelsoni, P. marinus* and *H. costale*, respectively. The *C. virginica* gene product tests the quality of extracted DNA used to support amplification in an optimized and appropriately performed PCR. In addition, we examined the species specificity and sensitivity of the newly modified MPCR for the detection of *H. nelsoni, H. costale* and *P. marinus* and compared its performance to that of the conventional diagnostic techniques of histopathological tissue examination and the Ray/Mackin fluid thioglycollate medium assay. Five hundred thirty oysters were sampled from 12 sites along the East Coast of the United States from the Gulf of Mexico to New England throughout the entire range of these parasites. Our results indicate that the newly modified MPCR is specific for the detection of *H. nelsoni, H. costale* and *P. marinus*. Through spike/recovery experiments, the sensitivity of the MPCR for *H. nelsoni, H. costale* and *P. marinus* was 100 fg, 10 fg and 100 fg, respectively, from 25 mg of oyster tissue. The modified MPCR detected 118 of 530 (22%) oysters with *H. nelsoni*, 12 (2%) oysters with *H. costale* and 212 (40%) oysters with *P. marinus* infections. The RMFT assay detected *P. marinus* infection in 163 (31%) oysters. Histopathological examination detected *H. nelsoni* and *H. costale* infections in 30 (6%) and 4 (0.8%) oysters, respectively. The MPCR is a more sensitive diagnostic assay for the detection of *H. nelsoni, H. costale* and *P. marinus*, and the inclusion of an oyster quality control product in the multiplex limits the number of false negative results from extraction or PCR failures.

DERMOWATCH: A WEB-BASED APPROACH FOR MONITORING THE OYSTER PARASITE *PERKINSUS MARINUS (DERMOCYSTIDIUM MARINUM)*.

Thomas M. Soniat,* Department of Biology, Nicholls State University, Thibodaux, LA 70310; **Enrique V. Kortright**, Kortright Corporation, 102 Allendale Dr., Thibodaux, LA 70301; **Sammy M. Ray**, Department of Marine Biology, Texas A&M University, Galveston, TX 77553.

A web site called DermoWatch (www.blueblee.com/dermo) is being used to monitor *Perkinsus marinus* (= *Dermocystidium marinum*) in Galveston Bay, Texas. The main page provides the most recent data from nine locations. Data include measured water temperature (T) and salinity (S), calculated percent infection and weighted incidence (WI) of parasitism, and estimated time to a critical level of disease (t-crit). (The t-crit is calculated as the time in days to reach a critical WI if 1.5, assuming no change in T and S.) By expressing the solution in days, oyster growers can make informed decisions about when to move or harvest their oysters. Furthermore, they can relate observed mortalities to estimates of t-crit, and thus *P. marinus* ceases to be an "unseen" killer. With a utility called the DermoCalculator the web site is useful, not just in Galveston Bay, but wherever *P. marinus* is found. It allows anyone with information on T and S, oyster length and initial WI to determine a t-crit. A limitation of the approach in Galveston Bay is that t-crit is calculated from a single (monthly) measurement of T and S. A monitoring station is being constructed in Louisiana with which real-time measures of T and S will be used to constantly update calculations of t-crit. More frequent inputs of T and S should increase the reliability of the t-crit estimates.

DETECTION OF A PREVIOUSLY UNDESCRIBED HAPLOSPORIDIAN-LIKE INFECTION OF A BLUE MUSSEL (*MYTILUS EDULIS*) IN ATLANTIC CANADA.

Mary F. Stephenson* and **Sharon E. McGladdery**, Gulf Fisheries Centre, Department of Fisheries and Oceans, P.O. Box 5030, Moncton, New Brunswick, Canada E1C 9B6; **Nancy A. Stokes**, Department of Fisheries Science, Virginia Institute of Marine Science, P.O. Box 1346, Greate Road, Gloucester Point, VA 23062.

Microscopic examination of a blue mussel, *Mytilus edulis* Linnaeus, with an unusual macroscopic appearance revealed the presence of a haplosporidian-like infection throughout the soft tissues. This is the first documented occurrence of this group of parasites in Atlantic Canada. Large numbers of blue mussels and American oysters, *Crassostrea virginica* Gmelin, are sampled on an ongoing basis to monitor their disease profiles within Atlantic Canada. Twelve years of histological sampling has established a disease profile including many protozoans and diseases of local concern but no infectious agents resembling those listed by the Office International des Epizooties (OIE). Samples were sent immediately to the Reference Laboratory for Haplosporidiosis at the Virginia Institute for Marine Science, where they were screened for OIE-notifiable disease agents by in situ hybridization using *Haplosporidium nelsoni* and *H. costale*-specific DNA probes. These did not hybridize with the parasite in the mussel. The spores of the parasite are operculate and measure 3–5 microns by 6–8 microns. They show a diversity of forms from roughly spherical to pyriform with or without filamentous extensions. These resemble the haplosporidians from *Mytilus californianus* and *Mytilus edulis* from California (*Haplosporidium tumefacientis*), as well as a *Haplosporidium* sp. described from mussels in Maine. As with these previous descriptions, the current infection, although massive, was not associated with any haemocyte defense response indicative of an acute pathogenic infection. No other infections have been found in Atlantic Canada, and the significance for the lucrative Atlantic Canadian mussel industry is unknown.

MONITORING BIVALVE HEALTH IN LONG ISLAND SOUND.

Inke Sunila, State of Connecticut, Department of Agriculture, Bureau of Aquaculture, Milford, CT 06460.

Long Island Sound (LIS) has a viable, economically important culture of eastern oysters (*Crassostrea virginica*) and quahogs (*Mercenaria mercenaria*). Connecticut has 65,000 underwater acres leased for bivalve culture, New York 3,500 in LIS. Bivalve health is constantly monitored in the field and hatchery operations, and diagnostic service is available in the case of mortalities. Oysters and clams are diagnosed for inflammatory responses (acute or chronic), degenerations (ceroidosis, atrophy), cell and tissue death (necrosis vs. apoptosis), hemodynamic derangements (hemorrhage, edema), growth derangements (hyperplasia, metaplasia) and tumors (benign or malignant). Possible pathological irritants, such as infective agents or environmental factors are identified. An epizootic caused by *Haplosporidium nelsoni* (MSX) in 1997–1998 caused a 76% reduction in oyster production. At the present time *Haplosporidium costale* (SSO) and possibly other haplosporidian species occur as coinfections with MSX contributing to an annual loss of 13% in oyster stocks. Impact of the 1997–98 MSX epizootic still affects the oyster industry since those year classes would be on the market now. Dermo disease (*Perkinsus marinus*) occurs with a high prevalence (80%) and a low intensity (1 on Mackin Scale). It has not been associated with significant field mortalities. On the contrary, hard clam harvest has seen a six-fold increase during the last five years. Hard clams in LIS are healthy, and the ecosystem does not appear to provide optimal conditions for the clam parasite QPX to proliferate. We have recently adapted molecular methods to monitor bivalve diseases.

DISEASES OF CRUSTACEA

ECOLOGICAL RAMIFICATIONS OF DISEASE IN THE CARIBBEAN SPINY LOBSTER, *PANULIRUS ARGUS*.

Donald C. Behringer, Jr.* and **Mark J. Butler, IV**, Old Dominion University, Norfolk, VA 23529; **Jeffrey D. Shields**, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

Spiny lobsters have few reported diseases. The identification and prevalence of pathogenic diseases in wild populations of spiny lobsters are poorly known. We recently discovered the first pathogenic viral disease (HLV-PA) known from a lobster, in this case the Caribbean spiny lobster, *Panulirus argus*. Our findings suggest that the disease alters the behavior and ecology of this species in fundamental ways, in part via remarkable changes in the social behavior of healthy individuals in response to diseased conspecifics. Both field and laboratory data show significant avoidance of infected lobsters by healthy conspecifics. Since 1999, we have identified infected juvenile lobsters at 75% to 100% of the 14 nursery habitat sites that we have surveyed twice a year (summer and winter) in the middle and lower Florida Keys, USA. The disease is highly prevalent with prevalences of up to 40% in juveniles (mean = 8%). Infected animals are often moribund, exhibit lethargy, and have milky or chalky hemolymph. Prevalences in initial challenge trials using infected hemolymph from infected donors resulted in a prevalence of 90% (n = 20, control n = 10). The virus appears to be highly pathogenic and moderately lethal with deaths occurring after 60–90 days in inoculation trials. An intriguing epidemiological twist is that commercial and recreational fishing activities for this economically valuable species may potentially contribute to the spread of the pathogen.

FIELD OBSERVATIONS ON THE DEVELOPMENT AND PROGRESS OF A SHELL DISEASE EPISODE FOR AMERICAN LOBSTER IN RHODE ISLAND: 1995–2001.

Kathleen Castro, University of Rhode Island Fisheries Center, Kingston, RI; **Thomas Angell**, RI Department of Environmental Management, Division of Fish and Wildlife, Wakefield, RI 02880.

From 1995 to 2001, shell disease in the American lobster was monitored in Rhode Island waters including Narragansett Bay, Rhode Island and Block Island Sound and the offshore areas of Block and Hudson Canyons. A tag-recapture study conducted by RI lobstermen also included a shell disease category. In the inshore population, a significant increase in frequency and severity of the disease was documented beginning in 1996, reaching an 31% proportion infected overall in 2001. Spatial information is available and describes a rapid increase in the Upper East, Lower East and West Passages from 1997–1998. Proportions in the Upper East Passage and West Passage in Narragansett Bay continue to rise, while the proportion infected in the Lower East Passage has declined. Proportion observed with the disease is correlated with the molting period, with rapid increases in September and October after the major molt. In 2000 and 2001, there appears to be a shift to higher infection rates in small animals and greater number of males and immature females than previously observed. Tag-recapture data is providing information on the progress of the disease on individual lobsters and re-infection percentages after a molt. Field data such as these may provide valuable information concerning the causes and consequences of the disease on the lobster populations.

EFFECTS OF PARASITES ON BEHAVIOR OF GRASS SHRIMP, *PALAEMONETES PUGIO*.

Terry Glover,* Social/Behavioral Sciences, Bloomfield College, Bloomfield, NJ 07003; **Lauren Bergey** and **Judith S. Weis**, Department of Biological Sciences, Rutgers University—Newark, Newark, NJ 07102.

The effect of parasites on grass shrimp *Palaemonetes pugio* was studied using shrimp from three sites which had varying levels of contamination. There was an inverse relationship between level of contamination and level of parasites. Parasitized shrimp had either *Microphallus sp.*, *Microphallus* hyperparasitized by *Urosporidium sp.*, or *Probopyrus pandalicola* parasites. *Microphallus* and its hyperparasite are endoparasites within muscle, while *P. pandalicola*, which lives in the gill chamber, is considered an ectoparasite. Parasitized shrimp were compared to unparasitized controls on latency to swimming in a novel environment, activity, freezing to a startle stimulus, and latency to finding food. Shrimp from the least contaminated site had the longest latencies and lowest activity levels. Shrimp with *P. pandalicola* had the longest freezing times. Shrimp with *Urosporidium* tended to have longer swimming latencies than controls. *Microphallus* did not systematically affect behavior, even in shrimp in which they were numerous. Although site differences have a greater effect on behavior than parasite load, there is a complex relationship between contamination, parasite levels and behavior.

CYTOCENTRIFUGE PREPARATIONS: AN ALTERNATE METHOD TO EXAMINE THE HEMOCYTES OF THE AMERICAN LOBSTER *HOMARUS AMERICANUS*.

Barbara Horney and **Andrea Battison,*** Department of Pathology and Microbiology; **Allan MacKenzie**, The AVC Lobster Science Centre, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, PE, Canada, C1A 4P3.

Current techniques used for examination of crustacean hemocytes can be labour intensive, costly, and have a slow turnaround time as is the case with transmission electron microscopy. Phase contrast microscopy, although inexpensive and rapidly performed, does not provide a permanent record of the results.

Cytocentrifugation of anticoagulated hemolymph samples, followed by staining with a modified Wright's-Giemsa stain, provided an excellent means to evaluate the hemocytes of *Homarus americanus*. The technique is simple to perform, requires relatively inexpensive laboratory equipment, and provides a permanent record of results within one hour of sample collection. Optimal results were obtained when slides were prepared within 6 to 8 h of sample collection.

Preliminary findings using hemolymph samples from the rock crab, *Cancer irroratus* suggest that this technique could be compatible for the examination of hemocytes of other crustacean species.

PARASITES IN *DIPOREIA* SPP. AMPHIPODS FROM LAKES MICHIGAN AND HURON.

Gretchen A. Messick* NOAA, National Ocean Service, Cooperative Oxford Laboratory, Oxford, MD 21654; **Tom F. Nalepa** NOAA, Great Lakes Environmental Laboratory, Ann Arbor, MI 48105.

Diporeia populations began to decline in Lake Michigan in 1992, just three years after the nonindigenous zebra mussel *Dreissena polymorpha* was first reported. *Diporeia* are detritivores, feeding upon organic material freshly settled from the water column. In turn, they are fed upon by most fish species found in Lake Michigan and are a major food-web link between pelagic production and upper trophic levels. Although the decline in *Diporeia* populations was thought to be due to zebra mussels intercepting food material (i.e., algae) before it settles to the bottom, sampling efforts indicate sufficient food is still available to the amphipods, and *Diporeia* lipid content remain high, indicating the population is not deprived of food. An alternative explanation for the amphipod population decline may be pathogens.

Diporeia amphipods were sampled to assay the prevalence of disease and see whether prevalence of disease varied by time or location. Surveys revealed numerous parasites in amphipod tissues including virus, rickettsia-like microorganisms, fungus, a haplosporidan, microsporidans, external ciliates, gregarines, and worms. Prevalence of nodules and parasites varied among surveys, dates sampled, and locations sampled. No one etiologic agent has been identified as causing the amphipod population decline but several parasites identified during this investigation including microsporidans, rickettsia-like microorganisms, haplosporidan, and fungus likely result in amphipod mortalities.

PATHOLOGICAL ALTERATIONS IN THE EYES OF THE AMERICAN LOBSTER, *HOMARUS AMERICANUS*, INFECTED WITH *PARAMOEBA* SP.

Jeffrey D. Shields,* Virginia Institute of Marine Science, Gloucester Point, VA 23062.

In September, 2001, 31 lobsters, *Homarus americanus*, from Western Long Island Sound were examined for pathologies associated with infection by *Paramoeba* sp. Only 1 animal (3.2%) presented with gross morbidity and pathology indicative of a presumptive infection by *Paramoeba* sp. Histologically, light to moderate infections were observed in 35.5% of the lobsters. Several altered tissues were observed in the lamina ganglionaris, optic nerve complex and ommatidia of the eyes. Eye pathologies ranged from minor shifts or losses of optic pigments associated with the optic nerves, to necrosis of the optic nerve with a complete shift of pigments into the ommatidia. In more severe cases, the optic nerves were obliterated, with a partial to complete disruption of the basement membrane proximal to the ommatidia. Necrosis of the retinular cells varied with the severity of the damage to the optic nerves. There was marked infiltration of hemocytes into the space formerly occupied by the optic nerves, and infiltration of hemocytes into the ommatidial complex. In addition, infected animals showed relatively high intensities of non-specific granulomas in many tissues. The high prevalence of non-specific granulomas indicates that the lobsters in WLIS continue to be subjected to a variety of disease-inducing stressors such as parasitic or microbial infection, or exposure to metals or other toxicants. Interestingly, the severity of the pathology in the eyes was not well correlated with the intensity of infection of the amoebae in the optic nerves. However, more lobsters should be examined to fully assess severity in relation to disease.

A PATHOGENIC HERPES-LIKE VIRUS FROM THE SPINY LOBSTER, *PANULIRUS ARGUS*.

Jeffrey D. Shields,* Virginia Institute of Marine Science, Gloucester Point, VA 23062; **Donald C. Behringer, Jr.**, Old Dominion University, Norfolk, VA 23529; **Mark J. Butler, IV**, Old Dominion University, Norfolk, VA 23529.

A pathogenic herpes-like virus was diagnosed from juvenile Caribbean spiny lobsters from the Florida Keys. Moribund lobsters had characteristically milky hemolymph that lacked the ability to clot. With light microscopy, the virus infected hyalinocytes and semigranulocytes, but not granulocytes. Infected hemocytes had emarginated, condensed chromatin, hypertrophied nuclei and faint nuclear bodies resembling Cowdry-type-A inclusions. With electron microscopy, the large (187 nm ± 15 nm sd.) icosahedral, capsid-enclosed nonoccluded virions were diffusely spread around the border of the condensed chromatin with virogenic stroma present in the cytoplasm and free in the hemolymph. In some cases, virions were found in connective tissue cells. Virion and capsid assembly occurred within the nucleus of infected cells, but envelopes were not apparent. The virus ranged in prevalence over time from 6% to 8% with certain foci reaching up to 40%. The virus was transmissible to uninfected lobsters using inoculations of raw hemolymph from infected animals and through feeding trials. Inoculated animals showed morbidity and began dying from the virus after 60–80 d. Adult lobsters have not been observed with the infection. Additional infection trials, impacts on the social behavior of juveniles, and a TEM study to identify the agent are currently underway.

BLUE MUSSEL BIOLOGY AND CULTURE

OBSERVATIONS ON GROWTH, GAMETOGENESIS, AND SEX RATIO OF TRIPLOID AND DIPLOID *MYTILUS EDULIS*.

John Brake,* Hatfield Marine Science Center, Newport, OR 97365; **Jeffrey Davidson,** Atlantic Veterinary College, Charlottetown, PEI, Canada, C1A 4P3; **Jonathan Davis** Baywater Inc., Bainbridge Island, WA 98110.

Concerns in the Prince Edward Island mussel aquaculture industry over product quality during, and immediately after the spawning period prompted research on developing triploid *Mytilus edulis*. Triploid shellfish are sterile and retain quality during and after the spawning period.

Field evaluations of diploid and triploid mussels demonstrated that triploids had a greater growth rate than diploids. The growth difference was evident in just nine months after deployment in highly productive waters. This difference was not detectable in less productive waters until the second year of growth, suggesting possible differential growth of triploids versus diploids, related to environment. Mussels in the less productive waters were notably less sexually mature in the first year, therefore the differential performance of triploids may have been related to spawning. Triploids had a mean shell length 1.05% larger than diploids in the less productive waters versus 8.09% larger in the highly productive waters. Triploids examined after a spawning event showed no histological evidence of spawning, while 71% of diploids showed some evidence of spawning. Shell length, relative soft tissue weight, and condition index were all higher in triploids. This resulted in an increase in dry tissue weight of 62.82% and a mean shell length increase of 10.95% when triploids were compared to diploids at one site after the local spawning event. As well, a highly skewed sex ratio confirmed a previous study on *Mytilus galloprovincialis* showing a male dominant sex ratio in triploid mussels.

THE DISTRIBUTION AND BIOLOGY OF AN INVASIVE TUNICATE IN PRINCE EDWARD ISLAND, CANADA.

Jeff Davidson* and **Frank Boothroyd,** Atlantic Veterinary College, University of Prince Edward Island, 550 University Avenue, Charlottetown, Prince Edward Island, Canada, C1A 4P3; **Neil McNair,** PEI Department of Fisheries, Aquaculture and Environment, P.O. Box 2000, Charlottetown, Prince Edward Island, Canada, C1A 7N8; **Thomas Landry,** Department of Fisheries and Oceans, Science Branch, Maritimes Region, Gulf Fisheries Center, P.O. Box 5030, Moncton, New Brunswick, Canada, E1C 9B6.

The presence of the club tunicate *Styela clava* was recently noted in Eastern Prince Edward Island (PEI), Canada. This tunicate presents a significant fouling problem for the blue mussel (*Mytilus edulis*) farms located in affected areas. The spread of this new tunicate species in the waters of PEI is presently limited to a few rivers and seems to be mainly from anthropological mode as opposed to natural mode. Investigation on its reproductive biology is being conducted through the monitoring of gonad development and seasonal recruitment. Preliminary results are suggesting that spawning may occur throughout the summer months, while recruitment is limited to a relatively short period. The impact of this new fouling organism is also being investigated by evaluating its competition for food in relation to the blue mussels. Methods to control this fouling problem are presently being developed and tested. The eradication of this invasive tunicate from PEI waters is considered impractical and therefore the development of farm management strategies is considered as the only economically viable solution.

A FIELD STUDY OF SETTLEMENT DEPTHS OF *MYTILUS EDULIS* AND *M. TROSSULUS* IN NOVA SCOTIA, CANADA, 1998–2000.

Ellen L. R. Kenchington, Kenneth R. Freeman,* Benedikte M. Vercaemer, and **Barry W. MacDonald,** Department of Fisheries & Oceans, Bedford Institute of Oceanography, PO Box 1006, Dartmouth, NS, Canada, B2Y 4A2.

Larvae of *Mytilus edulis* and *M. trossulus* were shown previously to have different settlement preferences in the laboratory. However, it was not known whether these results could be extrapolated to field conditions with the much greater degree of environmental variability. Consequently, both temporal and spatial variability in larval settlement between these species, with depth were examined in the field. The relative proportion of *M. edulis* spat was determined using genetic markers at each of 3 depths (1, 3, 5 m) at intervals over the spawning season (minimum 3 collections) for 3 consecutive years at one site in Parrang Cove, St. Margaret's Bay, Nova Scotia. In the last year a second site in Ship Harbour, Nova Scotia was studied to add a spatial dimension to the project. There was no significant interaction between sites, years and timing with respect to depth of settlement. *M. edulis* consistently settled deeper than *M. trossulus* although there was both temporal and spatial variability in the relative percentages of *M. edulis* collected. In addition to opening up certain ecological questions, these results show promise for direct application to husbandry practices at mussel farms having both species and where aquaculturists wish to preferentially collect the more commercially desirable *M. edulis*.

NUTRIENT UPTAKE AND RELEASE FROM FOULING ORGANISMS ASSOCIATED WITH CULTURED MUSSELS IN TRACADIE BAY, PEI. **Angeline R. LeBlanc*** and **Gilles Miron,** Université de Moncton, Moncton, NB E1A 9B6; **Thomas Landry,** Department of Fisheries and Oceans, Science Branch, Maritimes Region, Gulf Fisheries Center, P.O. Box 5030, Moncton, New Brunswick, Canada, E1C 9B6.

Fouling organisms are causing concerns among mussel growers in PEI, Canada. Most of these foulers are sedentary filter feeders, and are therefore a potential competitor with mussels for resources. This could translate into a reduction in meat yield in mussels. We carried an experiment to determine the relative impact of fouling organisms on the uptake and release of nutrients. Chlorophyll a, ammonium, suspended particulate matter and oxygen were investigated. This preliminary study was undertaken in December 2000, before the ice cover, and showed that foulers had only a small effect on nutrient use. Foulers accounted for about one tenth of chlorophyll *a* consumption by mussels and foulers together. They also contributed about one tenth of the ammonium released by mussels and foulers. There was no significant use of suspended particulate matter by the mussels or the foulers. The use of oxygen was not significantly different between mussels and mussels with foulers. A temporal and spatial investigation has been initiated in 2001 and preliminary results will be discussed.

SPECIES-SPECIFIC SETTLEMENT PATTERNS OF BLUE MUSSELS IN COBSCOOK BAY, MAINE. **Afton McGowen, Matthew Gordon,** and **Paul D. Rawson,*** School of Marine Sciences, University of Maine, Orono, ME 04468-5751.

The blue mussels *Mytilus edulis* and *M. trossulus* are sympatric throughout much of the Canadian Maritime Provinces, as well as in easternmost Maine. We have observed marked variation in the frequency of adult *M. trossulus* mussels among sites within Cobscook Bay, Maine. Little is known regrading the degree to which local variation in species-specific larval supply versus post-settlement mortality determine the relative frequency of this species in Gulf of Maine mussel populations. To examine the importance of larval supply, we deployed and sampled mussel spat collectors (ropes) on a monthly basis at three separate sites within Cobscook Bay during the summer and fall of 2000. There was significant spatial and temporal variation in the number of settlers observed on these collectors. Using molecular techniques, we have also estimated the frequency of *M. trossulus* and *M. edulis* spat in each sample. Appreciable frequencies of *M. edulis* spat were observed at all locations throughout much of the experiment wherease sizeable frequencies of *M. trossulus* were more temporally restricted. Our results suggest that species-specific differences in post-settlement mortality must be invoked to explain populations containing exclusively *M. trossulus* adults within Cobscook Bay.

GENETIC ASPECTS OF THE BLUE MUSSEL (*MYTILUS EDULIS* AND *MYTILUS TROSSULUS*) HYBRID ZONE IN ATLANTIC CANADA. **Marcelo Miranda*** and **David Innes,** Dept. Biology, Memorial University or Newfoundland, St. Johns, NF, A1C 3X9; **Raymond Thompson,** Ocean Science Center, Memorial University of Newfoundland, St. Johns, NF, A1C 3X9.

The blue mussel (*Mytilus edulis* and *M. trossulus*) hybrid zone in Atlantic Canada provides an opportunity to study the process of speciation, adaptation and species interaction. Species composition in different size classes was determined at several aquaculture sites and natural populations in Newfoundland using nuclear DNA markers. *M. trossulus* and hybrids occur at a higher frequency in the smaller size classes and *M. edulis* dominates in larger size classes. This pattern suggests that *M. trossulus* in these areas may have a higher mortality rate or a shorter life span than *M. edulis*. In addition, offspring from inter and intra-specific crosses were reared in the laboratory to study the dynamics of hybridization and species differences. Fertilization rate, larvae abnormality and sperm competition were used to estimate barriers to hybridization at the gamete stage. Growth rate and survival of the different families were compared during the larval stage, spat (6 months) and until maturity (18 months). These data were used to assess hybrid fitness and also to compare the performance of both species, which recently had been a major concern to the mussel industry.

SMALL SCALE DISTRIBUTION OF *MYTILUS EDULIS* AND *M. TROSSULUS* IN THE BAIE DES CHALEURS AND THE GASPÉ PENINSULA. **Valérie Moreau*** and **Edwin Bourget,** GIROQ, Département de biologie, Université Laval, Ste-Foy, Québec, Canada, G1K 7P4; **Réjean Tremblay,** Centre Aquicole Marin-Université du Québec à Rimouski, Grande-Rivière, Québec, Canada, G0C 1V0.

Mytilus edulis and *M. trossulus* are the two species found in the Baie des Chaleurs and the Gaspé Peninsula. To date, few studies bring out the effects of environmental factors (temperature, salinity, tidal height, wave action) on the local or regional distribution of these two species. Mussels were sampled on rocky shores according to a factorial design including six locations, three degrees of wave exposure (exposed, semi-exposed, sheltered) and two intertidal level (mid and low). PCR amplification using a diagnostic DNA marker (*Glu-5*) was used to distinguish species. Species relative frequencies show no clear patterns of distribution with wave exposure or tidal height. Although, there appears to be a pattern of distribution at the regional scale, this pattern could not be related to salinity or temperature gradients observed.

MUSSEL CULTURE IN A MIXED SPECIES (*M. EDULIS* AND *M. TROSSULUS*) ZONE—SOME COMMERCIAL IMPLICATIONS. **Randy W. Penney,* M. J. Hart,** and **N. Templeman,** Department of Fisheries and Oceans, Science, Oceans and Environment Branch, P. O. Box 5667, St. John's, Nfld, Canada, A1C 5X1.

The island of Newfoundland, Canada, is a zone where two blue mussel species, *M. edulis* and *M. trossulus,* overlap in distribution. Typically, indigenous populations at most sites contain mixtures of both species and hybrids. Sites in close proximity (eg. <10 kilometers) often vary as much in their relative species proportions as sites hundreds of kilometers apart. Intra-site growth variability is significantly affected by the mixed-species nature of these stocks. In a 14 month commercial rearing trial of rope-cultured mussels from sleeving to harvest at three farm sites, the *M. edulis* stock component had higher growth rates in shell and total weight than the sympatric *M. trossulus* at all three farms, while inter-specific shell length growth rates were different at only one farm. Growth rates of hybrids were typically intermediate between the two. Mortality rates were similar between sympatric *M. edulis* and *M. trossulus* at all three sites. We conclude that naturally-occurring stock genetic variability may have a significant impact on commercial production indices at farm sites within zones of species overlap.

CLADISTIC ANALYSIS OF GENETIC DIFFERENTIATION BETWEEN POPULATIONS OF THE BLUE MUSSEL, *MYTILUS TROSSULUS.* **Paul D. Rawson,** School of Marine Sciences, University of Maine, Orono, ME 04468-5751.

Two species of blue mussel, *Mytilus edulis* and *M. trossulus,* have overlapping distributions on the Atlantic coast of North America. Populations containing a mixture of these species and their hybrids are commonly observed throughout the Canadian Maritime Provinces. Recent work, in my lab, has shown that the range of *M. trossulus* extends well into the Gulf of Maine, much further south than previously observed. In this study, I have employed a DNA sequence-based cladistic analysis to examine whether the presence of *M. trossulus* in the Gulf of Maine is due to a recent range expansion. DNA sequences for a portion of the female mitochondrial lineage D-loop region (~670 base pairs) were obtained from 140 *M. trossulus* by PCR amplification and direct sequencing. Analysis of these sequences indicates there is significant genetic divergence between Atlantic and Pacific *M. trossulus* populations. In contrast, there was no evidence of genetic differentiation or a reduction in genetic diversity among the Atlantic coast populations. These results are contrary to what would be expected if Gulf of Maine *M. trossulus* populations have only recently been established.

BEHAVIOR AND GROWTH OF JUVENILE MUSSELS (*MYTILUS* SPP.) IN SUSPENDED CULTURE SOCKS. **Judith Senechal*** and **Jon Grant,** Oceanography Dpt, Dalhousie University, Halifax, NS B3H 4J1.

Suspended mussel culture is based on loading high densities of juvenile mussels into mesh socks, and hanging them from floats. This leads to severe intraspecific crowding, and potentially reduces growth and mussel yield. The highly mobile juveniles position themselves according to size, shell gape, ambient current and food, among other factors. Despite this critical stage in culture, there are little data on behavioral mechanisms that lead to adult density and growth rate. We conducted a series of field and laboratory experiments with culture socks to examine the effects of stocking density, species (*Mytilus edulis* and *Mytilus trossulus*) and environment on early development of the culture population. *In situ* photography was used to capture a time series of mussel images in experimental socks at a commercial farm in Ship Harbor, Nova Scotia. Moored CTD-current meters and water sampling were used to characterize the sites. Image analysis on mussel size, gape, and position was used to quantify temporal changes over several months in the socks. In the laboratory, socks were hung in a tall flow-through tank with variable temperature, current speed and direction, allowing controlled experiments on mussel emergence and growth. Initial results are discussed in the context of optimizing husbandry practices.

UPDATE ON THE DISTRIBUTION OF TWO MUSSELS SPECIES (*MYTILUS EDULIS* AND *MYTILUS TROSSULUS*) IN THE QUEBEC MARITIME REGIONS. **Benoit Thomas,*** Centre aquacole marin, MAPAQ, Grande-Rivière, Québec, G0C 1V0; **Valérie Moreau** and **Réjean Tremblay,** Centre aquacole marin-Université du Québec à Rimouski, Grande-Rivière, Québec, G0C 1V0.

This study attempted to determine the distribution of the two species of mussels and hybrids along the main Quebec maritime regions of the Gulf of St. Lawrence, as well as evaluate the biannual pattern of distribution among different sites. Following 1996 near shore mussel sampling, we started a study based on mussel spat fixed on artificial collectors immersed at 8 sites along the 460 km long Gaspe peninsula and at 5 sites along some 1000 km of the North Shore of the Gulf of St. Lawrence. Biannual sampling was conducted at these sites following initial results obtained in 1997. At all sites, collectors and thermographs were immersed at 2 m in mid-June (sea bottom depth: 18 m) and sampled in mid-October of the same year. Sampling the next June was also conducted along sites located along the North Shore, where spat growth was found to be low the first season and site accessibility was limited. In 1996 and 1997, analyses were done by electrophoresis on MPI and by diagnostic DNA marker (GLU-5) for other years. According to the initial two year results, a predominance of *M. trossulus* occurs on the northern side of the Gaspe peninsula as well as in the extreme east of the North Shore. The best sites for presence of *M. edulis* was in the mid-region of the Gaspe peninsula as well as the western side of the North Shore. Results show that some sites are variable, with yearly variations. This annual change or steadiness in the proportion of the two species will permit mussel growers to orient towards better *M. edulis* spat provision sites; accepting, for now, the hypothesis that the commercial value of *M. trossulus* is lower.

PERFORMANCE OF *MYTILUS EDULIS* AND *MYTILUS TROSSULUS* IN THE GULF OF ST. LAWRENCE: A LABORATORY EXPERIMENT. Réjean Tremblay* and **Valérie Moreau,** Centre aquacole marin-Université du Québec à Rimouski, Grande-Rivière, Québec, G0C 1V0; **Thomas Landry,** Gulf Fisheries Center, DFO, Moncton, New Brunswick, E1C 9B6; **Bruno Myrand,** Station technologique Maricole, MAPAQ, Cap-aux-Meules, Québec, G0B 1B0; **Cyr Couturier,** Marine Institute, Memorial University of Newfoundland, St John's, Newfoundland, A1B 3X5.

During the past 15 years, reciprocal transfer experiments with mussels, *Mytilus edulis* and *M. trossulus* in Gulf of St. Lawrence have shown that their performance, expressed in term of growth and survival, is different between stocks. Moreover, the relative performance level of a stock may vary between sites. These results suggest that the performance of mussels is probably genetically based. The genetic diversity of mussels in the Gulf of St. Lawrence could be very important in relation to their ability to adapt to the highly variable environmental conditions. The goal of this study, is to characterise the performance of different mussel stocks and to determine the relation between physiological parameters and genetic traits, for both species of mussels. These analysis were conducted on mussels spat sampled from artificial collectors in Québec, Prince Edward Island, New-Brunswick and Newfoundland. Bi monthy growth and survival data was collected from twelve different mussel stocks maintained in laboratory with non-treated seawater, over a one year period. Temperature, seston and chlorophyll-a were monitored. Physiological measurements, including scope for growth and basal metabolism, as well as genetic analysis, were conducted on each stock. Genetic analysis included species determination by PCR technique and genetics variability determined by electrophoresis technique. Results will be discussed in terms of mussel culture strategy for spat supply.

BLUE MUSSELS AS MODEL SYSTEMS TO INVESTIGATE PALLIAL CAVITY FUNCTION IN BIVALVES. J. Evan Ward,* and **Sandra E. Shumway,** Department of Marine Sciences, University of Connecticut, Groton, CT 06340; **Jeffrey S. Levinton,** Department of Ecology & Evolution, S.U.N.Y., Stony Brook, NY 11794.

For over fifty years, mussels in the genus *Mytilus* have been used as model systems to study aspects of bivalve behavior, physiology, and genetics. Because of their relatively simple, nonplicate, homorhabdic ctenidium, mussels are also ideal animals in which to investigate general mechanisms of particle handling. In this talk we will discuss our studies on particle capture, transport, and selection in mussels and how they have furthered our understanding of pallial cavity function and its connection to ecosystem processes. In particular, we will examine where gaps in our knowledge exist and compare and contrast feeding processes in mussels with those of other bivalves.

For our studies, mussels were delivered polystyrene tracer particles alone or in combination with defined diets consisting of either ground, aged *Spartina* sp. (3–10μm), similar sized phytoplankton (*Rhodomonas* sp.), or a 50/50 mixture of both at three concentrations (10^3, 10^4, 10^5 particles ml^{-1}). Particle capture, transport, and handling by the pallial organs were studied *in vivo* by means of video-endoscopy and discrete samples of particulate material were collected from various ciliated tracts. Image analysis was used to track particle movement on the ctenidia and labial palps, and flow cytometry was used to analyze samples for evidence of particle selection. Particle depletion and handling time experiments were also performed to measure residence times on the ctenidia and labial palps. Results indicate the following: 1. ctenidal filaments are directly involved in particle capture, 2. diet quality has little effect on particle handling mechanisms, 3. diet quantity has significant effects on particle handling mechanisms, and 4. particle selection is confined to the labial palps. Studies such as these will lead to a better understanding of pallial organ function in mussels, and allow us to better model the critical limiting factors that mediate particle-feeding in bivalves and ultimately affect the trophic dynamics of benthic ecosystems.

HARMFUL ALGAL BLOOMS

EFFECTS OF CLAY, USED TO CONTROL HARMFUL ALGAL BLOOMS, ON JUVENILE HARD CLAMS, *MERCENARIA MERCENARIA.* Marie-Claude Archambault* and **Jon Grant,** Oceanography Dpt, Dalhousie University, Halifax, NS B3H 4J1; **Monica Bricelj,** Institute for Marine Biosciences, National Research Council of Canada, Halifax, NS B3H 3Z1; **Don Anderson,** Biology Dpt., Woods Hole Oceanographic Institution, Woods Hole, MA 02543.

Increased interest in using ecologically inert clays to mitigate harmful algal blooms at nearshore mariculture sites has prompted studies on the effectiveness of this method on prolific U.S. blooms, such as Florida's neurotoxic blooms of *Karenia brevis*. Potential repercussions of this control strategy revolve around the increasing flux of suspended particles to the benthos. Juvenile suspension feeding bivalves are potentially vulnerable as they could suffer burial and a decrease in clearance rates and/or increase in pseudofeces production in response to suspended clay, leading to reduced growth and delay in attaining size refuge from predators. The main objective of the research was to assess lethal and sublethal effects on juvenile hard clams, *Mercenaria mercenaria*, in a two-week flume application of phosphatic clay (by-product of phosphate mining) to a simulated bloom of a non-toxic dinoflagellate (*Heterocapsa triquetra* or *Prorocentrum micans*). Flow regimes simulated two extreme conditions, representing end members of a continuum expected in the field, a) where low flow allowed complete settling and formation of a sediment layer, and b) where high flow maintained complete particle resuspension. No clam mortalities occurred in either treatment. The sedimentation treatment showed variable growth inhibition in shell and/or tissue, but effects were not significant compared to controls (no sediment layer), and clams rapidly resumed siphon contact with the overlying water column. In contrast, a highly significant growth effect (~90% reduction in shell and tissue growth) occurred in trials with suspended clay compared to no-clay controls. Analysis of particle size-spectra, using a sampling method designed to maintain the integrity of flocs, showed evidence of clay flocculation, such that clay particles were found above the 100% retention efficiency size limit of the clam gill. These results suggest that repeated clay applications in the field are likely more detrimental to clams under flow conditions leading to prolonged *in situ* resuspension of clay than under conditions that promote rapid sedimentation.

HISTORY, SOME RECENT HAB EVENTS, AND THEIR IMPACTS ON SHELLFISH AND FINFISH IN WASHINGTON STATE. **Rita A. Horner,*** School of Oceanography, University of Washington, Seattle, WA 98195-7940.

Harmful algal blooms and their effects, especially paralytic shellfish poisoning (PSP), have a long history in the Pacific Northwest starting in June, 1793, when one of Captain George Vancouver's crew members died and four others became ill after eating mussels in central British Columbia. The next known occurrence was in May, 1942, when three people died and eight became ill from eating clams or mussels in Barkley Sound, British Columbia, and three others died near Port Angeles, Washington, after eating clams. Investigations suggested that only beaches on the Strait of Juan de Fuca and the open Pacific coast were affected and the Washington Department of Fisheries issued an annual closure of these areas from April through October. Since then, PSP has spread to all of western Washington's inland marine waters, except Hood Canal, and is also present along the open Pacific coast and in coastal estuaries. Beach closures are frequent and human illnesses continue to occur, albeit infrequently, even with increased monitoring. In 1991, domoic acid was found in razor clams and Dungeness crabs on Washington's Pacific coast, where it continues to be found sporadically in razor clams with consequences for their harvest. The causative organisms, several species of the diatom genus *Pseudo-nitzschia*, are sometimes present in bloom concentrations in inland waters of Puget Sound and in coastal estuaries, but if domoic acid occurs, levels are low and no closures have been required. No confirmed cases of amnesic shellfish poisoning (ASP) caused by domoic acid have been reported in the state. Other potentially harmful phytoplankton species, including *Heterosigma akashiwo* and *Chaetoceros* spp. occur here, primarily affecting finfish in net pens. Reactive oxygen species and possibly an unknown toxin are associated with *Heterosigma*, while *Chaetoceros* effects are mechanical. Thus, western Washington waters harbor a variety of potentially harmful marine phytoplankton species that continue to plague shellfish and finfish growers in more places and usually without warning.

EFFECTS OF THE TOXIC DINOFLAGELLATE, *KARENIA BREVIS*, ON LARVAL MORTALITY AND JUVENILE FEEDING BEHAVIOR IN THE BAY SCALLOP, *ARGOPECTEN IRRADIANS*. **Jay R. Leverone*** and **Norman J. Blake,** College of Marine Science, University of South Florida, St. Petersburg, FL 33701.

Florida populations of the bay scallop, *Argopecten irradians*, occur in areas prone to recurring blooms of the toxic dinoflagellate, *Karenia brevis* (=*Gymnodinium breve*). These blooms can have serious consequences for bay scallop recreational fisheries, aquaculture and restoration activities. Surprisingly, there are few published data regarding the effects of *K. brevis* on any aspect of bay scallop biology or ecology in Florida. A series of laboratory experiments was conducted to observe the direct effects of exposure to *K. brevis* on early life stages of the bay scallop, *A. irradians*. For bay scallop larvae, an LC_{50} of 900 cells/ml *K. brevis* was calculated after a seven-day exposure. Larval development was delayed and metamorphosis inhibited at concentrations above 500 cells/ml. Larvae responded similarly when exposed to either "whole" or sonicated "lysed" cultures of *K. brevis*. Clearance rates of juvenile scallops (5–15 mm shell height) were size dependent and significantly ($p = 0.05$) reduced at *K. brevis* concentrations of

50 cells/ml and higher. At 100 cells/ml, reduced clearance rates resulted in slower growth and reduced weight gain after one-week exposure. At 500 cells/ml, clearance rates were irreversibly affected even 20 hours after a spiked exposure. Findings will be discussed in light of recent efforts to restore bay scallops along the west coast of Florida.

DETRIMENTAL EFFECTS OF A RECENT *PRYMNESIUM* ISOLATE FROM BOOTHBAY HARBOR, MAINE (USA) UPON JUVENILE BAY SCALLOPS, *ARGOPECTEN IRRADIANS.*

Gary H. Wikfors* and **Jennifer H. Alix**, NOAA Fisheries, NEFSC, Milford, CT 06460 USA; **Roxanna M. Smolowitz**, Marine Biological Laboratory, Woods Hole, MA 02543; **Lacey Wallace**, Southampton College of LIU, Southampton, NY 11968; **Hélène Hégaret**, École Nationale Supérieur Agronomique de Rennes, Rennes, France.

The brackish-marine flagellate *Prymnesium* has been known to be toxic to finfish for decades. Symptoms in fish exposed to toxic *Prymnesium* include copious mucuous production and bleeding from the gills, and death by asphyxiation. Two strains of *Prymnesium*, isolated recently by Dr. R.R.L. Guillard were tested for ichthyotoxicity using cunner (*Tautogolabrus adspersus*); we confirmed toxicity and histopathology of one isolate, strain 97-20-1. Further, we determined and documented effects of the toxic *Prymnesium* strain (97-20-1) to bay scallops, *Argopecten irradians.*

In one exposure experiment, 10-mm scallops were placed in basins of ultrafiltered seawater, and cultured (bacteria-free) *Prymnesium* 97-20-1 were added to achieve a cell density of 10^5 cells/ml. Controls were scallops given an equivalent quantity of *Isochrysis* sp, (strain T-ISO) or an equivalent volume of algal culture medium. Scallops given T-ISO fed normally and produced fecal pellets; whereas, scallops exposed to *Prymnesium* twitched violently, produced pseudofeces and abundant mucous, and eventually displayed valve gape that was not responsive to stimulation. Within 24 hours, all scallops exposed to *Prymnesium* were moribund or dead. Histopathological analysis revealed severe, acute, total or near-total necrosis of the digestive gland and ducts, gill, and other tissues in scallops exposed to *Prymnesium* and normal tissue histology in controls.

In a later experiment, larger scallops (50-mm) were exposed to *Prymnesium* 97-20-1 (again with T-ISO as the control), and hemolymph samples were removed after 2.5 hours for analysis of hemocytes by flow-cytometry. Significantly more dead hemocytes were seen in scallops exposed to *Prymnesium* than to T-ISO, but no differences in aggregation and adherence or phagocytosis of plastic microbeads were detected. We believe this to be the first report of HAB effects upon the bivalve immune system. These experiments revealed effects of an ichthyotoxic microalga upon scallops ranging from behavioral to histopathological and immunological, and may serve as a template for studies of additional HAB-bivalve trophic interactions.

SHELLFISH BIOLOGY

BURROWING-INDUCED INTERNAL FRACTURES AND EXTERNAL ABRASION IN SHELLS OF THE HARD CLAM *MERCENARIA MERCENARIA* FROM RARITAN BAY, NEW JERSEY.

Richard R. Alexander,* Department of Geological and Marine Sciences, Rider University, Lawrenceville, NJ 08648; **Robert M. Baron**, Institute of Marine and Coastal Studies, NOVA Southeastern University, Fort Lauderdale, FL 33004.

The hard clam *Mercenaria mercenaria* from Raritan Bay, New Jersey, reburrowed once a month into sediment in flow-through tanks for a period of one year. Twelve specimens, between 34 and 38 mm dorsal-ventrally, reburrowed in each of five different textured sediments, namely 100% mud, 100% sand, admixture of 25% by volume ground shell hash and 75% mud, admixture of 25% shell hash and 75% sand, and admixture of 50% sand and 50% mud. Lacking tidal flushing through the tanks, mean shell growth, dorsal-ventrally, was one mm/yr. Shell accretion was statistically significantly depressed in sand and shell-sand vs. mud, and mud-shell substrata, a disparity attributed to repeated abrasion of valve margin's during monthly reburrowing in coarser textured sediments. Clams in sand and shell-sand had more concentric, fine ornament or lamellae worn smooth relative to specimens in mud and mud-shell mixtures. Upon sacrifice, 30 clams revealed "stuccoed," internal fractures initiated at the shell margin. Five linear fractures radiate dorsally. Seven cracks curve or diagonal from the shell margin. Three show right angle deflections, twice through adductor muscle scars. Four merge or branch from the margin. In 12 specimens, fractures are in both valves. In ten specimens, fractures were faintly visible on valve exterior. In four and two specimens, respectively, fractures were initiated at the posterior or anterior margin. Repaired fractured shells are randomly distributed among sediment textures. Nevertheless, fractures were probably induced and/or exacerbated by the reburrowing process.

INFLUENCE OF ENVIRONMENT AND FOOD SUPPLY ON SURVIVAL OF *CRASSOSTREA GIGAS* LARVAE: A MODELING STUDY.

Eleanor A. Bochenek* and **Eric N. Powell**, Rutgers University, Haskin Shellfish Research Laboratory, 6959 Miller Avenue, Port Norris, NJ 08349; **John M. Klinck** and **Eileen E. Hofmann**, Center for Coastal Physical Oceanography, Old Dominion University, Norfolk, VA 23529.

A biochemically-based model was developed to simulate the growth, development, and metamorphosis of larvae of the Pacific oyster, *Crassostrea gigas*. The model is unique in that it: 1) defines larvae in terms of their protein, neutral lipid, polar lipid, carbohydrate, and ash content, 2) tracks weight separately from length to follow larval condition index, and 3) includes genetic variation in growth efficiency and egg quality to better simulate cohort population dynamics. Simulations show that departure of temperature, salinity or food content from optimum levels reduces larval cohort survival, generally either because some larvae fail to metamorphose successfully or because an increase in larval life span increases losses to predation. Also, different food compositions produce widely varying survivals at the same food concentration. The simulations suggest that the ratio of the combined carbohydrate and lipid pools to protein may best describe the overall quality of the food. In simulations emphasizing genetic variability within the cohort, larvae with high growth efficiency originating from large eggs outperform other egg quality-growth efficiency combinations for most environmental variables, including temperature, salinity, and food content. In contrast, whereas the simulations suggest that the influence of suboptimal temperature, salinity, or food content is to compress genetic variation by uniformly favoring high growth efficiency and large eggs, the simulations with food quality provide evidence of a mechanism that would expand genetic variation, because variations in food quality favor a much broader range of genetic types. The simulations support the supposition that food quality is an important variable controlling larval cohort success.

GROWTH CHARACTERISTICS OF *ARGOPECTEN GIBBUS* JUVENILES REARED IN TWO SUSPENDED CULTURE SYSTEMS.

Andrew T. Cogswell and **Samia Sarkis,** Bermuda Biological Station for Research, Inc., 17 Biological Lane, Ferry's Reach, St. George's, Bermuda, GE 01.

Grow-out of hatchery reared calico scallops (*Argopecten gibbus*) is conducted in Bermuda's inshore waters using square Irish scallop trays and triangular Japanese pearl nets. Both enclosures have advantages and disadvantages in both maintenance and handling throughout the grow-out phase. To assess optimum technology, yielding minimum labour demand and maximum scallop growth and survival, a comparative study was performed.

A pool of juvenile scallops was distributed in triplicate in 6.0 mm pearl nets, and in scallop trays lined with 6.4 mm black polyethylene "pouches". Scallop growth and survival were monitored monthly in trays and pearl nets of comparable mesh size and stocking densities ranging from 0.20 scallops-cm^{-2} to 0.10 scallops-cm^{-2}. At this time, sub-samples ($n = 50$) were collected from the pool of triplicates and both shell and tissue growth of juvenile scallops was recorded.

Preliminary results revealed that scallops cultured in pearl nets achieved higher growth rates than scallops in trays from juvenile to market size. Results also imply that the limiting effect of trays on scallop growth is immediate above the initial height and weight used in this experiment and increases until scallop growth nearly ceases. Comparisons for scallops grown in pearl nets and trays are made using Statview statistical package. Evaluation of trays and pearl nets as grow-out enclosures is discussed in terms of optimal grow-out strategy.

GROWTH AND DISPERSAL STUDIES OF *MYA ARENARIA* USING A NUMERICAL FLOW MODEL.

W. R. Congleton, Jr.,* Marine BioResources; **B. R. Pearce,** Civil and Environmental Engineering; **M. Parker,** Marine BioResources, Univ. of Maine, Orono, ME 04469.

Growth: Current velocities averaged over the flood tide were estimated by a numerical flow model and by clod cards for locations in an Eastern Maine bay and were compared to the annual shell size increment of clams collected at the same locations. Statistical models including initial shell size, year of sample, high-low current category estimated by clod cards or the numerical model and interactions explained 57–58% of the variability in growth increment after a difference transformation. High current simulated growth, although the effect on growth increment was less than that of sample year or initial size. The adjusted least squares mean for the growth increment at the sites with low flow, as identified by clod cards that averaged 4.35 ± .37 cm/s was 9.56 ± .247 mm, and low flow that averaged 2.99 ± .43 cm/s using the numerical model was 9.51 ± .274 mm. High flow sites averaging 5.86 ± .62 cm/s using clod cards had estimated growth increments of 11.90 ± .323 mm and high sites averaging 5.84 ± .46 cm/s using the numerical model had estimated growth increments of 11.70 ± .33 mm.

Dispersal: Clam populations, particularly in eastern Maine, are prone to recruitment failure of larvae onto intertidal flats due to the large tidal amplitude and resulting high flushing rates. Larvae move offshore during a larval development period that is extended in cool waters in the summer along the eastern coast. High variability in ME landings, mudflat sampling of settlement, spat bag studies of larval distributions are consistent with this theory. Presently, studies using Eulerian and LaGrangian numerical flow models are being utilized to determine the effect of tidal magnitude, length of dispersal period and variation in coastal geology on larval dispersal.

ESTIMATION OF INGESTION AND BIODEPOSITION RATES OF THE PACIFIC OYSTER, *CRASSOSTREA GIGAS*, IN A COASTAL LAGOON OF NW MEXICO.

Zaúl García-Esquivel,* **Marco A. González-Gómez,** and **Francisco Ley-Lou,** Universidad Autónoma de Baja California. Apdo. Postal 453, Ensenada, B.C. México.

Four short-term (6–8 h) experiments were carried out at San Quintin Bay (SQB) in 1999 (June, October) and 2000 (January, April) in order to estimate "in situ" ingestion rates (IR) of the Pacific oyster, *Crassostrea gigas*. Experiments were carried out by pumping seawater directly into experimental trays containing adult oysters (94 ± 1.7 cm shell height, 3.64 ± 0.45 g). Total and organic particulate matter (TPM and POM, respectively) were measured every 1.5 h in the feces and pseudofeces produced by oysters and in the input seawater. Clearance and ingestion rates were calculated by using the ash balance method. In situ POM/TPM ratio

(0.15 to 0.30) and oyster clearance rates (2 to 7.5 L h^{-1}) were inversely related to TPM concentration (2–14 mg L^{-1}), while feces (7.9–13.7 mg TPM $oyster^{-1}$ h^{-1}) and pseudofeces production (4.8–13.2 mg TPM $oyst^{-1}$ h^{-1}) were directly proportional to TPM concentration. Net organic ingestion rates (3–4.2 mg OM h^{-1}) were not dependent on total particle concentration. It is suggested that particle resuspension plays an important role in regulating the variability of food quality in SQB, but such variability does not affect the net amount of organic matter ingested by *C. gigas* throughout the year.

EFFECT OF DIETARY PROTEIN/ENERGY RATIO ON GROWTH AND METABOLISM OF JUVENILE GREEN ABALONE (*HALIOTIS FULGENS*).

Laura E. Gómez,* FES-Cuautitlán UNAM, México; **Ma. Teresa Viana** and **Zaúl García-Esquivel,** UABC, BC, México; **Armando Shimada,** UNAM, México; **Louis R. D'Abramo,** MSU, USA.

Juvenile green abalone (initial size = 11.84 ± 1.003mm) were fed different practical diets formulated to contain different P/E ratios (mg/kcal) ranging from 62 to 108 mg/kcal. The dietary protein level increased from 25.8 to 44.1% while the level of energy remained constant (4056 to 4154 cal/g). After 61 days in a flow through system at 21C, growth of abalone fed diets with a P/E ratio of 100 and 108 mg/kcal (SGR = 2.42 ± 0.11 and 2.51 ± 0.10) was significantly greater than that of abalone fed the other diets. Food intake and therefore ingested energy per g of abalone were similar for all dietary treatments. Protein and energy digestibility, amonia excretion and oxygen consumption were determined after the growth experiment was terminated. Intake of digestible energy was different among dietary treatments, but intake of digestible protein did not change. Abalones ingest food to satisfy their energy requirements, and digestibility of protein and energy decreases as the P/E ratio increases. The most efficient diet for growth probably consists of a 100 P/E ratio with lower levels of dietary protein and energy.

MODELING THE GROWTH OF THE HARD CLAM, *MERCENARIA MERCENARIA*.

John Kraeuter* and **Eric N. Powell,** Rutgers University, Haskin Shellfish Research Laboratory, 6959 Miller Avenue, Port Norris, NJ 08349; **Eileen E. Hofmann** and **John M. Klinck,** Center for Coastal Physical Oceanography, Old Dominion University, Norfolk, VA 23529; **Ray Grizzle,** Jackson Estuarine Laboratory, 85 Adams Point Road, Durham, NH 03824; **Monica Bricelj,** Institute for Marine Biosciences, National Research Council, 1411 Oxford Street, Halifax, NS, B3H 3Z1, Canada; **Stuart Buckner,** 23529 Town of Islip, Environmental Control, 401 Main Street, Islip, NY 11751.

A physiologically-based model that simulates the growth of the hard clam, *Mercenaria mercenaria,* in response to environmental conditions of temperature, salinity, and food supply has been developed. The processes included in the clam model are those that are responsible for changes in clam soft tissue weight, length, and condition. Changes in clam soft tissue weight over time result from the difference in assimilation and respiration. Changes in clam condition are determined from a length-weight relationship that is reflective of average clam growth. Changes in clam length (growth) occur only when condition index is greater than zero, which happens when the clam has attained excess weight for a given length. No change in length occurs if condition index is zero (mean case) or negative (less weight than expected at a given length). Initial simulations with the clam model, that used allometric relationships to relate weight and length, resulted in growth rates that did not match those observed for hard clams over a range of weights and lengths. However, when weight and length are related using a third-order polynomial the simulated growth rates match observed rates. The implication of this result is that small clams are heavier for a given length and that large clams are longer for a given weight. This approach represents a change in the way that models are formulated for growth of clams and potentially other bivalve species. Additional simulations illustrate the effect of changing salinity and food environments and genetic variation in growth efficiency and respiration on hard clam growth and survival.

INFLUENCE OF SHORT TERM VARIATIONS IN FOOD SUPPLY AND CRITICAL PERIODS ON SURVIVAL OF *CRASSOSTREA GIGAS* LARVAE.

Eric N. Powell* and **Eleanor A. Bochenek,** Rutgers University, Haskin Shellfish Research Laboratory, 6959 Miller Avenue, Port Norris, NJ 08349; **John M. Klinck** and **Eileen Hofmann,** Center for Coastal Physical Oceanography, Old Dominion University, Norfolk, VA 23529.

A biochemically-based model was developed to simulate the growth, development, and metamorphosis of larvae of the Pacific oyster, *Crassostrea gigas.* The model defines the larvae in terms of protein, lipid, carbohydrate, and ash content and includes genetic variation in growth efficiency and egg quality. This model is used to investigate the premise that certain periods of larval life are more critical than others with respect to the availability of food and that food quality is as important as food quantity. Simulation results indicate that critical periods in larval life do exist. However, the critical portion of larval life depends on the structure of the food that the larvae encounter. Overall, the most critical time is late in larval life as the larvae approach metamorphosis. Increased protein at this time always improves larval survival. Increased lipid has the most effect about midway in larval life, but also exerts a positive impact late in larval life. However, exposure to certain types of food early in larval life can dramatically change cohort survival. Additional simulations show that larvae with high growth efficiency are more successful, as are larvae coming from large eggs. Changes in food quantity influence larval survival primarily by varying the length of larval life. Changes in food quality, however, by restricting the range of genotypes in the cohort that survive, as well as by varying larval life span, produce large changes in survivorship. The simulations support the adaptive advantage of larval cohorts with a relatively wide range of genotypes and suggest the important influence of variations in food quality in maintaining genetic variability.

POPULATION STRUCTURE OF THE HARD CLAM, *MERCENARIA MERCENARIA*, IN HAMPTON ROADS, VIRGINIA.

Melissa J. Southworth,* Juliana M. Harding, and **Roger Mann,** Department of Fisheries Science, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

The hard clam, *Mercenaria mercenaria*, supports one of the most valuable fisheries in the Virginia Portion of the Chesapeake Bay. In recent years with the displacement of oystermen moving to clam harvesting as an alternative source of income, there has been a gradual decline in catch per unit effort in the clam fishery. Despite growing concern for the decreasing catch and the increasing pressure of proper management there has only been one survey in recent years that focused on stock assessment for management purposes (Wesson, 1995). Preceding this the last substantial surveys were prior to and just after Hurricane Agnes in the early 1970's. As such a survey of the Hampton Roads area was carried out in the summer of 2001. The survey documented the distribution of the current demographics including size and age structure of the hard clam stocks. The current distribution of hard clams exists over a cline of differing salinity and bottom types. From this we compare site versus size, age, and the frequency of recruitment. The frequency of recruitment, size, and age is then compared to the environment. Comparisons of historic data and current survey data show changes over decadal time scales that are useful indicators of long term environmental change in the Hampton Roads area.

AN EXAMINATION OF POTENTIAL CONFLICT BETWEEN HARD CLAM AQUACULTURE AND SAV IN THE LOWER CHESAPEAKE BAY.

Helen Woods,* Ken Moore, and **Carl Hershner,** Center for Coastal Resources Management, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

The Commonwealth of Virginia wishes to promote both hard clam (*Mercenaria mercenaria*) aquaculture and the growth of submersed aquatic vegetation (SAV) along its shallow subaqueous bottom. Conflict can arise in areas where aquaculturists plant clams in SAV habitat and/or when SAV colonizes an area being used for aquaculture. This project examined the issue of bottom use conflict on the Eastern Shore of Virginia involving clam aquaculturists and SAV interest groups. This issue was examined by studying historic SAV and aquaculture trends, creating spatial GIS models to predict areas suitable for the growth of SAV and the development of clam aquaculture, and examining the current laws in Virginia and neighboring states which affect this issue. Results suggest that a management approach which annually defines a 50 meter buffer surrounding existing SAV beds would adequately protect SAV while minimizing areas legally unavailable but otherwise suitable for clam aquaculture, thus minimizing conflict.

SCALLOP BIOLOGY AND CULTURE

POSTLARVAL DEVELOPMENT OF THE GILLS AND IMPLICATIONS FOR FEEDING IN THE SEA SCALLOP, *PLACOPECTEN MAGELLANICUS*.

V. Monica Bricelj,* Anne Veniot and **Céline Barré,** Institute for Marine Biosciences, National Research Council, 1411 Oxford St., Halifax, NS B3H 3Z1, Canada; **Peter Beninger,** Laboratoire de Biologie Marine, Faculté des Sciences, Université de Nantes, 44322 Nantes, France.

Hatchery-reared bivalves often experience poor growth and survival during post-settlement stages, yet limited information is available on postlarval morphogenesis and feeding, especially in scallops. Our research uses scanning electron microscopy to document critical changes during the ontogeny of pallial feeding organs (gills, mantle, foot, lips and labial palps) in sea scallops (and recently in bay scallops, *Argopecten irradians*) and their correlation with size, between 0.3 and 14 mm in shell height (SH). We present here the results concerning gill development in *Placopecten magellanicus*. Pronounced changes in morphology of the filibranch gill produce a transition from a homorhabdic gill basket to the heterorhabdic, W-shaped, plicate gill characteristic of adults. Suspension-feeding is probably rather ineffective prior to reflection of the inner demibranch (occurring at ~1 mm SH and followed by accelerated proliferation of gill filaments), and formation of the outer demibranch (completed at ~2 mm SH). The onset of the heterorhabdic condition via differentiation of principal filaments, which allows bidirectional particle transport and thus the potential for selection and ingestion volume regulation on the gill, occurs fairly late in development, at ~3.3 to 5.0 mm. Full plication of the gill is only achieved at ~7 mm SH. This protracted development in *P. magellanicus* contrasts with that in oysters, which undergo more rapid gill differentiation and metamorphosis. We thus demonstrate that the gills are relatively undifferentiated at 1–2 mm SH, when sea scallops are commonly transferred from the hatchery to field nurseries by commercial growers. We are currently investigating the relationship between these morphological changes and evolving mechanisms of food capture and ingestion, in order to better define stage-specific nutritional requirements and growth performance during nursery culture of this commercially important species.

THE EFFECTS OF STOCKING DENSITY IN PEARL NETS ON SURVIVAL, GROWTH, AND REPRODUCTIVE POTENTIAL OF THE BAY SCALLOP, *ARGOPECTEN IRRADIANS IRRADIANS*.

Maureen Davidson, New York State Department of Environmental Conservation, Bureau of Marine Resources, 205 North Belle Mead Road, East Setauket, NY 11733.

In order to investigate the influence of stocking density on scallop production, hatchery reared bay scallops were held in pearl nets at three densities, 80/pearl net, 240/per net and 800/per net for 67 days during the summer. Surviving scallops were counted and shell heights were measured to determine growth. The animals were transferred to lantern nets and stocked at two different densities, 50/tier and 200/tier, and overwintered, grouped by their initial densities in the pearl nets. The following spring survival, shell heights, and gonadal index (a measure of reproductive potential) were determined. Survival and growth were inversely proportional to stocking density in both pearl and lantern nets. Stocking density in the lantern nets was found to have a greater effect on overwintering survival than did the density in pearl nets. Gonadal indices indicated that scallops initiated spawning at the same time, regardless of density treatment. There was no significant pearl net effect observed on gonadal index. Bay scallops cultured for direct market should be held at low densities in pearl and lantern nets to maximize growth and survival. Bay scallops raised for resources restoration should be held at moderate densities in pearl nets and low densities in lantern nets to maximize survival and reproductive potential.

DEVELOPING A COASTAL MAINE SEA SCALLOP ENHANCEMENT PROGRAM.

Scott Feindel* and **Daniel Schick**, Maine Department of Marine Resources, W. Boothbay Harbor, ME 04575.

Increasing the stock of wild scallops along the Maine coast by capturing wild seed at spatfall, holding them captive through what would be a time of high mortality in the wild and then releasing them has captured the imagination of many Maine scallopers. This concept builds upon a Japanese methodology that was exported successfully to New Zealand several years ago. We are working collaboratively with several groups of fishermen with assistance from a New England Consortium grant. The project is currently into its third season of spat collection and millions of scallop seed were released this last fall in several locations along the coast from last years spatfall.

Future work will involve continued collection of spat, defining the best locations for spat collection, monitoring survival of released seed, looking at increasing survival through holding the seed beyond the first year, addressing the issues of ownership and adjusting harvest practices to maximize yield.

This paper will focus on current results and near future efforts.

GROWTH AND MOVEMENT OF SEA SCALLOPS IN THE SOUTHERN PART OF THE GREAT SOUTH CHANNEL ON GEORGES BANK: A TAGGING STUDY.

Brad Harris* and **Kevin Stokesbury**, Intercampus Graduate School of Marine Science and Technology, University of Massachusetts Dartmouth, 706 Rodney French Boulevard, New Bedford, MA 02744-1221.

A rotational fisheries management strategy is being considered for the sea scallop, *Placopecten mangellanicus*, fisheries of the northeast United States. To implement a rotational management strategy site-specific information on sea scallop population dynamics is required. For example, the sea scallop is the best swimmer of the 400 known species of scallops, and can move as much as 15 km on Georges Bank. This could influence the size of the rotational areas closed or open to harvesting. Further, sea scallop growth rates show substantial variability over their geographic range. This could influence the time period rotational areas are open or closed. To begin the development of a site-specific data set, a sea scallop growth and movement experiment was conducted in the southern part of the Great South Channel of Georges Bank. Approximately 13,000 scallops were tagged and released in May 2001. Presently, 677 tagged shells have been returned showing movement of up to 7 km. and growth spanning more than 9 months. This preliminary data illustrates the need for further site-specific movement and growth experiments over the sea scallops range.

INVESTIGATIONS WITH TRIPLOID ATLANTIC SEA SCALLOPS, *PLACOPECTEN MAGELLANICUS*.

Daniel L. Jackson,* **Barry W. MacDonald**, **Shaka James**, **Benedikte Vercaemer**, and **Ellen L. Kenchington**, Fisheries and Oceans Canada, Bedford Institute of Oceanography, Halifax, Nova Scotia, Canada B2Y 4A2; **Andre Mallet**, Mallet Research Services Ltd., Dartmouth, Nova Scotia, Canada, B2X 3H3.

Bivalve aquaculture has benefited from the introduction of triploids, but successful commercial production of triploid sea scallops, *Placopecten magellanicus*, remains elusive. Experiments were conducted to determine the optimum combination of incubation temperature (8°C and 14°C) and Cytochalasin B (CB) concentration (0.25 mg/l and 0.50 mg/l) for inducing triploidy in scallops. Two replicate spawning lots of larvae were produced (Lot 1; one female parent, one male; Lot 2: two females, two males), and ploidy analyses were performed via flow cytometry on Day 4 to determine the initial levels of triploid induction. In the 8°C incubation treatments, more triploids were found amongst the larvae from Lot 1 (~24% in both CB treatments) than in Lot 2 (13% in the 0.25 mg/l CB treatment, and 16% in the 0.50 mg/l CB treatment), numbers similar to those found in the untreated controls (16% in Lot 1 and 20% in Lot 2). Among embryos incubated at 14°C, both levels of CB produced ~60% triploids in Lot 1, while in Lot 2 more triploids were produced in the 0.50 mg/l CB treatment (61%) than in the 0.25mg/l CB treatment (39%). Many triploids were found in the 14°C controls (41% in Lot 1 and 22% in Lot 2). Studies comparing feeding rates between diploid and triploid sea scallop larvae will also be discussed.

A COMPARISON OF MICROALGAL DIETS FOR ENHANCED PRODUCTION OF *PLACOPECTEN MAGELLANICUS* POSTLARVAE.

Lisa M. Milke* and **V. Monica Bricelj**, Institute for Marine Biosciences, National Research Council, Halifax, NS B3H 3Z1; **Christopher C. Parrish**, Ocean Sciences Centre, Memorial University of Newfoundland, St. John's, NF A1C 5S7, Canada.

Little is known concerning stage-specific diets that optimize hatchery production of the sea scallop, *Placopecten magellanicus*, especially during vulnerable, post-settlement stages. Poor growth and survival of these developmental stages may be related to nutritional deficiencies. Therefore, our primary objectives were to identify high-performance algal diets, involving a minimum number of species, for cost-effective implementation in commercial hatcheries, and to determine algal properties (e.g., size, biochemical composition) which may contribute to differences in scallop growth. We also compared the lipid composition (including essential fatty acids) of postlarvae and their diets. To this end, *P. magellanicus* postlarvae (initial mean shell height = 388 μm) were exposed for 28 days at 14°C to five mixed microalgal diets, each consisting of one diatom and one flagellate, (at a constant, volume-equivalent concentration of 40 T-Iso cells μl^{-1}) in 400 L mesocosms. Diets consisted of one of three diatom species (*Thalassiosira weissflogii*, *Chaetoceros muelleri*, or *Fragilaria familica*), and one of three flagellates [*Pavlova lutheri*, *Pavlova* sp. (CCMP 459), or *Tetraselmis striata* (PLAT-P)]. Shell growth trajectories, determined by video imaging, showed that *F. familica*, a previously untested isolate from Mahone Bay, Nova Scotia, was the diatom yielding the highest growth rate (22.6 μm/day). *Pavlova* sp. (CCMP 459), which is known to support excellent growth of sea scallop larvae, yielded the highest growth rate (28.1 μm/day) of the three flagellates, perhaps due to its high levels of ARA (20:4n6; arachidonic acid). Although *T. striata* is known to be an excellent diet for oyster (*Crassostrea virginica*) spat, it resulted in the lowest scallop growth rate for both shell height (5.5 μm/day) and ash-free dry weight, providing a final mean size almost half that of scallops fed the highest performing diet. Poor performance of this diet may be partly related to the very low levels of DHA (22:6n-3; docosahexaenoic acid; as a % of total fatty acids) in its two algal constituents. Sea scallop growth rates on the two highest performing diets were comparable to maximum literature values for this developmental stage using 4 to 6-species diets.

IMPACTS AND CONTROL OF THE SPIONID POLYCHAETE, *POLYDORA WEBSTERI* ON THE SEA SCALLOP, *PLACOPECTEN MAGELLANICUS* IN MIDWATER CULTURE.

Shawn M. C. Robinson,* **Jim D. Martin** and **Eddy J. Kennedy**, Dept. Fisheries and Oceans, St. Andrews Biological Station, 531 Brandy Cove Rd., St. Andrews, New Brunswick, Canada, E5B 2L9.

Biofouling on culture structures and species is a normal phenomenon to shellfish growers in all countries, however, some fouling species are more damaging than others. In 1997, we initiated an experiment to look at the full-cycle grow-out characteristics of the sea scallop at a site in Passamaquoddy Bay that was judged to be the best oceanographically for culture based on food and circulation. Animals were grown at a depth of 5m and 20m from the surface in either pearl nets or lantern nets depending on the size of the scallops at the time. Nets were changed monthly during the period of highest biofouling (late spring to mid fall) and as required outside of that window. The results of the 20m treatment revealed that the shells were severely perforated by the polychaete *Polydora websteri* causing death. We postulated that the growing of the scallops in midwater effectively isolates them from their normal ecosystem with regular interspecific interactions (such as grazers) and allows commensal/parasitic organisms to grow out of control. Therefore, in the summer of 2001, we initiated a second phase to the project where we introduced juvenile green sea urchins grazers (*Strongylocentrotus droebachiensis*) to some experimental cages. Initial results indicated that the sea urchins were effective in reducing the density of *Polydora* on the scallop shells. Further results will be discussed during the talk as the study is still in progress.

DEVELOPMENT OF A STOCK ASSESSMENT PROGRAM FOR WEATHERVANE SCALLOPS IN ALASKA.

Gregg E. Rosenkranz* and **Douglas Pengilly**, Alaska Department of Fish and Game, 211 Mission Road, Kodiak, AK 99615.

Guideline harvest levels for Alaska's weathervane scallop (*Patinopecten caurinus*) fishery are currently based on historic average catches. Although vessels participating in the fishery are subject to a mandatory observer program that monitors catch and effort, research indicates that these statistics cannot reliably index changes in scallop abundance. In 2000, the Alaska Department of Fish and Game began work aimed at development of fishery-independent stock assessment methods that could ultimately be used to manage the fishery based on estimates of exploitable abundance. To date, we have made four research cruises that surveyed known scallop beds with a video drop camera, a towed video sled, and a New Bedford offshore survey dredge. Results indicate that the drop camera does not survey enough area to provide good density estimates. The video sled appears to be a more promising tool, but reviewing tapes to obtain scallop counts is time consuming. We are now experimenting with using the video sled to estimate dredge efficiency. A combination of video and dredge survey methods may ultimately prove to be the best choice for assessing weathervane scallop populations in Alaska.

BIOCHEMICAL INDICATOR OF GIANT SCALLOP *PLACOPECTEN MAGELLANICUS* QUALITY: LARVAL GROWTH, COMPETENCY AND SETTLEMENT.

Fabrice Pernet,* GIROQ, Université Laval, Cité universitaire, Québec, Canada, G1K 7P4; **Réjean Tremblay,** Centre Aquicole Marin, 6 rue du Parc C.P. 340, Grande-Rivière, Québec, Canada, G0C 1V0; **Edwin Bourget,** Rectorat à la recherche, Université de Sherbrooke, Québec, Canada, J1R 2R1.

The purpose of this study was to monitor the lipid class content of larvae over the entire cycle, to verify the potential effect of varying feeding regimes on larval lipid content, quality, growth and survival, to evaluate the potential use of lipid class ratios to forecast larval growth and survival, and finally, to examine the effect of larval quality on settlement behavior and success. When larvae were able to feed from exogenous sources at day 4, three diet treatments were applied. Larvae were periodically sampled for lipid class analysis, growth measurement and survival assessment. Behavior of pediveliger larvae for each diet treatment were recorded with a videotape and endoscope set-up during settlement period. During the course of experiment, lipid class composition of the three diets were different in terms of triacylglycerol (TAG) rich in saturated and monounsaturated fatty acids. Our study show that TAG level in larval food was positively correlated with growth rate, TAG content and as a consequence, larval quality—as expressed with TAG-sterol (ST) or TAG-phospholipid (PL) ratios—prior to settlement. A positive relation between number of competent larvae produced and larval quality at day 8 has been found, suggesting that survival at competency was partly explained by the recovery efficiency of energetic reserves after embryogenesis. Larval quality was correlated with settlement success in the way that higher quality larvae has lead to poor settlement but explore the same time whatever the age, whereas low quality larvae decrease exploration time with age. As a consequence, the low settlement success observed in our experiment with high physiological condition larvae might be the effect of metamorphosis delay in response to poor environmental conditions.

EXAMINATION OF SEA SCALLOP, *PLACOPECTEN MAGELLANICUS*, AGGREGATIONS USING A VIDEO SURVEY IN CLOSED AREAS OF GEORGES BANK.

Kevin D. E. Stokesbury* and **Brad Harris,** School for Marine Science and Technology, University of Massachusetts Dartmouth, 706 South Rodney French Boulevard, New Bedford, MA 02744-1221.

Georges Bank is the world's largest natural scallop resource. During the summer months of 1999/2000/2001 SMAST in association with the scallop industry developed and conducted 23 video surveys on Georges Bank. These surveys produced a series of maps of the sea floor of Georges Banks containing high aggregations of sea scallops. The video survey detailed the distribution of substrate, depth, number of live and dead scallops, and macroinvertebrates (sponges, starfish, filamentous fauna). The video technique allows a previously unattained precise, accurate measure of these variables and allows correlation analyses between them. Further, the closed areas of Georges Bank have scallop densities higher than any previously observed. For example, the three areas surveyed in 1999 (1940 km^2) contained approximately 652 million scallops representing approximately 17 million kilograms (32 million lbs worth approximately $161 million) of harvestable scallop meats. This research addresses scallop stock assessment and the critical regional and national issue of the effects of mobile fishing gear on the marine benthic community. It has direct implications for rotational fisheries management, on an appropriate spatial scale (km), under consideration by the New England Fishery Management Council.

PARASITE AND HOST DEFENSES

THE EFFECT OF PH ON THE KILLING ACTIVITY OF HEMOCYTES IN THE PACIFIC OYSTER, *CRASSOSTREA GIGAS.*

Steven M. Allen* and **Louis Burnett,** Grice Marine Laboratory, University of Charleston South Carolina, 205 Fort Johnson Rd., Charleston, SC 29412.

In recent years there has been an increase in the occurrence of summer mortalities of the commercially important Pacific oyster, *Crassostrea gigas.* These mortalities occur during the late summer when water and air temperatures are at their highest. *C. gigas* are grown intertidally and are, therefore, air exposed for hours at a time. An oyster closed during air exposure depletes the oxygen stores within the shell and builds up CO_2 acidifying the tissues. The average pH of hemolymph from an oyster which is submerged in well aerated water (18°C) and ventilating is 7.52 (0.04 SEM; N = 35). The average pH of of hemolymph from an oyster which is aerially exposed for 4h in 30°C air is 6.83 (0.02 SEM; N = 26). We hypothesize that stresses associated with air exposure inhibit the immune system of the oyster and contribute to the summer mortalities. The focus of the present study was to determine if the innate immunity provided by hemocytes was decreased by low pH. The ability of hemocytes to kill the bacterium *Vibrio parahaemolyticus* was assessed using an *in vitro* killing assay. Hemocytes were treated with low pH and challenged *in vitro* with *V. parahaemolyticus.* A tetrazolium dye reduction assay was used to quantify the number of viable bacteria, from which a killing index was calculated. No significant difference was found between the two treatments pH 7.6 and pH 6.6 ($p < 0.01$; N = 14). ODRP Grant No. NA96RG0488.

MUCOID SECRETIONS PROTECT QPX FROM ANTIMICROBIAL AGENTS.

Robert S. Anderson* and **Brenda S. Kraus,** Chesapeake Biological Laboratory, University of Maryland Center for Environmental Science, P. O. Box 38, Solomons, MD 20688; **Sharon McGladdery,** Oceans and Aquaculture Science, 200 Kent Street, Ottawa, Ontario K1A OE6; **Roxanna Smolowitz,** Marine Biological Laboratory, 7 MBL Street, Woods Hole, MA 02543.

Quahog parasite unknown (QPX) has recently caused significant mortality in aquacultured *Mercenaria mercenaria* in Massachusetts. It secretes a viscous, mucoid substance which may protect the parasite from host defense mechanisms; it has been reported that clams injected with QPX washed free of the mucus coat did not develop infections or disease. In this study the antimicrobial activity of *M. mercenaria* serum was measured against QPX with, or washed free of, its secreted coat. Massachusetts QPX cultures were grown for 7 days in the presence or absence of clam serum in the medium; the parasites were still in log stage growth. When coat-free QPX were added to serum-containing medium, dose-dependent growth inhibition was seen in cultures with 10–50 µg/ml serum protein; lower concentrations were often slightly stimulatory, higher concentrations produced ~100% inhibition. Growth of cultured QPX, when fully enveloped by mucus, was not inhibited by clam serum proteins at all concentrations tested (<60 µg/ml). If aliquots of coat-free QPX were incubated for various time intervals (during which time they produced mucoid envelopes) prior to the addition of clam serum to the cultures, there was a time-dependent reduction of serum-mediated growth inhibition.

MEASUREMENT OF *VIBRIO TAPETIS* CYTOTOXIC ACTIVITY ON *RUDITAPES PHILIPPINARUM* HEMOCYTES BY FLOW CYTOMETRY.

Gwénaëlle Choquet,* Philippe Soudant, Christophe Lambert, and **Christine Paillard,** IUEM-UBO, LEMAR, Technopôle Brest-Iroise, 29280 Plouzané, France; **Jean-Louis Nicolas,** LPI, IFREMER, Plouzané, France.

Vibrio tapetis is the causative agent of Brown Ring Disease which affects the clam, *Ruditapes philippinarum*. After incubation with *V. tapetis*, hemocytes loose filopods and become rounded, indicating production of a virulence factor by the bacteria. To rapidly quantify this factor, a flow-cytometric test has been developed. This test is based on the capacity of *V. tapetis* to inhibit adhesion of clam hemocytes to plastic. Several bacteria/hemocyte ratios, other *Vibrio* spp. pathogenic to bivalves and various *V. tapetis* isolates have been tested. Inhibition of adherence is detectable with as few as five bacteria per hemocyte. The greater cytotoxic activity of *V. tapetis* compared to *V. splendidus, Vibrio* sp. (*strain S322*), and *V. pectenicida* suggests a specific pathogenicity of *V. tapetis* to *R. philippinarum* hemocytes. Though all *V. tapetis* isolates possess the capacity to inhibit adhesion, significant variations of cytotoxicity among isolates has been demonstrated. These results are in agreement with *in vivo* pathogenicity tests. The identification and characterisation of the genes involved in *V. tapetis* cytotoxicity is in progress.

CHEMOTAXIS OF HEMOCYTES OF THE HARD CLAM, *MERCENARIA MERCENARIA*, TO QUAHOG PARASITE UNKNOWN (QPX) AND OTHER MICROORGANISMS.

Christie-Sue Decker* and **Robert S. Anderson,** University of Maryland Center for Environmental Sciences, Chesapeake Biological Laboratory, PO Box 38, Solomons, MD 20688.

Quahog Parasite unknown (QPX) is a protist pathogen in the phylum Labyrinthulomycota affecting the hard clam, *Mercenaria mercenaria*. It causes a disease that has impacted hatchery and broodstock clam populations in Canada and the United States. Chemotaxis is the directed migration of cells in a chemical gradient, and is a well-documented immune response of hemocytes. It is postulated that there is a correlation between pathogenicity and chemoattraction; invading organisms able to escape detection by hemocytes would be better able to colonize their host. *M. mercenaria* hemocytes are known to exhibit chemotaxis in response to live *Escherichia coli* bacteria and to cell-free *E. coli* culture fluid. This study is the first investigation into host chemotactic response to QPX or other Labyrinthulomycota species. The chemotactic effects of several pathogenic and non-pathogenic organisms were compared. There was no chemotaxis by clam hemocytes toward QPX cells devoid of their mucofilamentous secretions, but positive chemotaxis for spent QPX media. There was positive chemotaxis for *Bacillus megaterium*, a non-pathogenic bacterium. Other organisms investigated included a non-pathogenic Labyrinthulomycota, a non-pathogenic Protist, and a pathogenic bacterium. Comparisons yielded a profile of *M. mercenaria* chemotactic response for a broad range of parasitic challenges.

EFFECT OF DIETARY FATTY ACID COMPOSITION ON LIPID PROFILES OF HAEMOCYTE MEMBRANES IN OYSTERS AND CLAMS AND ITS IMPACT ON IMMUNE FUNCTIONS.

Maryse Delaporte,* Jeanne Moal, and **Jean-françois Samain,** LPI, Ifremer de Brest, 29280 Plouzané, France; **Philippe Soudant, Gwénaëlle Choquet, Christophe Lambert,** and **Christine Paillard,** LEMAR, IUEM, 29280 Plouzané, France.

This study was designed to assess the influence of micro-algal diets on the fatty acid profile of haemocyte membranes and on immune functions. The oyster *Crassostrea gigas* and the clam *Tapes philippinarum* were fed three diets with varying PUFA composition.

The fatty acid composition of haemocyte and gill membranes of both bivalves was greatly influenced by the diet. Nevertheless, a selective retention of certain specific PUFA was observed in the analysed tissues: 22:6(n-3) for clam and 20:5(n-3) for oyster. Immune parameters were also affected. Indeed, a 20:5(n-3) and 20:

4(n-6) enrichment appeared to increase the phagocytic rate and the metabolic activity of clam haemocytes. A smaller positive effect of 20:5(n-3) on metabolic activity of oyster haemocytes was observed. Interestingly, when oyster haemocytes were incubated one hour at 18°C or 30°C, a positive correlation between the 22:6(n-3) content of haemocytes and the phagocytic rate was noticed.

ACTIVATION OF OYSTER DEFENSES BY ENVIRONMENTAL CONTAMINANTS. William S. Fisher* and **Leah M. Oliver,** U. S. Environmental Protection Agency, National Health and Environmental Effects Research Laboratory, Gulf Ecology Division, Gulf Breeze, FL 32561.

Four field studies performed on eastern oysters *Crassostrea virginica* support a hypothesis that Cu, Zn, and perhaps butyltins and polycyclic aromatic hydrocarbons (PAH) can stimulate hemopoiesis, hemocyte locomotion and hemocyte bactericidal capacity. The first study found circulating hemocyte numbers and locomotion were positively associated with contaminated sites in Tampa Bay, particularly those where pooled oyster tissues contained high concentrations of trace metal and PAH analytes. Subsequently, the relationships between these particular contaminants and hemocyte activities were extended to four additional bays (St. Andrew, Choctawhatchee, Pensacola, and Biscayne). A third study, which analyzed chemicals from individual oysters in Pensacola Bay, verified that circulating hemocyte numbers and bactericidal activity were positively correlated with Cu, Sn, Zn, butyltin, total metals, total polychlorinated biphenyls and total PAH. A fourth study showed that circulating hemocyte number and bactericidal activity were significantly elevated when oysters were moved from a relatively clean site to one with high concentrations of Cu, Zn, butyltins and PAH. These data provide a weight of evidence that certain chemical contaminants can stimulate defense-related hemocyte activity in oysters. Although chemical contaminants are generally suspected to suppress defense functions of oysters, these chemicals, for unknown reasons, appear to have the opposite effect.

IMPROVEMENT BY PROBIOTICS OF *PECTEN MAXIMUS* LARVAE DEFENSE CAPACITY, MEASURED BY CHEMILUMINESCENCE. Christophe Lambert* and **Christine Paillard,** LEMAR, IUEM-UBO, Place Copernic, Plouzané, France; **Jean-Louis Nicolas,** LPI, IFREMER, Plouzané, France.

Literature concerning evaluation of defense system capacity of bivalve larvae are scarce. It's why this work intended to adapt to oyster and scallop larvae a chemiluminescence (CL) test to measure oxygen intermediate synthesis (mainly H_2O_2) during phagocytosis of zymosan particles and inhibiting effect of *Vibrio pectenicida,* pathogenic for scallop larvae on this activity. As a result, activation of whole alive *Crassostrea gigas* and *Pecten maximus* larvae by zymosan particles have been shown to increase respectively 9.9 and 2.4 times the chemiluminescence activity. The peak level was obtained about one hour after activation. This CL test was used to compare CL activity of scallop larvae reared with antibiotic (Chloramphenicol 4 ppm), probiotic bacteria (available in our laboratory) or without treatment. The defense capacity of larvae reared with probiotic was higher than those with antibiotic or without treatment. Moreover, probiotic reared larvae were shown to be less sensitive to *in vitro* CL inhibition of *V. pectenicida.* This led to the conclusion that probiotics not only compete with bacterial flora but were also able to improve scallop larvae defense system (oxidative burst).

DEVELOPMENT OF A FLOW CYTOMETRIC MEASUREMENT OF OXIDATIVE METABOLISM PRODUCT FORMATION BY *CRASSOSTREA GIGAS* HEMOCYTES AND APPLICATION TO EVALUATE PATHOGENIC *VIBRIO* INHIBITING CAPACITY. Christophe Lambert,* Philippe Soudant, Gwénaëlle Choquet, and **Christine Paillard,** LEMAR, Laboratoire des Sciences de l'Environnement Marin, UMR6539, IUEM-UBO, place Nicolas Copernic, Plouzané, France.

A flow cytometric method to measure the production of oxidative metabolism products was adapted to *Crassostrea gigas* hemocytes. Measurement was based on the oxidation by hydrogen peroxide (H_2O_2) of intracellular 2′,7′-dichlorofluorescin (DCFH) in green fluorescent dichlorofluorescein (DCF). Activation by zymosan particles of the respiratory burst metabolic chain was shown to stimulate the DCFH oxidation in *C. gigas* hemocytes and a rate of 20 zymosan particles per hemocytes was found to be optimal. At the opposite, DCFH oxidation using phorbol myristate acetate (PMA) was not obtained. Anti-aggregant solution, used to avoid hemocytes clamping after bleeding, was shown to inhibit the respiratory burst measured by DCFH oxidation. Finally, the flow cytometric method developed during this work was used to evaluate and grade the DCFH oxidation inhibiting capacity of four *Vibrio* species, known or suspected to be pathogenic for bivalves.

PURIFICATION OF A NOVEL ANTIMICROBIAL PEPTIDE FROM THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA*). Ann C. Mountz* and **Robert S. Anderson,** University of Maryland Center for Environmental Science, Solomons, MD 20688.

Oysters are routinely exposed to a variety of microbes; few of these microbes are pathogenic, however oyster diseases, such as Dermo and MSX, have lead to drastic reductions in oyster populations along the Atlantic coast of the United States. Understanding the oyster's immune system is an important element in determining how the remaining populations can best be protected or increased. Many aspects of the eastern oyster immune system have been characterized, including reactive oxygen species, phagocytosis, and lytic enzymes. Antimicrobial peptides are a more recently recognized component of the bivalve defensive capabilities, which have not yet been identified in the eastern oyster. A new antimicrobial peptide was purified from oyster serum via methanol precipitation, size-exclusion centrifugation, Sep-Pak filtration, and reverse-phase HPLC. Activity against the model Gram-positive bacterium was measured at all steps using a tetrazolium dye reduction assay. The purified peptide is 4.3 kDa based on mass spectrometry analysis and has preliminarily been named CVAP-1.

TEMPERATURE EFFECT ON IMMUNOCOMPETENCE OF CLAM *R. PHILIPPINARUM* AND ON *V. TAPETIS* CYTOTOXICITY. Christine Paillard,* Gwénaëlle Choquet, Christophe Lambert, and **Philippe Soudant,** IUEM-UBO, LEMAR Laboratoire de l'environnement marin, Technopôle Brest-Iroise, 29280 Plouzané, France; **Helen Reid** and **Harry Birbeck,** University of Glasgow, Division of Infection and Immunity, GLASGOW G12 8QQ, Scotland.

Adult clams, *R. philippinarum*, were conditioned for one month in the laboratory at three temperatures 7, 13 and 21°C, and then inoculated with *V. tapetis*. One month after *V. tapetis* challenge, clam phagocytic activity and *V. tapetis* cytotoxicity were measured. An increase of phagocytic activity was demonstrated in control clams maintained at the highest temperature. At 13°C, higher phagocytic activity was measured in *V. tapetis* inoculated clams compared to controls. Also, highest Brown Ring Disease prevalence and intensity was obtained at 13°C. Cytotoxic assays based on hemocyte-bacteria interactions were performed with bacteria grown at these three different temperatures. Generally, higher cytotoxicity was found when *V. tapetis* was grown at 13°C, which corresponds to the lower end of its optimal growth range. Further, cell rounding percentage depends on whether the clams were experimentally challenged with the bacterium and temperatures at which clam are maintained.

REPEATED HEMOLYMPH SAMPLING OF INDIVIDUAL CLAMS: WHAT DOES IT TELL US ABOUT SAMPLING PROCEDURES? Christine Paillard,* LEMAR, UMR 6539, IUEM-UBO, Plouzané, France, **Susan E. Ford,** Haskin Shellfish Research Laboratory, Rutgers University, Port Norris, NJ.

Hemocyte concentrations, protein levels, and enzyme activities are often used as measurements of the health status of marine bivalves and are frequently considered an index to assess their susceptibility to infectious agents. Yet these parameters are known to vary considerably on a seasonal, regional, and individual basis, and are likely to be affected by laboratory procedures. Sources of variation such as these add uncertainty to the interpretation of hemolymph assays. We repeatedly sampled the hemolymph of clams, *Ruditapes philippinarum*, in both laboratory and field conditions, to determine 1) how consistent measurements were over time for the same individual, 2) whether time of sampling affected results, and 3) how much repeated sampling itself altered the measurements. Most parameters were relatively consistent over time (individuals had consistently high or low values), but more so in the field than in the laboratory. There were significant day-to-day variations when sampling occurred over a several-day period, but, sampling time explained very little of the overall variation. Repeated sampling increased mortality and altered hemolymph constituents in the laboratory, but not the field, study.

THE ANTIOXIDANT SYSTEM OF THE PROTISTAN PARASITE *PERKINSUS MARINUS*. Eric J. Schott,* José A. F. Robledo, Wolf T. Pecher, Florence A. Okafor, and **Gerardo R. Vasta,** COMB, UMBI, University of Maryland, Baltimore, MD 21202.

Spread of the protistan parasite *Perkinsus marinus* within the oyster *Crassostrea virginica* is believed to be via engulfment and migration by phagocytic hemocytes. Because phagocytosis of killed *P. marinus* trophozoites elicits production of reactive oxygen intermediates (ROIs) by oyster hemocytes, but phagocytosis of live trophozoites does not, *P. marinus* appears to have mechanisms to prevent the accumulation or production of ROIs. We previously described two Fe-type SOD genes (*PmSOD1, PmSOD2*) from *P. marinus* and demonstrated the ability of their products to convert $O_2^- \cdot$ to H_2O_2. *P. marinus* is resistant to moderate levels of H_2O_2, suggesting that it also possesses a mechanism for H_2O_2 removal. However, significant efforts to detect *P. marinus* catalase activity and gene sequences have been unsuccessful. Instead, we have found that *P. marinus* trophozoites possess abundant ascorbate dependent peroxidase (APX) activity. We have partially purified *P. marinus* APX, which co-migrates with a 35 kD band on non-denaturing gels. Continuing genetic, biochemical, and cellular studies of *P. marinus* FeSODs and APX will contribute to further characterize the *P. marinus* antioxidant defense system. [Supported by Grant No NA06RG0101-5 from ODRP, NOAA, through the Maryland Sea Grant, to GRV].

SEASONAL AND CULTURE SITE EFFECTS ON THE PHYSIOLOGICAL, IMMUNOLOGICAL AND BROWN RING DISEASE STATUS OF THE MANILA CLAM *RUDITAPES PHILIPPINARUM*. Philippe Soudant,* Gwénaëlle Choquet, Christophe Lambert, Alain Marhic, and **Christine Paillard** LEMAR UMR 6539, IUEM-UBO, Place Nicolas Copernic, Plouzané, France.

To assess the effects of environmental conditions on Brown Ring Disease (BRD) expression, physiological and immunological status, juveniles of clams were distributed in four rearing sites selected for their varied ecological characteristics. Clams were sampled for analysis every three months for eighteen months in each sites. Significant site and seasonal effects have been established for the condition index, the growth rate, the haemocyte concentration and cytomorphology, and the enzymatic activities and protein content of the total hemolymph. Some significant relationships between immunological and physiological parameters were observed. The haemocyte concentration was correlated with size and mortality rate of haemocytes while their complexity was correlated with phenoloxidase activity. Also, correlation was shown between the haemocyte concentration and the size of clams while haemocyte size and hemolymph protein content were correlated to condition index. Surprisingly, the seeded clams showed very low BRD prevalence in all sites and for all seasons. Meantime, high prevalence was observed in natural stock from one of the site. This suggests hatchery seeded clams may be BRD resistant and claimed further studies.

RELATIONSHIPS BETWEEN SUMMER MORTALITIES AND DEFENCE MECHANISMS IN FAMILIES OF *CRASSOSTREA GIGAS* REARED IN DIFFERENT ENVIRONMENTAL CONDITIONS. P. Soudant,* C. Lambert, G. Choquet, S. Ford, and **C. Paillard,** LEMAR, IUEM-UBO, Place Nicolas Copernic, Plouzané, France; **L. Degremont, M. Delaporte, J. Moal, P. Boudry, P. Soletchnick, J.-P. Joly, M. Ropert, E. Bédier, A. Huvet,** and **J.-F. Samain,** LGP, LPI, LCs of IFREMER, France.

High individual variability is often encountered when measuring defence mechanisms in bivalves. Such variation is suspected to result from both environmental and genetic factors. Determine whether defence mechanisms of *C. gigas* are genetically based was thus part of a national program conducted by IFREMER and dedicated to understand the causes of summer mortalities in *C. gigas* juveniles. Fifteen bi-parental families, obtained from a nested half-sib crossing design, were reared four months in three sites. Six families were selected on their survival performance (three "good" and three "bad" ones) to compare their immunological status. As expected, most of immunological parameters tested were significantly different according to the culture site. More interesting is the significant differences measured between good and bad families. For instance, higher total haemocyte counts and lower oxidative metabolism were observed in good families. Moreover, incubation with pathogenic *Vibrio* sp. S322 inhibited significantly more the adhesion capabilities and oxidative metabolism of haemocytes from bad families.

PURIFICATION AND CHARACTERIZATION OF LYSOZYME FROM PLASMA OF EASTERN OYSTERS (*CRASSOSTREA VIRGINICA*). Qing-Gang Xue* and **Jerome F. La Peyre,** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803; **Aswani K. Volety,** Division of Ecological Studies, Florida Gulf Coast University, Fort Myers, FL 33965; **Fu-Lin E. Chu,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Lysozymes are antimicrobial proteins which are defined as 1,4-β-N-acetylmuramidases cleaving a glycosidic bound between N-acetylmuramic acid and N-acetylglucosamine of peptidoglycan. Lysozyme activity has been detected in the body fluids and tissues of many bivalve molluscs but lysozymes from only a few bivalve species have been purified. The molecular weights of the purified lysozymes range from 11 to 18 kDa. The analysis of N-terminal amino acid sequences, when determined, indicated that they all belong to a distinct type of lysozyme, the i-type. Lysozyme from plasma of eastern oysters was recently purified by a combination of ion-exchange chromatography on CM-Sepharose Fast Flow and gel filtration chromatography on a Superdex G-75 column. The final preparation showed a single band on SDS-PAGE gel with a molecular weight of 18.4 kDa. About 1.5 mg of lysozyme was purified from one liter of oyster plasma and the lysozyme specific activity increased 150 fold. The enzymatic properties, stability and antimicrobial activity of the purified plasma lysozyme are currently being determined.

SEA URCHIN BIOLOGY, PATHOLOGY AND CULTURE

SEA URCHIN MORTALITY IN MAINE, INITIAL CASE REPORT AND OVERVIEW. Ralph Elston, AquaTechnics/Pacific Shellfish Institute, PO Box 687, Carlsborg, WA 98324.

Compared to some other species of marine invertebrates, health parameters and disease conditions of sea urchins are less well studied. The purpose of this case report is to present initial observations that may suggest causes or significant factors related to sea urchin mortalities occurring in Maine in 1999 and 2000. These observations may be useful in indicating what further investigations are needed to make a more definitive diagnosis regarding cause of the losses.

Sea urchin (*Strongylcentrotus droebachiensis*) mortalities were observed in two areas of Frenchman's Cove, Maine in late October 2000. Previously, urchin mortalities were reported in August 1999 by divers and during an urchin transfer in August 2000. The samples from 1999 were examined bacteriologically and histologically by Dr. Paul Waterstraat of the Maine Department of Natural Resources. The presence of a purple exudate from the teste was reported. The urchins were also examined for the presence of a paramoeba, previously associated with urchin mortalities in Nova Scotia, and none of these parasites were found.

Two groups of urchins were received live and chilled on November 29, 2000. One group consisted of four urchins collected from Winter Harbor and the other group consisted of two urchins collected from Schoodic Point. All urchins were examined on receipt, and processed for necropsy and histological examination. The teste diameter/height ranged from 53/34 mm to 58/35 mm. Clinically, three of six urchins appeared healthy and exhibited mobility of the spines. Two urchins showed loss of spines, one from all except the oral surface and the second unilaterally in a band from the oral to aboral surface. Three were confirmed males and three were females.

Of six animals examined histologically, no lesions were found in two of the healthy appearing individuals. In both urchins with loss of spines, there were multifocal areas of eosinophilic intranuclear inclusion bodies in epithelium of the spines and their musculature and associated necrosis of epithelium and myocytes. These inclusion bodies were relatively common in one individual but rare in another. This finding corresponds to the loss of urchin spines noted by divers and other on site investigators. Such inclusion bodies may represent a viral infection but there are other non-infectious causes of inclusion bodies. Verification of a viral infection would require examination by transmission electron microscopy.

IMPORTANCE OF DIETARY MINERALS AND PIGMENTS FOR INCREASING SOMATIC GROWTH OF JUVENILE GREEN SEA URCHINS (*STRONGYLOCENTROTUS DROEBACHIENSIS*).

Eddy J. Kennedy,* **Shawn M. C. Robinson,** and **John Castell,** Department of Fisheries and Oceans, Biological Station, 531 Brandy Cove Rd., St. Andrews, NB, Canada, E5B 2L9; **G. Jay Parsons,** Dept. of Fisheries and Oceans, 200 Kent Street, Ottawa, ON K1A 0E6.

Understanding the nutritional requirements of juvenile sea urchins is necessary for diet formulation and optimizing somatic growth. From Feb 2000 to July 2000, different mineral sources and concentrations (modified Bernhart-Tomerelli salt mix at 0%, 1.5%, 3%, 6%, and 15% and Shur-Gain at 3% and 6%) were incorporated in pigmented (beta-carotene) diets to determine the effect on juvenile sea urchin (14 mm to 15 mm initial test diameter) somatic growth. Non-pigmented diets were also used with 3% of each mineral source incorporated in the diet. After the 154-day experiment, the juveniles fed the non-pigmented diets were smaller (20 mm average TD) than those fed the 3% mineral pigmented diets (23 mm average TD) ($P<0.001$). The juveniles fed the 15% mineral diet were larger (24.3 mm average TD) than those fed the 0% and 1.5% mineral diets (22 mm average TD) ($P<0.001$). As well, the juveniles fed the pigmented diet with 3% Shur-Gain mineral (which lacked magnesium) were smaller (21 mm average TD) than those fed the diet with 3% Bernhart-Tomerelli mineral (which included magnesium) (23.5 mm average TD) ($P<0.001$). From Nov 2000 to April 2001, a pigmented (beta-carotene) prepared diet with 15% Bernhart-Tomerelli salt mix was compared to kelp (the natural sea urchin diet) to determine differences in juvenile somatic growth production between diets. After the 159-day experiment, the juveniles (1 mm to 2 mm initial average test diameter) fed the prepared diet were larger (7.4 mm average TD) than the kelp-fed juveniles (4.4 mm average TD) ($P<0.001$). Prepared diets require pigments and high mineral content to optimize juvenile sea urchin somatic growth.

SEA URCHIN DISEASE CONCERNS IN ATLANTIC CANADA.

Gregory MacCallum,* Atlantic Veterinary College, University of Prince Edward Island, 550 University Ave., Charlottetown, PE, C0A 1YO; **Shawn Robinson,** Biological Station, Department of Fisheries and Oceans, 531 Brandy Cove Rd., St. Andrews, NB, E5B 2L9; **Sharon McGladdery** and **Mary Stephenson,** Gulf Fisheries Centre, Department of Fisheries and Oceans, 343 University Ave., PO Box 5030, Moncton, NB, E1C 9B6.

The green sea urchin (*Strongylocentrotus droebachiensis*) has been fished in Atlantic Canada since the 1950's with a commercially developed fishery emerging in the 1980's in the Bay of Fundy, New Brunswick and southwestern Nova Scotia (NS). In the 1990's, Newfoundland, Quebec and to some extent Prince Edward Island, also began fishing this species. The total Atlantic Canadian sea urchin landings in 2000 were 3,050 MT (live weight) with a value of $7.08 million.

The fishery, however, has not been without disease setbacks. Between 1980 and 1983 sea urchin mortalities in NS were estimated at 245,000 tons associated with a parasitic amoeba, *Paramoeba invadens*. Since 1995, a die-off associated with paramoebisasis of 50,000 to 100,000 tons has occurred representing an estimated 10 to 100 times the weight of urchins taken by the NS fishery. Currently, the Department of Fisheries and Oceans Canada lists *P. invadens* and Bald-Sea-Urchin disease as "regional concerns" with trematode metacercariae and turbellarian parasitism listed as "negligible significance". The objective of this presentation is to give an overview and update on the current disease concerns facing the green sea urchin fishing and aquaculture industry in Atlantic Canada.

PHOTOPERIOD, URCHIN "EYES" AND GAMETOGENESIS.

Michelle Moody and **Charles W. Walker,** Department of Zoology and Marine Biomedical Research Group, University of New Hampshire, Durham, NH 03824.

Shortening daylength in the fall results in the initiation of changes in two populations of cells within the gonads of both sexes of the green sea urchin, *Strongylocentrotus droebachiensis*. These cellular populations include spermatogonia in males and oogonia in females and somatic cells called nutritive phagocytes (NP) in both sexes. During the summer, gonial cells are amitotic and NP store nutrients; during the photoperiod changes in the fall, gonial cells begin mitosis and NP mobilize nutrients. Details of these processes can be addressed on the web page http://zoology.unh.edu/faculty/walker/urchin/gametogenesis.html The detectors for these changes in day-length are unknown, but might include tube feet, spines, the dermis or the gonads themselves. We are using western blots and immunocytochemistry to detect PAX6 (the complex eye master control switch gene) and rhodopsin proteins within each of these tissues.

It is also unknown whether the response to photoperiod occurs at the level of the NP, which then mobilize nutrients and thus cause gonial cells to divide, or whether both populations of cells are independently effectors for the photoperiod cue. In order to distinguish between these two possibilities, we are examining the expression of the *c-myc* protooncogene and of the SEAW1 stem cell controlling gene in both males and females during the months when the photoperiod que occurs (August—October).

Practical applications of this research for aquaculture might result from preventing the photoperiod and thus suppressing gametogenesis in the green sea urchin. Gonads in such sea urchins should contain principally or exclusively nutritive phagocytes and should be of superior size, taste, texture and firmness. Ovaries and testes containing fewer gametes relative to NP are actually preferred in most cultures that each sea urchin gonads and such conditions exist naturally in sea urchins during the summer.

Supported by USDA Competitive Grants Program, Hatch and Sea Grant to CWW.

ABIOTIC AND BIOTIC THREATS TO SEA URCHIN HEALTH: WHAT PRICE CULTURE?

Esther C. Peters,* Tetra Tech, Inc., 10306 Eaton Place, Suite 340, Fairfax, VA 22030.

Understanding how environmental factors affect urchin health will be important to ensure a consistent supply of urchins for human food resources; however, unlike other fisheries, our knowledge of their susceptibility to toxicants and pathogens has been limited and based on sporadic efforts. Sea urchin gamete fertilization and embryo survival have been developed into a standardized test to evaluate the toxicity of coastal sediments and used in research on mechanisms of toxicity suggesting that toxicants entering nearshore waters or culture facilities might have adverse effects. Mass mortalities of adult urchin populations have occurred because of bacterial, protozoal, or unknown pathogens, which might be influenced by temperature, water movement, and population densities, but the role of toxicants is unknown. No cases of neoplasia in urchins have been submitted to the Registry of Tumors in Lower Animals. Multidisciplinary approaches must be consistently applied in monitoring urchin health, with more research on the immune system and impacts of environmental factors. Funds to support these studies must be factored into the fishery equation.

GROWTH RESPONSE AND ACCLIMATION OF GREEN SEA URCHINS TO FLUCTUATING SALINITY.

Michael P. Russell,* Biology Department, Villanova University, Villanova, PA 19085-1699.

Echinoderms are osmoconformers—external salinity determines internal osmotic concentrations. Green sea urchins are exceptional among echinoderms because they occur in brackish-water environments. These habitats are among the most productive fishing grounds and populations in these areas often have some of the largest individuals. The states of Maine and New Hampshire have granted sea urchin lease sites in these habitats and leaseholders plan to seed these areas with hatchery-reared juveniles. However, previous workers have documented that larger sea urchins can tolerate bouts of low salinity of both greater intensity and duration than smaller individuals. I tested the growth response of juvenile sea urchins to periodic bouts of sub-lethal hyposaline conditions. I collected samples from an area not exposed to low salinity and divided them into two groups: treatment (bouts of hyposaline conditions) and control. After an initial acclimation period, the treatment group displayed the same growth rate as the control group despite repeated exposures to hyposaline conditions. The acclimation period was equivalent to 10 days of growth. These experiments demonstrate the importance and the feasibility of acclimating juveniles to hyposaline conditions before releasing them into lease sites.

URCHIN HEALTH ISSUES IN MAINE.

Paul Waterstrat and **Ted Creaser,** Maine Department of Marine Resources, Boothbay Harbor Laboratory, PO Box 8, West Boothbay Harbor, ME 04575.

Maine urchin harvesters have reported mortalities of green sea urchins, *Strongylocentrotus droebachiensis*, over the last three years. The urchin mortalities have been observed in at least 19 locations along the coast of Maine. Gross examination of urchins taken from areas of mortality revealed a progression of lesions ranging from the presence of an inflammatory exudates, loss of tube feet and spines to complete denudement of the urchin test. Examination of wet mount or squash preparations of coelomic fluid, organ samples, and culture failed to indicate the presence of *Paramoeba invadens*, the agent responsible for recurring mortalities of urchins in Nova Scotia. Elevated temperature, mortality from draggers, and crashes of significant phytoplankton blooms have each been implicated as a cause of mortality, but no consistent etiology has yet been determined for the outbreaks. Attempts at restoration by transplanting juvenile urchins or reseeding beds have likewise met with limited success. Given the multifactorial nature of aquatic disease, the occurrence of disease outbreaks in a fishery experiencing a significant declines in harvest landings, does not bode well for the sustainability of the population. Rather than attributing urchin mortalities to "natural causes", there is clear need to establish a mechanism for disease surveillance and control. Unfortunately, there appears to be a surprising lack of information about the pathobiology of sea urchins, despite the considerable use of sea urchins as a laboratory model.

LOBSTER BIOLOGY AND FISHERIES

THE EFFECTS OF HABITAT ADDITION AND STOCK ENHANCEMENT FOR AMERICAN LOBSTERS, *HOMARUS AMERICANUS* ON ARTIFICIAL REEFS IN RHODE ISLAND.

Kathleen M. Castro* and **J. Stanley Cobb,** University of Rhode Island, Kingston, RI 02881; **Richard Wahle,** Bigelow Laboratory for Ocean Sciences, Boothbay Harbor, ME 04575; **John Catena,** Restoration Center, National Marine Fisheries Service, Gloucester, MA 01930-2298.

Six experimental artificial reefs were established in Narragansett Bay, RI in February 1997. These have been monitored according to a before-after-control-impact design by means of visual surveys, traps, tag-recapture, photoquadrats and airlift sampling for 6 years. Juvenile and adult lobster density at the reef site increased from near zero to >1 lobster/m^2, significantly higher than before reef placement. Settlement of young-of-the-year lobsters significantly increased. We used microwire tags to mark hatchery reared lobsters and released them as 5th-6th stage lobsters onto three of the reefs at a density of 4.5/m^2 for three years. However, subsequent density of young-of-the-year lobsters on the enhanced treatment sites was not significantly different from the non-enhanced sites. Despite intensive sampling, only three of these tagged lobsters were recovered after placement. Placement methods may contribute to survival possibilities. Field and lab observations confirm behavioral differences between 4th stage and 5th stage hatchery-reared lobsters as compared to field-caught lobsters. Predation rates in the lab were significantly higher for the 4th stage hatchery-reared lobsters raised in the URI facility compared to the RI field-caught lobsters and hatchery-reared lobsters obtained from Maine.

CHARACTERIZATION OF MICROBIAL ASSEMBLAGIES INVOLVED IN THE DEVELOPMENT OF SHELL DISEASE IN THE AMERICAN LOBSTER, *HOMARUS AMERICANUS.*

Andrei Y. Chistoserdov* and **Feliza Mirasol,** Marine Sciences Research Center, SUNY at Stony Brook, Stony Brook, NY 11720; **Roxanna Smolowitz,** Marine Biological Laboratory, Woods Hole, MA 02543.

A combination of culture-based and molecular techniques was used to study the consortia of bacteria isolated from shell lesions and hemolymph of lobsters. Diseased lobsters used in this study were collected in the Eastern Long Island Sound, NY (ELIS), Buzzards Bay and Vineyard Sound, MA. Preliminary denaturing gradient gel electrophoresis (DGGE) data indicate that up to five independent phylotypes of bacteria are present in lobster lesions. At least two of them were found in all lobsters from ELIS. This is consistent with the five to six morphotypes of bacteria which were cultured on a marine agar. All isolated bacteria were either aerobic or facultatively anaerobic. No strictly anaerobic or microaerophilic bacteria were isolated from lesions. Only two different types of fastidious chitinolytic bacteria were isolated on a medium containing chitin. One of the two is a motile bacterium forming bright yellow colonies, which was present in all analyzed lobsters (from Buzzards Bay, Vineyard Sound and ELIS). The second is a bacterium forming white colonies. It was isolated from only two Buzzards Bay lobsters. No correlation has been found between the presence or severity of shell disease and the presence of bacteria in hemolymph.

CHANGES IN LOBSTER POPULATIONS IN NARRAGANSETT BAY, RHODE ISLAND, 1959–2000.

J. S. Cobb and **M. Clancy,** Department of Biological Sciences, University of Rhode Island, Kingston, RI 02881.

The past 35 years have seen an extraordinary increase in the catch of lobster (*Homarus americanus*) along the northeast coast of North America. Rhode Island landings have tripled since the late 1960s. We explored a fishery-independent data set of lobster abundance developed from weekly research otter trawls made at two locations in Narragansett Bay, RI by the University of Rhode Island on a continuing basis since 1959. The patterns of abundance over time differed substantially at the two stations; one of the stations was highly correlated with the NMFS catch data set for the same time period. Water temperature, which has increased steadily since 1960, was significantly correlated with commercial landings and with abundance at one of the stations. Lobster abundance at both stations and the commercial landings were significantly correlated with the NAO winter index. At one of the stations the timing of greatest abundance in the trawl samples shifted to earlier in the summer. It seems likely that there have been effects of climate on lobster abundance, however the effect appears to have acted differentially at the two stations in Narragansett Bay.

THE ROLE OF *VIBRIO FLUVIALIS* AND OTHER BACTERIAL SPECIES IN LOBSTER MORTALITIES IN MAINE.

Cem Giray* and **Deborah A. Bouchard,** Micro Technologies, Inc., 41 Main Street, Richmond, ME 04357.

Weak lobsters (*Homarus americanus*) and mortalities have been reported by pounds in Maine for several years with *Vibrio fluvialis* implicated as the etiological agent responsible. Bacterial screening of moribund lobsters was performed by Micro Technologies, Inc. through a contract with the Maine Department of

Marine Resources. The majority of isolates collected were putatively identified as *Hyphomicrobium indicum* through 16S rRNA sequencing while *V. fluvialis* was not isolated from any of the lobsters. Further characterization demonstrated that *H. indicum* could grow at a temperature range from 3°C to a higher limit between 16–20°C while *V. fluvialis* grew best between 16–30°C with minimal growth at 8°C. The virulence of *H. indicum* and *V. fluvialis* was tested by injection into lobster hemolymph at various dosages. Both isolates resulted in 75–100% mortality within 24 hours when injected at 10^8 colony-forming units (CFU), but only *H. indicum* resulted in mortalities (12.5%) when injected at 10^6 CFU/lobster. *V. fischeri* was used as a negative control while *Listonella anguillarum* and *Aerococcus viridans*, both indicated as lobster pathogens, were utilized as positive controls. The identification of *H. indicum* as the primary isolate collected from moribund lobsters and the observation of lobster mortalities mainly during lowered water temperatures suggest that the isolate responsible could be *H. indicum* but not *V. fluvialis*.

SHELL DISEASE PREVALENCE AND SEVERITY IN OFFSHORE AMERICAN LOBSTER POPULATIONS. **Diane Kapareiko, Richard A. Robohm, John J. Ziskowski, George R. Sennefelder,** and **Anthony Calabrese,** National Marine Fisheries Service, Milford Laboratory, 212 Rogers Avenue, Milford, CT 06460.

During the period 1990–1992, 15,004 lobster from 146 commercial catches at nine offshore canyon sites surrounding the 106-Mile Sewage-Sludge Disposal Site were examined for signs of shell disease. Overall, 1,184 lobster (7.9%) had lesions. Females were more affected by this condition than males. Shell-lesion occurrence was independent of carapace length (CL), but strongly related to location (proximity to the 106-Mile Dumpsite as well as to the 12-Mile Dumpsite). Data collection for the shell-disease study included not only evaluation of presence or absence of disease, but also measurements of lesion size and carapace length. This was done in anticipation of developing a method that would determine the percentage of total surface area of each lobster affected by shell disease; this percentage is the basis of a Disease Severity Index (DSI). An estimate of lobster surface area could be derived mathematically from carapace length, for both male and female lobster in our database, using the formula $y = 1.1034 + 1.9677 * \log(CL)$. The percentage of surface area covered by shell lesions, multiplied by 10^3, provides a DSI that may allow better statistical correlations between mean disease severity and site of lobster collection.

Regression Tree analysis of this multi-variate database indicated that, unlike prevalence, the most important variable affecting the DSI was carapace length. Overall, DSI's for smaller lobsters ($CL < 95$), were significantly higher ($p < 0.02$) than larger lobsters, regardless of sex or location. Small females had significantly higher DSI's ($p < 0.04$) than large females. Males showed no significant differences when similarly compared. A complete nonparametric regression analysis of our DSI in relation to proximity to the 106-Mile Site, may indicate whether sewage sludge dumping had any effect on the severity of shell disease lesions in offshore American lobster populations.

DEPTH-RELATED PREDATION PRESSURE ON LARVAL LOBSTERS (*HOMARUS AMERICANUS*) PRIOR TO SETTLEMENT. **Wendy Norden** and **J. Stanley Cobb,** University of Rhode Island, Kingston, RI 02880.

Prior to settlement, lobster postlarvae swim near the surface of the water for several days. Settlement behavior begins between two and six days after metamorphosis from the third larval stage. During settlement, postlarvae dive from the surface to the benthos to seek out suitable habitat. This potentially exposes the postlarvae to a variety of predators not present at the surface. Understanding where in the water column predation pressure is the greatest will help in understanding behavioral strategies used by lobster postlarvae when seeking appropriate habitat. We tethered postlarvae at various depths to experimentally test the potential predation pressure throughout the water column. Tether lines were deployed over mud and cobble substrate types to look at the difference in predation pressure as it relates to habitat with four depths (0.5m, 1.5m, 2.5m, 4m) above substrate. Higher predation occurred over cobble substrate than over mud. Most of the predation occurred within 1.5m of the bottom and was probably primarily due to the cunner, *Tautogolabrus adspersus*. Laboratory observations with epibenthic fish species confirmed their ability to consumer postlarvae.

THE EFFECT OF TEMPERATURE ON SEXUAL MATURITY IN THE FEMALE LOBSTER, *HOMARUS AMERICANUS*. **Susan A. Little*** and **Win Watson,** University of New Hampshire, Zoology Department, Durham, NH 03824; **Bonnie Spinazzola,** Atlantic Offshore Lobstermen's Association, 114 Adams Road, Candia, NH 03034.

The purpose of this study was to determine if female American lobsters (*Homarus americanus*) inhabiting areas with dissimilar annual temperature profiles (measured in degree days >10°C), reached sexual maturity at different sizes. We compared the size at maturity of lobsters captured in 3 different offshore locations (two southern and one northern), 1 inshore site (Isles of Shoals, NH) and one estuarine site (Great Bay Estuary, NH). Lobsters inhabiting the Great Bay Estuary experienced the warmest temperatures (1320 degree-days), followed by the southern offshore sites (876; 906), the northern offshore site (669), and the Isles of Shoals (416). Lobsters that migrate could gain a considerable thermal advantage. For example, southern offshore lobsters would increase their degree-days from 216 to 906. For this reason temperature exposure for the offshore lobsters was calculated assuming a seasonal migration. The maturity of female lobsters was determined using a combination of abdominal width/carapace length ratios, cement gland stages, and egg stages. As expected, lobsters that experienced the most degree-days above 10°C reached sexual maturity at smaller sizes. The size at which 50% of the lobsters were mature was 84 mm CL for the Great Bay estuary (n = 71), <83 mm CL for the two southern offshore sites (n = 80 lobsters), 91 mm CL for the northern offshore site (n = 40), and 89 mm CL for the Isle of Shoals (n = 33). This difference in size at maturity was also manifested in the average size, and range of sizes of berried females captured in each location. These data suggest that regional differences in size at maturity should be taken into account when managing the fishery. However, it is important to fully understand all the behavioral, developmental and oceanographic processes that influence size at maturity before implementing any new regulations. This project was funded by the Northeast Consortium.

ENVIRONMENTAL MONITORS ON LOBSTER TRAPS.

James Manning, Northeast Fisheries Science Center, Woods Hole, MA, **Bonnie Spinazzola,** Atlantic Offshore Lobster Association; **Patrice Farrey,** Maine Lobstermen Association; **David Casoni,** Mass Lobstermen Association; **Clare Grindal,** Downeast Lobstermen Association.

Beginning in early 2001, electronic temperature probes were distributed to over 70 New England lobstermen by the four largest associations. These units are recording hourly temperatures at fixed locations throughout the Gulf of Maine including many offshore canyons sites. The objective is to occupy these same locations year-after-year for documenting interannual variability of the deeper bottom water. Phase II of the project, just getting underway in 2002, will deploy several salinity sensors around the region. The primary objective is to characterize the water mass and to assess the influence of remote source water. Participating lobsteren are asked to record catch wherever probes are attached. Understanding the biological significance of the physical variability is a secondary but a potentially worthwhile bi-product of the study. Details are posted on the project website http://www.nefsc.nmfs.gov/~jmanning/emolt.html.

LESIONS ASSOCIATED WITH RECENT EPIZOOTIC SHELL DISEASE IN *HOMARUS AMERICANUS* ON THE NORTHEAST COAST.

Roxanna Smolowitz,* Andrea Hsu, and **Erin Summers,** MBL, 7 MBL St., Woods Hole, MA 02543; **Andrei Christoserdov,** Marine Sciences Research Center, SUNY, Stony Brook, NY 11794.

Shell disease is a commonly recognized problem in lobsters held in impoundments during winter months. However, recently, the economically devastating disease has reached high proportions in free-living populations along the coast from Eastern Long Island Sound, New York, to the Vineyard Sound, Massachusetts. The disease is characterized by multifocal to confluent, shallow to deep erosions, primarily of the dorsal carapace, often resulting in thin, easily compressed shells and, rarely, ulcerations. Grossly, lesions usually show marked melanization, but no obvious pathogen.

Histopathologically, carapace erosions are of variable depth; but deeply extensive erosions are common. Carapace matrix in the erosions is usually missing, but in some instances, unlike lesions noted in impoundment disease, pillars of carapace matrix still remain attached in the eroded tissue. Inflammation is composed of increased numbers of hemocytes in the underlying connective tissues and accumulations of usually necrotic hemocytes between layers of carapace. A second type of inflammation consists of variable amounts of carapace proliferation produced by the intact hyperplastic epithelium underlying the eroded site. Various organisms are identified in the erosions, but the predominate organism found at the interface of necrotic and live shell are bacteria. Work is underway to identify the pathogenic bacteria at the lesion interface.

WHAT CAN DATA FROM INDUSTRY CONDUCTED TAG-RECAPTURE PROGRAMS TELL US? A STUDY OF THE AMERICAN LOBSTER (*HOMARUS AMERICANUS*).

Barbara A. Somers,* and **Kathleen M. Castro,** University of Rhode Island, Fisheries Center, East Farm, Kingston, RI 02881; **John Sorlien,** Rhode Island Lobstermen's Association, Box 421, Wakefield, RI 02880; **Tom Angell,** Department of Environmental Management, Coastal Fisheries Lab, Wakefield, RI 02880.

Tag-recapture data for the American lobster (*Homarus americanus*) compiled from a two year experimental tag-recapture program done by the Rhode Island Lobstermen's Association (RILA) in cooperation with Rhode Island Sea Grant and the Rhode Island DEM is being used to determine migration and life-history characteristics for the Southern New England lobster stocks. Twenty boats participated in the program; number of lobsters tagged and recaptured varied among fishing areas, taggers and recapture reporters. A total of 11,964 lobsters were tagged and released over a 16-month period. The majority of the lobsters were tagged in August and September of 2000 and the months with the highest recapture rates were July, August and September of 2000 and 2001. 982 lobsters have been recaptured to date giving a recapture rate of 8.2%. Recaptures were received by phone and by mail with a total of 91 fishermen returning tags. Biological data estimating growth, egg frequency, shell disease and movement will be reported as well as perceptions about cooperative research from the project participants.

OYSTER REEFS AND RESTORATION

A CHARACTERIZATION OF IDEAL HABITAT STRUCTURE FOR THE STRIPED BLENNY *CHASMODES BOSQUIANUS*. **Elizabeth M. Flynn*** and **Kennedy T. Paynter, Jr.**, Department of Biology, University of Maryland, College Park, MD 20742.

Historically, oyster reefs dominated the trophic interactions of the Chesapeake Bay. Besides improving water quality and forming an integral link in the food web, oysters provided the physical structure that facilitated the development of a complex benthic community. In the past 150 years, disease, overfishing, and pollution have decimated the oyster population and destructive harvesting methods have reduced complex, high relief reef structures to flat "footprint" bars. The impact of this systemic loss of vital habitat on the small demersal reef fish has gone relatively unstudied. The objective of this study is to separate and identify the structural components of shell aggregations that constitute desirable habitat for the striped blenny, *Chasmodes bosquianus*.

Disarticulated oyster shells were arranged in a 30-gallon glass aquariumin various vertical, horizontal and angled arrays to tested for spatial preferences. Individuals were released into the tank and remotely observed via overhead video for one hour. Mean perch duration, perch frequency, minimum and maximum perch durations, and total duration of association with the shell arrays were analyzed. The results indicate that *C. bosquianus* prefer 1–2 cm NN distances. *C. bosquianus* similarly preferred 60 degree arrays as compared to 90 degreeswith regard to total association, maximum perch duration, and frequency. The short-term behavioral patterns analyzed here suggest that purely structural elements of oyster reefs are critical factors influencing demersal fish population distributions.

A COMPARISON OF ACOUSTIC TECHNIQUES, VIDEOGRAPHY, AND QUADRAT SAMPLING FOR CHARACTERIZING SUBTIDAL OYSTER REEFS. **Raymond Grizzle,*** **Larry Ward**, and **Jamie Adams**, Jackson Estuarine Laboratory, University of New Hampshire, Durham, NH 03824; **Semme Dijkstra**, Center for Coastal & Ocean Mapping, University of New Hampshire; **John Nelson**, New Hampshire Fish & Game Department, Marine Fisheries Division, Durham, NH 03824.

Acoustic techniques, videography, and quadrat sampling were used to characterize several subtidal oyster reefs in the Great Bay Estuary in New Hampshire and to compare their effectiveness, with the long-term goal being a general protocol for reef mapping and monitoring. The acoustic techniques consisted of single beam, multibeam, and sidescan sonar. Preliminary analysis of the acoustics data indicated that reef boundaries could readily be mapped. Videography was conducted by systematically imaging each of 40 sampling cells in a grid covering the approximate area of each reef. A single drop was made in each cell and a 5 to 10-s recording made of a 0.25 m^2 area. A still image was produced for each of the 40 cells and all were combined into a montage that revealed the approximate boundaries of the reef. Five to ten cells on each reef were randomly chosen and sampled by divers using a 0.25 m^2 quadrat; all live oysters were measured (shell height) to nearest millimeter using calipers. Oyster counts were also made directly from each video image and compared to the quadrat data from the same photo; preliminary analyses showed good correlations between these counts. Overall, our results to date indicate that acoustic techniques generally can delimit the boundaries of oyster reefs, as has been demonstrated in other studies. Their potential for inferring other reef characteristics (e.g., oyster densities), however, is being assessed. Thus far, the major finding is that videography may be a powerful and relatively inexpensive tool for detailed reef mapping, including inferring oyster densities and perhaps other characteristics.

PREVALENCE OF ENTERIC MICROORGANISMS IN THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA*) AND THEIR OVERLYING WATERS AT REPRESENTATIVE SITES OF AN OYSTER GARDENING PROGRAM IN MOBILE BAY, ALABAMA. **Kimberly A. Hamilton,*** **D. LaDon Swann**, and **William Burkhardt, III**, Department of Fisheries and Allied Aquacultures, Auburn University, Auburn, AL 36849 and U.S. Food and Drug Administration, 1 Iberville Dr., Dauphin Island, AL 36528-0158.

An oyster gardening program for the restoration of the eastern oyster, *Crassostrea virginica*, in Mobile Bay, AL began in May 2001. Thirty study locations were established in Mobile and Baldwin counties along Mobile Bay. Of these sites three from Mobile county and two from Baldwin county for a total of five sites were purposefully selected in July 2001 to determine if a relationship exists between enteric microorganisms in oysters and their overlying waters at different geographic locations along Mobile Bay. The oysters were suspended under piers inside Eastfields floats (surface area of 0.35 m^2) which positioned the oysters directly below the surface of the water. Oyster and water samples were taken from each site on a monthly basis and levels of fecal coliforms, *Escherichia coli*, and male-specific bacteriophage (an enteric viral simulant) were quantified using pre-established protocols.

The results have shown intermittent high levels of coliforms in the shellfish, but levels in their overlying waters were low. The bacteriophage levels have been consistently lower than the level of detection; thus indicating that human wastewater treatment source is not a likely cause of fecal coliforms. A high number of birds and their droppings have been observed at some of the study sites from which the Eastfields floats are suspended. These results may have implications for future site selection of the gardening program. Findings from these analyses will be used to inform local communities and regulatory agencies of any impacts water quality may have on shellfish quality.

USE AND VALUE OF OYSTER REEFS AMONG RECREATIONAL FISHERMEN IN LOUISIANA.

J. C. Isaacs,* Louisiana Department of Wildlife and Fisheries, Baton Rouge, LA 70898; **W. R. Keithly,** Coastal Fisheries Institute, Louisiana State University, Baton Rouge, LA 70803; **A. Diagne,** University of Arkansas at Pine Bluff, Department of Business Administration, 1200 North University - Mail Slot 4976, Pine Bluff, AR 71601.

Oyster reefs serve a wide variety of purposes. Until recently, the majority of research has focused on the relationship between the quantity and quality of reefs and commercial harvests derived therefrom. Recreational fishermen in Louisiana, however, also make extensive use of oyster reefs. This study serves two purposes. First, it provides an examination of catch rates and species diversity among inshore recreational fishermen fishing over oyster reefs in comparison to inshore fishermen not fishing over oyster reefs. Second, it provides an estimate of 'willingness to pay' among individual recreational fishermen for the privilege of fishing over oyster reefs. This study employed a telephone survey of Louisiana anglers to generate an estimate of the value of oyster reefs in Louisiana to the recreational fishing sector. Overall, the value is found to be significant, gives a justification for maintaining oyster reefs in addition to commercial harvest.

RELAYING AS A METHOD TO REMOVE HOOKED MUSSELS FROM OYSTERS PRIOR TO REHARVEST FOR SALE.

Earl J. Melancon, Jr.,* Biology Department, Nicholls State University, Thibodaux, LA 70310; **Dale Diaz,** Mississippi Department of Marine Resources, Biloxi, MS 39530; **Badiollah Asrabadi,** Math Department, Nicholls State University.

The hooked mussel, *Ischadium recurvum*, is considered a native species of the northern Gulf of Mexico, but introduced in the Chesapeake. It is a small bivalve that can be found in great numbers attached to subtidal oysters located in low salinity environments. In the northern Gulf of Mexico, oystermen have traditionally relayed mussel-laden oysters to higher salinity waters with the expected results of killing them, and thereby removing them, before reharvest of the cleaned oysters for sale.

Results of laboratory, small-scale field and two commercial-scale field experiments indicate that removal of mussels due to transplanting to higher salinity waters is less a function of physiological salinity stress and more a function of the transplanting process itself. The hooked mussels were crushed, dislodged or stressed to the point of permanent gaping during the commercial-scale relaying operations. This resulted in an immediate 32–34% mussel mortality, with a corresponding negligible oyster mortality. The dead and dying mussels attracted predators, such as the blue crab, *Callinectes sapidus*, and the southern oyster drill, *Stramonita haemastoma*, which resulted in continued mussel losses in the ensuing weeks.

In the more coastal location, where salinity is relatively high, mussel-fouled oysters were cleaned by the third week after a summer transplant. The dilemma is that oysters in the higher salinity waters may also become more vulnerable to predators and the oysterman must consider reharvest in a short time. In the more inland location, where salinity is more intermediate, and perhaps with less abundant oyster predators present, mussel removal was a longer process with 76% removed by the fifth week. Results of these experiments strongly suggest that salinity is a key element in the removal of mussels from oysters, but more in the role of a habitat response and less as a physiological response to salinity.

MODELING THE INFLUENCE OF FILTRATION BY OYSTER STOCKS ON TURBIDITY AND SEAGRASS GROWTH.

Roger I. E. Newell,* **Evamaria W. Koch, Melissa K. Wood, Ray E. Grizzle,** and **Raleigh R. Hood,** Horn Point Laboratory, University of Maryland Center for Environmental Science, PO Box 775, Cambridge, MD 21613-0775.

Chesapeake Bay has undergone severe ecological changes. Oysters are almost completely absent due to overharvest and diseases and seagrass beds either are in decline or have disappeared due to high water turbidity reducing light availability. Oyster reefs and seagrass beds tended to improve water quality by actively filtering particles out of the water, reducing wave energy, and minimizing sediment resuspension. In part because of the loss of these ecosystem functions water quality is poor and seagrass restoration not always successful. We hypothesized that the reestablishment of oyster stocks, either via restoration of reefs or aquaculture, could benefit seagrass populations. Results from laboratory experiments and field studies were used to paramterize a model predicting the extent to which oysters and seagrasses can affect water quality and enhance the chances of survival and expansion of seagrasses. Oysters were capable of increasing light penetration due to high summer filtration rates. The ability of seagrass beds to minimize resuspension was a function of water depth and their capacity to attenuate waves. Large reproductive seagrass plants that occupied the entire water column were more effective at minimizing resuspension than small vegetative plants. Our model results suggest that increasing oyster stocks can dramatically enhance light penetration and thereby increase the area of Bay bottom where seagrasses can grow.

THE EFFECT OF STOCKING DENSITY ON BENTHIC COMMUNITY DEVELOPMENT AND SHELL HEIGHT IN THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*.

Stewart Harris* and **Kennedy T. Paynter**, University of Maryland, College Park, MD 20742.

The eastern oyster, *Crassostrea virginica*, is a gregarious, reef-forming organism. Oyster populations that once dominated the Chesapeake have declined significantly and interest has recently arisen to restore the economic and ecological benefits of native oyster populations. Understanding the ecological importance of oysters and oyster reefs is critical to the restoration of the estuary's ecosystem as a whole. Oyster densities on most Maryland reefs are very low (about 3 oysters/m^2), however, natural reefs formed in other areas are comprised of high densities of oysters (>500/m^2). In order to maximize the effectiveness of oyster restoration, it is important to determine how oyster density may affect oyster growth, parasite prevalence and the formation of reef habitat utilized by the benthic community.

In the fall of 1999, twelve 0.2-acre experimental plots were constructed in the Patuxent River by placing fossil oyster shell on a barren natural oyster bar. The plots were assigned one of four treatments, zero, 124, 247, 494 oysters/m^2, in a randomized design. Oyster growth was 0.12 (± 0.004 SEM) mm/day for the 2000 season and slowed to 0.07 (± 0.006) mm/day in 2001. The data did not show any effect in shell height due to density of oysters. Colonization of the oyster reefs with fouling organisms was related to density of oysters. In summer and fall of 2000, barnacle density declined with increasing oyster density.

EVALUATING THE CONTRIBUTION OF COMMERCIAL OYSTER AQUACULTURE TO RECRUITMENT.

Rachel E. Sackett,* **Russ Peterson,** and **Ami E. Wilbur,** Department of Biological Sciences and the Center for Marine Science, 5600 Marvin K. Moss Lane, University of North Carolina at Wilmington, Wilmington, NC 28409; **Jim Swartzenberg,** J&B AquaFood, Holly Ridge, NC 28445.

Commercial oyster (*Crassostrea virginica*) aquaculture operations concentrate large numbers of potentially reproductive animals. Such aggregations may function to produce large numbers of larvae that subsequently recruit to natural beds. Anecdotal observations have suggested the enhancement of recruitment in the vicinity of commercial aquaculture operations; however, confirmation of such an effect has generally not been possible, as new recruits derived from the cultured stock generally cannot be distinguished from those resulting from the spawning of wild oysters. Recent stocking of commercial leases in North Carolina with oysters produced in a hatchery in Louisiana has provided an opportunity to evaluate the potential for the enhancement of local recruitment due to the spawning of cultured stock. Oysters from the Gulf coast and Atlantic coast have been previously shown to exhibit genetic differences in mitochondrial DNA (mtDNA) haplotype. PCR (polymerase chain reaction) amplification and DNA sequencing of 409 base pairs of the 16s ribosomal gene are being used to screen recent recruits collected from 7 natural beds surrounding 1.5 acres of leased bottom (stocked with ~70, 000 Gulf oysters), as well as a sample of the culture stock. Sequence data will be analyzed to determine what proportion of recent settlers exhibited mtDNA haplotypes consistent with the hypothesis that they were produced by the spawning activity of the culture stock. Preliminary analyses revealed some recruits exhibit mtDNA haplotypes identical to those exhibited by the culture stock, suggesting that there is some local recruitment resulting from reproduction of commercial aquaculture stock.

RECRUITMENT OF THE OYSTER *CRASSOSTREA VIRGINCA* ON INTERTIDAL REEFS IN AREAS WITH INTENSE BOATING ACTIVITY IN THE INDIAN RIVER LAGOON, FLORIDA.

Lisa Wall,* **Linda Walters**, **Kevin Johnson**, and **Neysa Martinez**, Department of Biology, University of Central Florida, 4000 Central Florida Blvd. Orlando, FL 32816; **Ray Grizzle**, Jackson Estuarine Laboratory, University of New Hampshire, Durham, NH 03824.

Productivity, diversity and survival of estuaries are threatened by explosive coastal population growth and associated recreational activities. One major area of recreational growth has been the number of people motoring in small pleasure craft at high rates of speed. In counties bordering Mosquito Lagoon (northernmost section of the Indian River Lagoon system, east coast of central Florida), there were 51,000 registered boaters in 1998. Numbers have increased 10% annually since 1986 and continue to grow. In areas of Mosquito Lagoon with intense boating activity, intertidal reefs of *Crassostrea virginica* with dead margins commonly occur. The dead margins consist of mounds of disarticulated shells. The cause(s) of the reef die-offs is unclear. However, the disarticulated shells may be reducing reef sustainability if these surfaces are unavailable for oyster recruitment. Recruitment trials were run on eight reefs (4 impacted, 4 healthy) in two eight-week trials in Summer 2001 and Winter 2001–2002. Sediment loads, temperature and water motion at all sites were monitored. In the Summer 2001 trial, no significant differences were found between or within sites for settlement or recruitment. However, temperatures reached over 40°C on portions of the dead reef. Data of this type is needed to identify causes of reef declines, habitat-specific management protocols and appropriate restoration techniques.

OFFSHORE FISHERIES

INTEGRATING VESSEL TRACKING, CATCH DATA, AND DEPLETION MODELS TO ESTIMATE COMMERCIAL SCALLOP DREDGE EFFICIENCY. Todd Gedamke* and **William DuPaul,** Virginia Institute of Marine Science, School of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

In June of 1999, Georges Bank Closed Area II was opened to the United States sea scallop fleet after a five-year multi-species fishing closure. During the five-month opening, nearly six million pounds of scallop meats were harvested, catch-per-unit effort data were collected from over 1,000 commercial tows, and the fine-scale distribution of fishing effort was recorded hourly by mandatory vessel monitoring systems. A spatial analysis of both catch and effort data was performed to locate areas consistent with the DeLury model assumptions. Gear efficiency was estimated to be 45% utilizing a combined maximum likelihood analysis of CPUE declines in all suitable regions. An additional independent estimate of efficiency was generated from survey stations that were sampled before and after the opening. A kriging analysis was used to determine mean catch rates and the index-removal method was applied to compare the change in catch rates to the total landings reported for the opening. Dredge efficiency was estimated to be 54%.

The results of this study suggest that the 25% efficiency estimate used in calculations prior to the opening resulted in the overestimation of absolute biomass and the setting of a quota that exceeded target exploitation levels. In addition, the results of this study suggest that information from the vessel monitoring systems, now in use on many commercial fleets, can provide the fine scale spatial details necessary to successfully apply depletion models to open-ocean commercial fishing operations.

THE USE OF A 4-INCH (101 MM) SEA SCALLOP (*PLACOPECTEN MAGELLANICUS*) RING DREDGES IN THE CONTEXT OF AN AREA MANAGEMENT STRATEGY. Kevin D. Goff, William D. DuPaul,* and **David B. Rudders,** Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062.

Early attempts to manage the sea scallop (Placopecten magellanicus) fishery focused on establishing age-at-entry controls. Since 1994, the primary management strategy shifted to an effort control program and an increase in scallop dredge ring size to 3.5 inches (88 mm) from 3.0 inches (76 mm), with the intent of increasing yield per recruit.

Dramatic increases in scallop biomass in three areas of Georges Bank closed to mobile fishing gear in 1994 and two areas in the mid-Atlantic closed in 1998 to protect concentrations of small (<80 mm) scallops have stimulated interest in developing an area wide management strategy for sea scallops.

During commercial openings of these areas during 2000–2001, the performance of a 4-inch (101 mm) ring scallop dredge was evaluated against the standard 3.5-inch (88 mm) ring dredge. Detailed catch data from 208 tows on eight commercial trips showed a reduction in scallop harvest of up to 42.5% for scallops <90 mm and increases in harvest efficiency of up to 12.9% for scallops >115 mm. These results are closely related to the size frequency distribution of the scallop resource. When the size frequency distribution of the scallop population has a modal shell height of greater than 110 mm, the use of a 4-inch ring dredge may play a significant role in realizing the benefits of area-based management.

REBUILDING SEA SCALLOP (*PLACOPECTEN MAGELLANICUS*) STOCKS USING AREA CLOSURES AND ROTATIONAL FISHING. Deborah Hart* and **Paul Rago,** NOAA Fisheries, Northeast Fisheries Science Center, 166 Water St., Woods Hole, MA 02543.

In the seven years since the closure of three large areas on Georges Bank to trawling and dredging in December, 1994, sea scallop biomass on Georges Bank has increased by more than a factor of twenty. Limited fishing in the closed areas in 1999 and 2000 yielded about 11 million lbs of scallop meats while still allowing for increases in biomass in these areas. Dramatic increases in biomass have also been seen in the Mid-Atlantic Bight after two areas there were closed to scallop fishing for three years in 1998. These experiences indicate that area closures can be an effective way to rebuild shellfish stocks and alleviate growth overfishing. Strong recruitment observed since the closures suggests that the closed areas have also become important sources of scallop larva. Both theory and practice indicate that rotational management, where areas are successively closed and then opened to fishing, can increase both yield and spawning-stock biomass in the sea scallop fishery.

FLEET DYNAMICS OF THE ATLANTIC SEA SCALLOP FISHERY. Paul J. Rago and **Deborah R. Hart,** NOAA Fisheries, Northeast Fisheries Science Center, 166 Water St., Woods Hole, MA 02543.

The sea scallop (Placopecten magellanicus) supports the second most valuable commercial fishery in the northeast USA. Closure of large areas of Georges Bank to scallopers in 1994 not only resulted in rapid increases in scallop biomass but also altered the spatial distribution of fishing effort. Detailed electronic information on the hourly position of each vessel was used to study the behavior of the fishing fleet for the period 1998 to 2000. Additional information from at-sea observers corroborated the analyses of vessel monitoring data. Limited re-openings of the closure areas in 1999 and 2000 induced marked shifts in fishing effort. Fine-scale changes in fishing patterns can be related to the scallop density, size composition and economic value as well as the presence of bycatch species. The scallop fishery is conducted over an area of about 12,000 nm^2, but more than 75% of fishing activity is concentrated within an area of about 3,000 nm^2. When scallop density is low, however, fishing vessels disperse more widely. Such variations in the concentration of fishing activity have important implications for impacts on habitat and finfish bycatch and provides insights into management strategies for bivalve fisheries.

POPULATION STRUCTURE OF THE INDIAN SQUID, *LOLIGO DUVAUCELII* ORBIGNY, 1848, IN IRANIAN WATERS OF THE OMAN SEA. **Farhad Rajabipour,*** Offshore Fisheries Research Centre, Chabahar, Iran.

The population biology of the Indian squid *Loligo duvauceli* Orbigny, 1848 was described from monthly sampling, December 1997 to January 1999. Samples were caught as by-catch of bottom fishing trawlers from continental shelf area of Oman Sea at southeast of Iran. 1281 samples including 694 males and 587 females with the mean length of dorsal mantle and weight of 109.8 ± 34.95 mm and 48.32 ± 36.23 gr for males, and 110.6 ± 22.4 mm and 54.34 ± 28.35 gr for females, were collected. Maximum length (ML) of dorsal mantle in males and females was observed in January and June. Length-weight relationship was acquired. It is reversed at 72 mm length of dorsal mantle in logarithmic model. ML50 of males and females is 15.4 cm and 8.7 cm. There is no significant difference between females and males frequencies at the beginning of summer and ending of winter. NGI and GSI indices detected that the pick of reproduction occurs at the beginning of summer and winter. Males have three length classes, two recruitment peaks at beginning of summer (17.4%) and winter (82.6%), but females have only one length class and two recruitment peaks at beginning of winter (58.97%) and summer (41.3%); (t0 = 1.4/year). Age and mortality indices were measured. Catch rate of *L. duvauceli* in Iranian waters of Oman Sea was 0–100 kg/hour.

RECRUITMENT DYNAMICS OF NORTHERN SHRIMP (*PANDALUS BOREALIS*) IN THE GULF OF MAINE. **Anne Richards,* Michael Fogarty,** and **David Mountain,** NOAA Northeast Fisheries Science Center, Woods Hole, MA 02543; **Mirta Teichberg,** Boston University Marine Program, Woods Hole, MA 02543.

The western Gulf of Maine is the southern limit of distribution for northern shrimp *Pandalus borealis.* Previous studies showed that recruitment of northern shrimp in the Gulf of Maine is significantly affected by spring surface temperatures as well as spawning stock biomass. The temperature effect corresponds to the period of planktonic larval development. The purpose of this study was to extend these analyses by examining the influence of additional environmental factors (freshwater runoff, wind patterns, and climate indicators) on recruitment and to consider mechanisms for the spring surface temperature effect. Runoff and wind patterns strongly affect circulation within the western Gulf of Maine and thus may affect recruitment through effects on retention and/or transport of larvae. Results to date indicate no significant effect of mean river discharge, timing of peak discharge, other temperature effects, or the NAO winter index; however, the spring surface temperature effect continues to be significant. The match-mismatch hypothesis is a possible explanation for this effect, and we are evaluating the hypothesis by developing estimates of timing of onset of the spring phytoplankton bloom along with estimates of timing of the shrimp hatch.

DEEP SEA RED CRABS OFF SOUTHERN NEW ENGLAND: HAS THERE BEEN A FISHERY IMPACT ON THE POPULATION? **James R. Weinberg*** and **Charles Keith,** NMFS, NEFSC, 166 Water St., Woods Hole, MA 02543.

A directed trap fishery for the deep-sea red crab, *Chaceon* (formerly *Geryon) quinquedens* Smith, has taken place off the coast of southern New England since the mid-1970s. These slow-growing crabs occur from about 250–1000 m, and males grow larger than females. The National Marine Fisheries Service conducted a survey of population size-structure in 2001 and measured the relationship between carapace width and body weight. This information had not been updated since the late 1970s. Given that the fishery targeted large males, we examined whether there was a decline over time in the percentage of large males in the population and in the individual weights of large males. Overall, the percentage of large males in 2001 was lower than in 1974, whereas the fraction of large females either stayed the same or increased slightly during the same time period. Data collected between 1973 and 2001 suggested that male body weight, for a given body size, has declined over time. There was no trend over time in female body weight. Thus, compared to the 1970s, the population appears to have a lower percentage of large males in 2001, and these males have lower biomass for their carapace size. The results might be due to harvesting of large, heavy males over time; however, the surveys are too widely spaced in time, and too few in number, to draw strong conclusions about causality.

DISEASES OF SHELLFISH: CONTRIBUTED SESSION

MORTALITIES OF CULTURED ABALONE, *HALIOTIS IRIS*, INFECTED BY A NOVEL HAPLOSPORIDIAN. B. K. Diggles, P. M. Hine, V. L. Webb, and **E. W. Maas,** National Institute of Water and Atmospheric Research, Kilbirnie, Wellington, New Zealand; **J. Nichol** and **S. Wakefield,** School of Medicine, University of Otago, Wellington South, New Zealand; **R. Roberts,** Cawthron Institute, Nelson, New Zealand; **C. S. Friedman,** School of Aquatic and Fishery Sciences, University of Washington, Seattle, WA; **N. Cochennec-Laureau,** Laboratoire de Genetique et Pathologie, IFREMER, La Tremblade, France; **K. S. Reece** and **N. A. Stokes,*** Virginia Institute of Marine Science, Gloucester Point, VA.

Chronic mortalities of juvenile abalone, *Haliotis iris,* occurred in a commercial culture facility in New Zealand during the Austral summer and autumn of 2000 and 2001. Histopathology of moribund abalone showed heavy systemic infections of a uni- to multinucleate protozoan parasite associated with severe tissue damage. Heavily infected abalone exhibited lethargy, loss of righting reflex, and weak surface adherence. Mortality levels reached 90% in the affected raceways. The parasite was identified as a haplosporidian based on TEM and molecular analyses. Ultrastructural characteristics of the parasite included the presence of multinucleate plasmodia, lipid droplets, an anastomosing endoplasmic reticulum and the production of haplosporosome-like bodies from nuclear membrane-bound golgi apparatus that matured into haplosporosomes. Molecular confirmation of the TEM identification was accomplished by performing in situ hybridization (ISH) and by PCR-amplifying and sequencing the parasite's small subunit ribosomal RNA (SSU rRNA) gene. A DNA probe specific for several members of the haplosporidia exhibited hybridization to the plasmodia in ISH of infected animals. The SSU rRNA gene sequence was novel, but phylogenetic analyses strongly supported grouping this parasite with the haplosporidians. The parasite was at the base of the phylum Haplosporidia, ancestral to *Urosporidium crescens* and the *Haplosporidium, Minchinia,* and *Bonamia* species.

LOW SALINTY TOLERANCE IN MANILA CLAMS *VENERUPIS PHILIPPINARUM.* Ralph Elston, AquaTechnics/Pacific Shellfish Institute, PO Box 687, Carlsborg, WA 98324 USA; **Dan Cheney, Brian MacDonald,** and **Andrew Suhrbier,** Pacific Shellfish Institute, Olympia, WA.

The manila clam, *Venerupis philippinarum,* is the second most important product of molluscan aquaculture on the west coast of the United States and is grown on several other continents. We evaluated the tolerance and the low salinity response in this clam species using experimental exposures of 17 populations of manila clams. Ambient seawater (30 psu) and freshwater were first temperature conditioned, then mixed using aperture controlled flows into incremental salinity head tanks that supplied the test chambers. Water supplied to the test tanks was supplemented with algal feeds. Low salinity tolerance of clams was determined by performing exposures of up to four weeks in duration at constant salinities, followed by a recovery period. Clams were tested in salinity increments of 2.5 psu (= ppt).

Tolerance to low salinity events in clams is both a function of survival response (duration of shell closure) and the physiological adaptability of the clams to exist in low salinity environments. All individual clams from all sources were tolerant to 15 psu but populations showed variable proportions of individuals with tolerance to 12.5 psu and none were tolerant to long term exposure to 10 psu. Variable tolerance to 12.5 psu appears to be a function of the effectiveness and duration of the shell closure response. All clams could withstand 6 days at 5 psu, but complete group mortality occurred by 12 days at 5 psu. All clams could withstand 8 days exposure to 10 psu but complete group mortality occurred by 14 days at 10 psu. Little effect of temperature was found on the clams' tolerance to marginal low salinities. The low salinity exposures resulted in alterations in the digestive gland epithelium including loss of granulation, cellular swelling and cellular sloughing. We concluded that candidates to select for low salinity tolerance are available in most populations but some populations are enriched with individuals with tolerance to the marginal salinity (12.5 psu).

A SPECIFIC PATHOGEN FREE CULTURE SYSTEM FOR *C. GIGAS* LARVAE AND SPAT. Sean E. Matson* and **Christopher Langdon,** Hatfield Marine Science Center, Oregon State University, Newport, OR 97365.

The Molluscan Broodstock Program (MBP), a selective breeding program for the Pacific oyster, *Crassostrea gigas,* uses a Specific Pathogen Free culture system for all production and maintenance of larvae, spat, broodstock and microalgae. This system is necessary to exclude infectious agents of *Haplosporidian costale* (Seaside Organism, SSO), which has been found in Pacific oysters grown in Yaquina Bay, Oregon, where the program draws its seawater, and for the safe outplanting of MBP spat in field test sites along the West coast (USA). All seawater entering MBP facilities is filtered through sand, diatomaceous earth, and a series of 20, 5, and 1 μm cartridge filters. Seawater to mass algal cultures and the nursery is also irradiated with UV-light at >30,000 micro-

Watts-sec/cm^2 (MWS) as a back-up precaution. Since the system's inception, no MBP spat have been identified as being contaminated with SSO, or any other infectious agent. A series of laboratory experiments was performed to assess the effects of UV water on larval growth and survival, spat growth and survival, and microalgal culture density. Experiments with oyster larvae indicated that both the micro-filtration system and UV water treatment had a significant negative effect on larval growth ($p = 0.0001$). A significant reduction in growth was evident at UV intensities as low as 10,000 MWS ($p < 0.05$). Methods that have significantly improved larval growth, survival, speed to metamorphosis and spat growth within the SPF culture system include substituting a 0.2μm filter and charcoal for a UV filter when rearing larvae, and the addition of calcium bentonite (2mg/ml/day) or calcium montmorillonite (5mg/ml/day) to larvae and spat cultures ($p < 0.05$).

INTRAMITOCHONDRIAL CRYSTALS WITHIN THE HAEMOCYTES OF MUSSELS (*MYTILUS EDULIS*) EXPERIENCING UNEXPLAINED MORTALITIES.

Gary R. Meyer,* and **Susan M. Bower,** Department of Fisheries and Oceans, Pacific Biological Station, Nanaimo, British Columbia, V9R 5K6, Canada.

Persistent mortality (having a cumulative total of about 75%) was observed between August 1999 and April 2000 amongst a stock of cultured blond mussels (*Mytilus edulis* selectively bred for their blond coloured shell trait) grown near Quadra Island, British Columbia, Canada. During this period, 7 samples of mussels ($n = 30$ per sample) were examined. Up to 27% had macroscopic lesions (orange pustules) and up to 50% had histopathology consisting of multifocal and or diffuse haemocyte infiltration that contained abundant phagocytic cells and necrotic cellular debris usually in the mantle/gonad and digestive gland. However in some instances, this pathology was also observed in the adductor muscle, gills, kidney or heart tissue. No etiological agent was evident. Intracellular mycobacteria-like organisms were observed within a few haemocytes in up to 20% of the mussels examined however their role in the disease remains unknown. During ultrastructural examinations, intramitochondrial crystalline arrays were commonly observed within necrotic or lysed haemocytes. These crystals were not observed "free" within the cytoplasm of affected cells and never observed in adjacent "healthy-looking" cells. The chemical composition and significance of these crystals is unknown. However, we speculate that they are likely composed of condensed protein. Similar crystals have been reported from the mitochondria of a wide variety of organisms and were usually affiliated with an abnormal situation such as disease, pathological process, or response to cell damage.

ENVIRONMENTAL DETECTION OF THE RICKETTSIALES-LIKE PROKARYOTE CAUSING WITHERING SYNDROME IN ABALONE.

James D. Moore,* California Department of Fish and Game, UC Bodega Marine Laboratory, 2099 Westside Road, Bodega Bay, CA 94923; **Carolyn S. Friedman,** School of Aquatic and Fishery Sciences, Box 355020, University of Washington, Seattle, WA 98195.

A gastrointestinal Rickettsiales-like prokaryote (WS-RLP) was recently identified as the causative agent of Withering Syndrome, a chronic, fatal disease of wild and cultured California abalone. Using a polymerase chain reaction (PCR) diagnostic method developed to detect the WS-RLP in abalone gut tissue samples, we have amplified WS-RLP DNA from necrotic tissue held at room temperature for up to 7 days, from samples fixed and embedded in paraffin, and from seed abalone as small as 2mm. A non-destructive WS-RLP sampling method is desired since both wild and farmed abalone are highly valued. We developed a method involving tangential flow filtration that concentrates particles > 0.1 μm from large volumes of seawater, allowing purification of DNA for PCR from 15+ liter samples. Although sample processing is laborious, using this method we have detected the pathogen DNA in effluent from abalone holding units in both experimental and culture facilities. The WS-RLP is present in feces from infected animals, and PCR using fecal material appears to be useful for efficiently detecting the WS-RLP in various stages of farm production. We are currently investigating an hypothesis that filter-feeding organisms concentrate the WS-RLP from endemic waters and can, thereby, be used to monitor WS-RLP presence in natural populations. Initial attempts to amplify WS-RLP DNA from gill or gut tissue of mussels (*Mytilus* spp.) being held with WS-RLP positive abalone have been unsuccessful. Yet it is clear that molecular-based tools will significantly aid management of this devastating disease. Supported, in part, by California Sea Grant College and the Marine Region, California Department of Fish and Game.

VIBRIO ASSOCIATED WITH JUVENILE OYSTER DURING SUMMER MORTALITY IN FRANCE.

J.-L. Nicolas and **M. Garnier** Laboratoire de Physiologie des Invertébrés, Ifremer BP 70, 29 280 Plouzané, France; **M. Gay** and **F. Leroux,** Laboratoire de Génétique et de Pathologie, Ifremer, Ronces Les Bains, BP133, 17390 La Tremblade.

Among the hypotheses advanced to explain summer mortalities of oyster in France (Morest program), the bacterial disease appeared one of most relevant. Indeed, recent works of Lacoste (2001) and Waechter (thesis 2001) showed that of *Vibrio splendidus* (I and II) strains were able to kill the juvenile or adult oysters by bath or injection. To verify this hypothesis, oysters were sampled along the French coasts and analysed during mortality period. Only the half of moribund oysters were invaded by dominant bacteria. Haemolymph of other diseased oysters as well as healthy oysters was often colonised by more or less abundant and diversified bacterial flora. The isolation of a same dominant bacterial strain on several oysters of the same batch, occurred only in hatchery and on only one oyster park. The taxonomic studies (by ARDRA of gyrase B, and sequences of 16S DNAr) made it possible to classify in 3 species these opportunist bacteria: *V aestuarianus* (3 types), *V. splendidus* (II) and *V anguillarum*. Except V. *aestuarianus* (type II). Phenotypical characters of these strains were fickle and could not be used to identify the bacteria.

FURTHER MOLECULAR CHARACTERIZATION OF *PERKINSUS ANDREWSI* AND RELATED ISOLATES.

Wolf T. Pecher, José A. F. Robledo, Cathleen A. Coss, and **Gerardo R. Vasta,** COMB, UMBI, University of Maryland, Baltimore, MD 21202.

We previously described ultrastructure, behaviour in culture, and the rRNA locus of a *Perkinsus* species isolated from the baltic clam *Macoma balthica*. The morphological characterization did not reveal features remarkable enough to clearly indicate that the isolate was a distinct *Perkinsus* species (Coss et al. 2001a). However, the degree of difference of all rRNA genes and intergenic regions examined was comparable to or greater than differences between accepted *Perkinsus* species, which lead to its designation as *P. andrewsi* n. sp. (Coss et al 2001a, b). Here we report further molecular characterization of *P. andrewsi* and the characterization of an additional isolate from the hard clam *Mercenaria mercenaria*. Based on the molecular characterization both isolates are closely related. Their relationship with other recognized *Perkinsus* species will be discussed. [Supported by Grant No. NA06RG0101-5 from ODRP, NOAA, through the Maryland Sea Grant College, to GRV].

IN VITRO CULTURE OF *PERKINSUS ATLANTICUS* FROM CLAMS *TAPES DECUSSATUS:* CHARACTERIZATION OF THE rRNA GENE.

José A. F. Robledo* and **Gerardo R. Vasta,** COMB, UMBI, University of Maryland, Baltimore, MD 21202; **Patrícia A. Nunes** and **M. Leonor Cancela,** Molecular Biology and Biotechnology, CMS-CCMar, University Algarve-UCTRA, Campus Gambelas, 8000-810 Faro, Portugal.

Perkinsus atlanticus cultures were derived from fresh hemolymph and gills, and from tissues incubated in fluid thioglycollate medium from infected clams *Tapes decussatus* from Algarve (South of Portugal). *P. atlanticus* cultures were established in the medium developed and optimized for *P. marinus*. Proliferating cells were cloned by limiting dilution, and the species identity was established by applying two PCR-based *P. atlanticus*-specific diagnostic assays and by sequencing the RNA locus. We provide for first time the complete sequence of the rRNA locus of a *P. atlanticus* and compare by alignment with those partically characterize rRNA loci from other *Perkinsus* species. Actively growing cultures exhibited considerable size heterogeneity with a large proportion of clusters constituted by small cells. Behavior of *P. atlanticus* in culture resembles that of *P. marinus*. Optimization of the culture conditions for *P. atlanticus* is underway. Established clonal cultures will be useful for genetic characterization of this species, and to increase our understanding of its pathogenicity. [Supported by Grant NA06RG0101-5 from ODRP, NOAA, through the MD Sea Grant College, to GRV, and the Portuguese Government PERKLAM Program to MLC].

GENE DISCOVERY IN *PERKINSUS MARINUS* USING EXPRESSION SEQUENCE TAGS (EST).

José A. F. Robledo,* Eric J. Schott, Adam G. Marsh, and **Gerardo R. Vasta,** COMB, UMBI, University of Maryland, Baltimore, MD 21202.

Since the late 1940s the protistan parasite *Perkinsus marinus* has been associated with mass mortalities of the eastern oyster, *Crassostrea virginica*. Based on decades of research, several approaches have been proposed to control "Dermo" disease including early disease detection, selective breeding of disease-resistant oysters, and treatment with anti-parasitic agents. However, none of these approaches has proven effective. In recent years virtually all fields of biology have benefited from the information generated by genomic approaches. We are building a *P. marinus* EST database sequencing cDNAs from two *P. marinus* Lambda ZAP libraries constructed using *P. marinus* propagated in standard culture medium and in medium supplemented with *C. virginica* serum. From the first 300 ESTs two findings are evident: there are many expressed genes whose products are known to be involved in virulence of other parasites and there are notable differences in the classes of genes expressed in control versus serum-supplemented cultures. As the number of ESTs increases, so will prospects for identifying new targets for therapy and for understanding the biological basis of parasite virulence, infectivity, and pathology.

THE NRAMP GENE AND COMPETITION FOR AVAILABLE IRON BETWEEN *CRASSOSTREA VIRGINICA* AND *PERKINSUS MARINUS*.

José A. F. Robledo* and **Gerardo R. Vasta,** COMB, UMBI, University of Maryland, Baltimore, MD 21202.

In the past decades *Perkinsus marinus* has produced extensive damage to oyster bars with catastrophic consequences for shellfisheries and the health of coastal waters. Despite intense parasite pressure, no Dermo-resistant oysters have been identified so far in natural populations. The identification of genes that are directly linked to disease-resistance and assessment of their value as genetic markers, may facilitate the establishment of disease-resistant oyster strains. Most parasites have strong iron requirements and have developed efficient mechanisms for iron acquisition from their hosts. Reciprocally, most hosts have developed mechanisms to prevent pathogens from acquiring iron while maintaining availability for their own cells. Iron sequestration from the pathogen is also a non-specific host response to infection (nutritional immunity). The mammalian natural resistance-associated macrophage protein (Nramp) is a membrane transporter thought to be a determinant of resistance/susceptibility to intracellular pathogens. We have cloned Nramp from *C. virginica* and *P. marinus*, used them to screen genomic libraries, and examine their gene organization. The characterization of these genes and their products in both host and parasite will provide insight into their competition for iron, and yield information on the mechanisms underlying disease susceptibility [Supported by Grant No NA06RG0101-5 from ODRP, NOAA, through the Maryland Sea Grant College, to GRV].

CHARACTERISATION OF GENE EXPRESSION IN RESPONSE TO *PERKINSUS MARINUS* AND *HAPLOSPORIDIUM NELSONI* INFECTIONS IN THE EASTERN AND PACIFIC OYSTERS. Arnaud Tanguy,* Susan E. Ford, and **Ximing Guo,** Haskin Shellfish Research Laboratory, Institute of Coastal and Marine Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

The eastern oyster *Crassostrea virginica* has two major diseases: Dermo caused by the parasite *Perkinsus marinus* and MSX by *Haplosporidium nelsoni*. Effects of infection in *C. virginica* range from reductions in condition index, hemolymph protein concentrations and lysozyme activity to decline in reproductive output, retarded growth and death. MSX-resistant strains of *C. virginica* have been developed at Rutgers University, and the Pacific oyster *C. gigas* appears to be resistant to both diseases. At present, however, we know little about molecular mechanisms of infection and host defense against the two parasites. We have begun a study searching for genes involved in host response to Dermo and MSX infections, using subtractive expression analyses. For Dermo, controlled artificial infections are conducted in both *C. virginica* and *C. gigas*. For MSX, infected wild oysters and uninfected resistant oysters, which were naturally exposed to the parasite, were used to construct the subtractive library. Nine subtractive libraries were made: six for Dermo and three for MSX exposures. About 70 clones were selected for sequencing from each library. Among the first batch of sequences analyzed, one-third matched with known genes in GenBank, and the other represent unknown genes. A detailed characterization of all sequences will be presented at the meeting.

BIVALVE HABITAT SUITABILITY AND THE ROLE OF BIVALVES IN ECOSYSTEMS

HOW COMMUNITY-BASED OYSTER RESTORATION CAN ENHANCE RESEARCH EFFORTS: EXAMPLES FROM SOUTH CAROLINA AND ALABAMA. Loren D. Coen,* Marine Resources Research Institute, SCDNR, 217 Fort Johnson Rd., Charleston, SC 29412; **Richard K. Wallace,** Auburn University Marine Extension and Research Center, 4170 Commanders Dr., Mobile, AL 36615; **Nancy Hadley,** Marine Resources Research Institute, SCDNR, 217 Fort Johnson Rd., Charleston, SC 29412.

In both South Carolina and Alabama, we have been utilizing community-based programs to construct and/or enhance larger scale oyster restoration efforts at selected sites using criteria based on science and best management policies. We are trying to use these sites as research platforms to test various restoration methodologies such as type of shell, alternative substrates, reef configurations, time/method of planting, and stabilizing meshes. In South Carolina we are actually placing 'habitat' (over 40 tons of shell in 2001), rather than oysters into tidal creeks across the state. Routine monitoring (chemical, physcial and biological parameters) is being conducted by both trained volunteers (students and adults) and researchers. In South Carolina, we have also meshed our reef monitoring efforts with HAB efforts through the NOS's South Carolina Phytoplankton Monitoring Network (SCPMN) and we are using the reefs also as 'living classrooms' for a variety of groups (e.g., one built adjacent to the SC Aquarium). In Alabama, oysters produced by volunteers using gardening techniques are being planted at relic reef sites that were already enhanced for sportfishing (as artificial reef fish habitat). This strategy creates opportunities for restoration research which can be supported by multiple interest groups. By constructing oyster reefs, we are improving the suitability of sites for oyster reestablishment, thereby improving habitat quality for reef residents and transient species.

OYSTER HABITAT SUITABILITY AS A COMPONENT OF RESOURCE MANAGEMENT. William S. Fisher,* U.S. Environmental Protection Agency, National Health and Ecological Effects Research Laboratory, Gulf Ecology Division, Gulf Breeze, FL 32561.

Economic and ecological issues have led resource managers to examine depletion of eastern oyster reefs along the U. S. Gulf of Mexico and Atlantic coasts. *Crassostrea virginica* is a lucrative commercial species (over $60M in 2000) that also supports ecosystem integrity by providing enhanced vigor, organization and resilience. These values are threatened by overfishing, habitat perturbation and land use changes that are also economically-driven, but diminish the survival of both oysters and reefs. Relevant and defensible scientific information is required to assess costs and benefits of healthy and productive oyster reefs and to establish management goals for their conservation, mitigation and restoration. Characterization of environmental conditions that support oyster survival and propagation is a requisite for this assessment. In this regard, habitat suitability indices (HSI) have been developed that can be used to identify potential sites for mitigation and restoration. However, greater attention is needed on conditions for spat settlement, a bottleneck life-stage for oyster populations. Although spat may settle on many substrates, success is greatest on bivalve shells and limited by even thin layers of sediment deposition. Better understanding of currents, turbidity, sediment deposition and other conditions that influence larval settling are needed to improve HSI evaluations and the potential for successful oyster reefs.

CONTINUOUS MONITORING OF PUMPING PRESSURE AND VALVE GAPE IN THE OYSTER *CRASSOSTREA VIRGINICA* IN RESPONSE TO CHANGES IN ENVIRONMENTAL PARAMETERS.

Dana M. Frank* and **J. Evan Ward,** University of Connecticut, Department of Marine Sciences, 1080 Shennecossett Road, Groton, CT 06340.

We have developed an optical biomonitor capable of continuous short and long-term recording of pumping pressure and valve gape in bivalve molluscs. The pressure sensor is situated in the suprabranchial chamber of the oyster. The valve gape sensor is attached to the right valve during experimental trials. With this arrangement, we are able to examine the relationship between valve gape and pumping pressure, in response to measured changes in environmental parameters such as temperature, food availability, dissolved oxygen concentrations and current velocity. Laboratory trials are currently underway to establish responses to some of these variables with the goal of deploying the system, along with sensor arrays to measure these parameters, in the field. Using this method, we hope to expand the scope of our understanding about the compensatory responses of bivalve molluscs to changes in environmental parameters *in situ*. Additionally, it allows us to explore more thoroughly the mechanisms available to shellfish for controlling pumping rates. Results of laboratory trials have revealed multiple patterns of association between pumping and valve gape and have established that the system is able to record changes in these physiological parameters in real time.

A SIMPLIFIED SESTON UPTAKE MODEL FOR BIVALVES: PRELIMINARY FIELD TESTS.

Raymond Grizzle* and **Jennifer Greene,** University of New Hampshire, Jackson Estuarine Laboratory, Durham, NH 03824; **Mark Luckenbach,** Virginia Institute of Marine Science, Gloucester Point, VA 23062.

A spreadsheet-based model was developed to predict the percent of the total water column cleared of seston by suspension feeding bivalve molluscs on a daily basis:

$$\% \text{ Water Clearance} = (A \times B \times C)/(D \times E) \times 100$$

where A = mean bivalve density (# ind/m^2), B = mean individual clearance rate (m^3/individual/da), C = bottom area of reef (m^2), D = cross-sectional area of water column (m^2), and E = mean water flow speed (m/da). It is designed for use in estimating the impacts of shellfish reef restoration projects on water quality. The major simplifying assumption is a completely mixed water column, and mean clearance rates are based on literature values. We tested the model over a portion of one tidal cycle at two different sites, both blue mussel (*Mytilus edulis*) reefs, one natural and one constructed. On both occasions, upstream and downstream locations were sampled concurrently at 30-min intervals for 2 to 5 hr for in situ fluorometry and/or chlorophyll *a* from a fixed height ~10 cm above the bottom, and water depth and mid-depth water flow speed were measured. Replicate 0.16 m^2 quadrats were sampled on each reef, and mean density and size (shell length) of the live mussels were determined. The model predicted average clearance/seston uptake for the ambient water flow conditions, mussels densities, and other conditions measured on the constructed reef to be <2% of the total water flow. The field trial data corroborated the model predictions, showing no significant differences between mean upstream and downstream samples of chlorophyll *a*. For data from the natural reef, the model predicted a mean of 17.6% total clearance. During the field trial, measured chlorophyll concentrations were significantly lower downstream with a mean difference (representing seston uptake) of 16.3%. In situ fluorometry indicated an overall uptake of 28%. In conclusion, both preliminary tests showed good agreement with model predictions. Further testing is underway to determine the model's general applicability.

THE INFLUENCE OF REEF ARCHITECTURE AND SCALE ON SUCCESS OF OYSTER REEF RESTORATION.

Mark Luckenbach,* Janet Nestlerode, Paige Ross, Jr. and **Alan Birch,** Virginia Institute of Marine Science, College of William and Mary, Wachapreague, VA 23480.

Current efforts to restore oyster reefs in the Chesapeake Bay entail the placement of substrate on the shallow seabed to promote oyster settlement and reef development. Because oyster shell and other alternative cultch are in short supply and/or costly, it is important that we optimize our placement of this material to maximize restoration success. In several field experiments we have been investigating the role of three components of reef architecture—vertical relief, interstitial space and spatial scale—on the development of oyster populations and associated fauna on restored reefs. Our results indicate that modest differences in vertical relief and interstitial space have dramatic effects on early post-settlement survival of oysters and the development of viable reefs. To investigate the issue of scale and the role of reef size we have initiated a large-scale restoration experiment in the Chesapeake Bay. In a replicated block design, we have constructed high relief reef bases ranging in size from 400 m^2 to 8000 m^2 and are characterizing the development of oyster populations and associated assemblages on the reefs. Oyster recruitment and survival patterns from the first year of this study reveal significant effects of scale.

EFFECTS OF *CRASSOSTREA VIRGINICA* POPULATIONS ON SEDIMENTATION, PHYTOPLANKTON SPECIES COMPOSITION AND AMMONIA CYCLING IN EXPERIMENTAL MESOCOSMS. Jennifer Mugg Pietros and **Michael A. Rice,** Department of Fisheries, Animal and Veterinary Science, University of Rhode Island, Kingston, RI 02881.

To determine the effects of oyster populations on water quality, a mesocosm study was performed from June to October 2000. Mesocosms with a volume of 13,000 L were used, in which there was triplicate control tanks without oysters and triplicate experimental tanks each with 200 oysters (≈35 mm in valve height; nominally filtering about 55L day^{-1} ind^{-1}). Experiments were run sequentially in time for three week periods with water exchange rates ranging from 0% to 100% per day (0 to 13,000 L day^{-1}). Several parameters were measured and compared between the control and experimental tanks, including chlorophyll-a, particulate organic and inorganic matter, sedimentation rates, nitrate, ammonia, phytoplankton species and numbers, and oyster growth rates. There were no significant ($P < 0.05$) differences between tanks for most parameters, with the exceptions of rates of sedimentation and species composition of phytoplankton in the water column. Diatoms of the genus *Nitzschia* were predominant in mesocosms with oysters, and in control tanks, *Skeletonema* were dominant. Rates of ammonia excretion by oysters of various sizes was determined by the sensitive salicylate-hypochlorite method, allowing for rapid determination of excretion rates to minimize biases introduced by volatilization or tranformation of the ammonia over time. The excretion of ammonia by oysters can be described by the allometric equation $E = 50.65w^{0.6992}$, when E is the excretion rate in μg NH_3-N hr^{-1} and w is the dry soft tissue weight in g. Based upon these data, it would be expected in the three-week experimental period that an additional 470 $\mu g\ L^{-1}$ ammonia above the average control concentrations of about 40 $\mu g\ L^{-1}$ would be present in each mesocosm with oysters, but no significant difference was noted between the experimental and control tanks. This suggests that there is rapid cycling of ammonia, perhaps by uptake by the rapidly regenerating phytoplankton populations. This is publication number 3910 of the College of the Environment an Life Sciences at the University of Rhode Island, with support from the RIAES under project number H-886.

A MODIFIED HABITAT SUITABILITY INDEX FOR THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA*. Thomas M. Soniat,* Department of Biology, Nicholls State University, Thibodaux, LA 70310.

A series of habitat suitability index (HSI) models have been developed for the U.S. Fish and Wildlife Service for use in environmental impact and planning studies. HSI models assess habitat quality for particular species; their output is a numerical index from 0 to 1, where 1 represents optimal habitat and 0 represents unsuitable habitat. An HSI for eastern oysters was developed by Cake (1983) and modified by Soniat and Brody (1988). The Cake model includes variables important to larval stages (presence of cultch, mean summer salinity and a gregarious settling factor, measurable as the mean abundance of living oysters) and post-settlement stages (historic mean salinity, frequency of killing floods, substrate firmness, oyster drill density and intensity of the parasite *Perkinsus marinus*). The modification of Soniat and Brody removes the gregarious settling factor from the model, simplifies model structure, and better accounts for the negative effects of high salinity, parasitism and drill predation on oysters. The modified HSI should be tested against a new, independently-collected data set.

USE OF OYSTER HABITAT BY REEF-RESIDENT FISHES AND DECAPOD CRUSTACEANS IN THE CALOOSAHATCHEE ESTUARY, FLORIDA. S. Gregory Tolley,* Aswani K. Volety, and **Emily C. Lindland,** Florida Gulf Coast University, Fort Myers, FL 33965; **James T. Winstead,** United States Environmental Protection Agency, Gulf Breeze, FL 32561.

Habitat suitability of oyster reefs for fishes and decapod crustaceans was examined monthly at three sites in the lower Caloosahatchee Estuary. At each site, 1-m^2 lift nets containing approximately 5 liters (volume displacement) of oyster clumps were deployed for a period of two weeks. Fishes and decapods sampled averaged 94 individuals m^{-2} or 23 individuals l^{-1} oyster cluster. Nine species of decapods and 18 species of fishes were identified: reef-resident fishes included *Gobiesox strumosus, Chasmodes saburrae, Gobiosoma robustum,* and *Opsanus beta;* the xanthid *Eurypanopeus depressus* and the porcellanid *Petrolisthes armatus* represented the dominant decapod crustaceans. Organism abundance ranged from 30–197 individuals m^{-2}, density ranged from 5.2–63.3 individuals l^{-1} oysters, species diversity (H′) ranged from 0.05–1.75, species richness ranged from 4–11 species per sample, and species dominance ranged from 24.8–97.7%. Species diversity, species dominance, and organism abundance all differed significantly among stations. Among-station differences in organism density (individuals l^{-1} oyster cluster) were found for the fishes *Chasmodes saburrae*, *Gobiesox strumosus*, and *Opsanus beta*, and for the crabs *Eurypanopeus depressus*, *Menippe mercenaria*, *Panopeus* sp., and *Petrolisthes armatus*. Of these, only *E. depressus* exhibited significant seasonal variation in density (Kruskal-Wallis test: n = 79, p = 0.00007), being more abundant during the warmer months.

EFFECTS OF FRESHWATER RELEASES AND SEASON ON OYSTERS (*CRASSOSTREA VIRGINICA*) IN CALOOSAHATCHEE ESTUARY, FLORIDA.

Aswani K. Volety* and **S. Gregory Tolley**, Division of Ecological Studies, Florida Gulf Coast University, Fort Myers, FL 33965; **James T. Winstead**, U.S. Environmental Protection Agency, Gulf Ecology Division, Gulf Breeze, FL 32561.

The influence of freshwater releases and season on disease prevalence and intensity of *Perkinsus marinus*, condition index, gonadal condition, recruitment potential, and growth of oysters was examined monthly at five locations along the Caloosahatchee estuary, Florida. Temperatures and salinities at the study sites ranged from 16–33°C and 3–39 ppt respectively. Higher temperatures and salinities favored *P. marinus*. While prevalence of *P. marinus* ranged from 0 (after heavy rainfall and/or freshwater water releases) –70% (during dry winter months), overall intensity was light (0–1.3). Comparison of mortality among sites indicated that juvenile oysters tolerated salinities of 5–38 ppt. Condition index of oysters was influenced by reproductive cycle and spawning events. Spat recruitment (1–5 spat/shell) and growth of juvenile oysters was higher at sudtidal than at intertidal locations, where sparse oyster distribution and swift currents appeared to limit growth and settlement success. Oysters were reproductively active between March and October, with peak reproduction occurring from June–October. Overall, results suggest that periodic short-term freshwater releases may benefit oysters by lowering the salinity and thus the intensity of *Perkinsus marinus*. Laboratory studies suggest that adult oysters can tolerate low salinities (3ppt) for 1–2 weeks. Given high salinities and infection intensities during winter months, it is recommended that freshwater releases take place during winter instead of current summer releases.

PARASITIC AND SYMBIOTIC FAUNA INHABITING OYSTERS (*CRASSOSTREA VIRGINICA*) AND MUD CRABS (*PANOPEUS HERBSTII*) SAMPLED FROM THE CALOOSAHATCHEE ESTUARY, FLORIDA.

James T. Winstead,* United States Environmental Protection Agency, Gulf Breeze, FL 32563; **Aswani K. Volety** and **S. Greg Tolley**, Florida Gulf Coast University, Fort Myers, FL 33965.

Oysters, *Crassostrea virginica*, inhabiting five sites in the Caloosahatchee River estuary were studied over a 13 month period to determine the suitability of oyster habitat in relation to their health and condition. Histological examination of 650 oysters (10 animals per station per month) revealed a varied parasitic and symbiotic fauna inhabiting these molluscs at all stations. Organisms found included protozoans (*Nematopsis* sp. and *Perkinsus marinum*), digenetic trematodes (*Bucephalus cuculus* and the first report from this area of what appears to be *Echinostoma* sp.), cestode larvae (*Tylocephalum* sp.) and a hydrozoan inquiline symbiont (*Eutima* sp.). In addition, a significant number of mud crabs, *Panopeus herbstii*, inhabiting oyster habitat at two sites were found to be parasitized by rhizocephalan barnacles, *Loxothylacus* sp. Prevalence and pathological consequences of these organisms and the role oyster-parasite relationships may play as an indicator of ecosystem complexity (biodiversity) is discussed.

POSTERS

HABITAT AND ECOLOGY OF GREEN MUSSELS, *PERNA VIRIDIS*, IN FLORIDA.

Patrick Baker,* Fisheries and Aquatic Sciences, University of Florida, Gainesville, FL 32611; **Amy Benson,** Florida Caribbean Science Center, USGS, Gainesville, FL 32653.

The green mussel, *Perna viridis*, was introduced to Tampa Bay, Florida, prior to 1999. It is abundant from Tampa Bay to Charlotte Harbor and has appeared elsewhere in Florida. As with invasive freshwater zebra mussels (*Dreissena polymorpha*), early green mussel sightings were in industrial water intake systems, and green mussels currently foul many industrial and municipal structures. Green mussels show other parallels to invasive zebra mussels, such as reaching densities of over 10,000 per m^2 in an ecosystem that lacks a close native analog. It was with zebra mussels in mind that we initiated a study to examine the habitat and ecological impacts of green mussels. Based on preliminary results, however, predictions of green mussel ecological impacts should not be modeled upon zebra mussel impacts, for several reasons. First, green mussels in Tampa Bay have been limited to artificial substrata, such as pilings and buoys. Contrary to expectations, they rarely appear on mangroves, nor do they overgrow benthic sediments. Second, green mussels have invaded a habitat that already has a high diversity of potential competitors, such as barnacles and oysters, and known molluscivores, including flatworms, crabs, stingrays, and fish. Third, there is no early evidence of negative impacts on native taxa, with the possible exception of oysters on artificial substrata. Green mussels increase the structural diversity of the fouling community on pilings, and both the shells and the interstitial space are occupied by numerous other taxa, both native and nonindigenous. At least five native bivalves commonly occur in green mussel aggregations, for example. Ecosystem impacts of this abundant invader are almost certain to develop, but may differ considerably from those of other mussel-like invaders.

Green mussels have survived several winters in Florida, and appear to reproduce more than once annually. Their initial spread southward is consistent with dominant coastal currents, which could eventually carry larvae around to Florida's east coast. Additionally, juveniles have become abundant in aquaculture systems in Charlotte Harbor, and culturists are concerned about both their impacts on seawater systems and their potential spread via human vectors. The northern (thermal) limit of green mussels has not yet been determined.

INTRODUCING THE CLAMMRS PROJECT: CLAM LEASE ASSESSMENT, MANAGEMENT AND MODELING USING REMOTE SENSING.

Shirley Baker,* **Ed Phlips,** and **David Heuberger,** Department of Fisheries and Aquatic Sciences, Institute of Food and Agricultural Sciences, University of Florida, Gainesville, FL 32653; **Clay Montague,** Department of Environmental Engineering Sciences, University of Florida, Gainesville, FL 32653; **Leslie Sturmer,** Cooperative Extension Service, Institute of Food and Agricultural Sciences, University of Florida, Cedar Key, FL 32625.

In cooperation with the Florida Department of Agriculture and Consumer Services, Division of Aquaculture, we are addressing the needs of the emerging Florida hard clam (*Mercenaria mercenaria*) aquaculture industry. The needs we are addressing include: 1) Risk of catastrophic crop loss; 2) Optimum farm management practices; and 3) Selection of new aquaculture areas. Adoption of remote sensing technologies in management practices will enhance the sustainable development of open-water clam farming by increasing production, farm efficiency, and profitability. Specific objectives are to: 1) Install remote water-quality and weather stations in clam aquaculture areas to provide growers with timely information important to their management decisions; 2) Create a water-quality database to be used by the pilot Cultivated Clam Crop Insurance program to document events associated with crop loss; 3) Develop new techniques to monitor changes in natural food abundance and quality, such as the use of satellite imaging; 4) Develop a clam production model to examine optimum management practices to increase production and profitability; and 4) Use the production model and remote water-quality monitoring in selection of new highly productive aquaculture areas in Florida.

HEMOCYTES OF *HOMARUS AMERICANUS* STAINED WITH A MODIFIED WRIGHT-GIEMSA STAIN: DESCRIPTION AND COMPARISON TO CURRENT CLASSIFICATION SCHEMES.

Andrea Battison* and **Barbara Horney,** Department of Pathology and Microbiology; **Richard Cawthorn** and **Allan MacKenzie,** The AVC Lobster Science Centre, Atlantic Veterinary College, Charlottetown, University of Prince Edward Island, Charlottetown, PE, Canada, C1A 4P3.

Transmission electron microscopy and phase contrast light microscopy are common methods used to examine crustacean hemocytes. Using these techniques, three types of hemocytes are currently recognised in *Homarus americanus* and many other decapod crustaceans: Large Granule, Small Granule, and Hyaline hemocytes. These procedures are, however, either time consuming, costly or, do not provide a permanent record of the results. Hemocytes of *H. americanus* were classified, based on cytoplasmic and nuclear morphology, after staining cytocentrifuged preparations with a modified Wright-Giemsa stain. Up to 11 different hemocytes, Types 1 to 11, could be identified in some samples. Morphologic similarities to the Large Granule and Small Granule hemocytes were observed. Based on similarities in appearance and alterations in number during *Aerococcus viridans* infections, the Type 1 hemocyte is considered the morphologic and functional equivalent of hemocytes in the Small Granule hemocyte category with the Type 6 hemocyte being its immediate precursor. Types 2, 7, and 8 may be subsets of hemocytes included in the Large Granule hemocyte category. A counterpart of the hyaline cell has yet to be conclusively identified. This technique should prove useful in a research setting when alterations in number and types of hemocytes are being evaluated for assessment of lobster health.

IMPACT OF ATRAZINE ON ANEUPLOIDY IN THE PACIFIC OYSTER, *CRASSOSTREA GIGAS*.

Karine Bouilly, Alexandra Leitão, Helen McCombie, and **Sylvie Lapègue,** IFREMER, Laboratoire de Génétique et Pathologie, B.P. 133, 17390 La Tremblade, France.

Aneuploidy has previously been reported in the Pacific oyster, *Crassostrea gigas,* and has been shown to be negatively correlated with growth. This is especially important since high variability of growth rate is one of the major problems in the aquacultural production of the species. The present study investigated the effect of an environmental factor on the level of aneuploidy. *Crassostrea gigas* animals at adult and spat stages were subjected to different concentrations of atrazine representing peak values found in the Marennes-Oleron Bay (A: 0.01 mg/l) and a value ten times higher (B: 0.1 mg/l). Although atrazine did not show any effect on the oyster mortality, significant differences in aneuploidy level were observed between the different treatments (8% for control, 16% for treatment A and 20% for treatment B). Moreover, the same level of response was observed at adult and spat stages. Finally, the offspring of oysters previously exposed did not show any difference in larval growth but the hatching rate differed (74% for control, 62% for treatment A and 55% for treatment B). This is the first evidence for an environmental cause of aneuploidy in the Pacific oyster, *Crassostrea gigas*.

STATUS OF THE *MYTILUS EDULIS* STOCK WHICH SUPPLIES HIGH-QUALITY SPAT TO MUSSEL GROWERS IN ILES-DE-LA-MADELEINE (GULF OF ST. LAWRENCE).

François Bourque and **Bruno Myrand,** Station technologique maricole des Iles-de-la-Madeleine, Cap-aux-Meules, Canada, G0B 1B0; **Marcel Roussy,** Centre aquacole marin, Grande-Rivière, Canada, G0C 1V0.

Mussel growers in Iles-de-la-Madeleine rely mostly on Bassin du Havre-Aubert for spat supply. This small (~3 km^2) and shallow (max. depth = 3.5 m) basin have only a restricted opening to the sea and mussels spawn earlier than in any other local areas while larval growth is rapid. Thus, spat reaches sleeving size in early September. These mussels have a higher mean heterozygosity than all other local stocks and they show rapid growth and higher resistance to stress (including summer mortalites). This basin is dedicated only to spat collection and no grow-out is allowed. An unknown but possibly important harvest of wild mussels by local residents arose questions about the status of this stock which produces larvae for spat collection. In a 1997 survey, the low abundance of young mussels added worry about the future of this population. Surveys were repeated in 1999 and 2001. A very limited recruitment was observed in 1999 while large numbers of adults were moved to a new area possibly by the action of currents. However, the overall population remained stable at about 11 million individuals. In 2001, the area covered with mussels expanded considerably and recruitment was abundant. The near future of this population, and thus spat collection, seems not at risk in terms of potential for larvae production.

PREDATOR INDUCED PHENOTYPIC RESPONSE BY THE COMMON PERIWINKLE (*LITTORINA LITTOREA*).

Jason P. Breves,* RWU Box 5327, Roger Williams University, One Old Ferry Road, Bristol, RI 02809; **Andrew E. Tate,** Center for Economic and Environmental Development, Roger Williams University, Bristol, RI 02809.

An organism's phenotype depends upon both genetics and environmental influences. The relative importance of these factors is of great importance to the field of evolutionary biology. Phenotypic plasticity, the ability to provide a single generational response to an environmental pressure, has been used to describe this relationship between genetics, the environment and phenotype. Northern Yellow Periwinkles (*Littorina obtusata*) exhibit intraspecific variance in shell thickness when exposed to predation by Green crabs (*Carcinus maenus*). This response is believed to give Periwinkles a competitive advantage compared to other prey not exhibiting phenotypic plasticity. It is unknown if the Common Periwinkle (*Littorina littorea*) can alter shell morphology when exposed to predatory stress. This study examines the morphological response of Common Periwinkles to the threat of Green crab predation. Periwinkles (n = 96) were assigned in equal numbers to one of three treatment means. Mass, operculum diameter, and shell length, width and thickness were compared among Periwinkles exposed to ambient seawater (negative control), seawater containing crab effluent, or seawater with crabs and their effluent. Initial data analysis indicates differences in growth rates among the treatments. Periwinkles exposed to crabs and their effluent grew more rapidly than those in the other treatments, suggesting that rapid growth may be a response to the threat of predation.

CONTINUOUS *IN VITRO* CULTURE OF *PERKINSUS ATLANTICUS*, PARASITE OF THE CARPET SHELL CLAM *TAPES DECUSSATUS*.

Sandra M. Casas* and **Antonio Villalba,** Centro de Investigacións Mariñas, Xunta de Galicia, aptdo. 13, E-36620 Vilanova de Arousa, Spain; **Jerome F. La Peyre,** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803; **Kimberly S. Reece,** Department Virginia Institute of Marine Science, Gloucester Point, VA 23062; **Carlos Azevedo,** Department of Cellular Biology, Institute of Biomedical Sciences, University of Oporto, P-4050 Porto, Portugal.

Continuous *in vitro* cultures of the clam *Tapes decussatus* parasite *Perkinsus atlanticus* were established from infected clam gill fragments, infected clam haemolymph and parasite hypnospores isolated from infected clam gill fragments incubated in Ray's fluid thioglycollate medium (RFTM). No continuous cultures could be initiated from *P. atlanticus* zoospores. The highest success rate in establishing continuous cultures was obtained with cultures initiated from hypnospores (100%), followed by cultures initiated from gill fragments (93%) and from haemolymph (30%). The source of parasite also influenced the time taken to establish cultures and the size of cultured cells. *In vitro* proliferation of parasites was mostly by vegetative multiplication. Zoosporulation yielding motile biflagellated zoospores was observed in low proportion (<1% of dividing cells) in every culture. Morphology of cultured parasites corresponded to that of *P. atlanticus* found in clam tissues. Cultured parasites enlarged in RFTM and stained blue-black with Lugol's solution, which are characteristic of *Perkinsus* spp. DNA sequences of the internal transcribed spacer region of the ribosomal RNA gene complex matched those of *P. atlanticus*. All cultures were established in a medium designated JL-ODRP-2A which was similar in composition to the culture medium JL-ODRP-1 originally used to propagate *Perkinsus marinus in vitro*. The commercial culture medium (1:2 v/v) DME:Ham's F-12 with fetuin supported the proliferation of *P. atlanticus in vitro*.

A R&D PROGRAM TO DEVELOP *MYA ARENARIA* CULTURE IN ILES-DE-LA-MADELEINE (GULF OF ST. LAWRENCE).

Lise Chevarie, Société de développement de l'industrie maricole, Capaux-Meules, Canada, G0B 1B0; **Bruno Myrand** and **François Bourque,** Station technologique maricole des Iles-de-la-Madeleine, Cap-aux-Meules, Canada, G0B 1B0; **Michel Giguère, Lizon Provencher,** and **Philippe Archambault,** Institut Maurice-Lamontagne, Mont-Joli, Canada, G5H 3Z4; **Réjean Tremblay,** Université du Québec à Rimouski-Centre aquacole marin de Grande-Rivière, Canada, G0C 1V0.

A 5-yr R&D program started in summer 2000 to develop a profitable soft-shell clam culture in the lagoons of Iles-de-la-

Madeleine. This program looks at a scenario based on the transfer of undersized clams from an unexploited population to an aquaculture site for grow-out until legal size (>51 mm) is reached. We have focused mainly on the potential of this population to provide an annual harvest of 5 million clams. It should not be a problem considering its >265 million individuals of 15–45 mm and high recruitment. Further, the low predator abundance and the absence of pathologies (e.g. neoplasia) suggest it should not suffer heavy losses. The small hydraulic device used to resuspend the top surface layer and ease collection seems not to have negative impacts. The large size of these clams should minimize predation and net protection over seeded areas could possibly be avoided. Work has been initiated to optimize storage of large quantities of clams during the extended periods between harvesting and subsequent seeding. Experiments were also initiated to define the optimal seeding period and optimal density according to shell length.

LOSS OF EYE PIGMENTATION IN TWO GAMMARIDEAN AMPHIPODS FROM THE BIOSPHERE. Vania R. Coelho, Columbia University, Biosphere 2 Center, Oracle, AZ 85623; **Jeffrey D. Shields,*** Virginia Institute of Marine Science, Gloucester Point, VA 23062.

During an ecological assessment of amphipod populations in the Biosphere 2, several specimens of *Ceradocus rubromaculatus* and *Leucothoe spinicarpa* were observed with alterations in their eye pigmentation. For *C. rubromaculatus,* 1768 specimens were examined and 64 (%) presented with some degree of alteration. For *L. spinicarpa,* 150 specimens were examined and 91 (%) presented with some degree of alteration. Grossly, the eyes appeared either completely white with the individual retinas unpigmented, or the eyes were partially pigmented with pigmentation loss surrounding a pigmented core within the ommatidia. Histologically, the optic nerves showed a range of pathologies from minor losses of pigmentation, especially in the centrally-located ommatidia, to complete loss of pigmentation. In all cases, there was little to no damage associated with the optic nerves or the ommatidia. There was also no indication of increased infiltration of hemocytes into the optic nerve complex or the ommatidia. Pigment cells can be negatively affected by contaminants or by the lack of phytopigments in the crustacean diet. For example, crustaceans lack the ability to synthesize carotenoids and must obtain them from their diets. We speculate that the loss of pigmentation in the eyes of amphipods from the Biosphere may be caused by the lack of certain dietary phytopigments.

SHELL REPAIR RATES IN SURGICALLY DAMAGED VALVES OF THE BLUE MUSSEL (*MYTILUS EDULIS*) AND THE RIBBED MUSSEL (*GEUKENSIA DEMISSA*) FROM NEW JERSEY. Tricia L. Cranmer, Department of Marine and Environmental Studies, University of San Diego, San Diego, CA 92110; **Daniela Zima,*** Richard Stockton College of New Jersey, Pomona, NJ 08240; **Richard R. Alexander,** Department of Geological and Marine Sciences, Rider University, Lawrenceville, NJ 08648.

The blue mussel *Mytilus edulis* and the ribbed mussel *Geukensia demissa* were collected ($n = 120$) from the salt mashes of Tuckerton, New Jersey. Equal numbers of specimens ($n = 15$) were notched at, or had holes drilled near, the posterior or ventral margin of the valves of each species. These shell regions bear scars from shell-crushing crabs and holes drilled by moonsnails. Repair progresses through four stages: 1) tissue plugging the shell gap or hole, 2) extension of the periostracum over exposed tissue, 3) calcification beneath the periostracum, and 4) valve-thickening, pigmentation, and expression of a ny ornamentation. Shell repair was completed between two to seven weeks. Average repair rates are statistically significantly faster for epibyssate *M. edulis* relative to the endobyssate *G. demissa* (Mann-Whitney U test; $p < 0.05$) pooled for all types and location of shell damage. Correspondingly, field surveys show that shell repair frequency is greater among blue mussels (19% of all specimens) than ribbed mussels (10% of all specimens). Mantle tissue repaired posterior shell notches faster than the ventral margin in *M. edulis,* although shell repair rate is statistically indistinguishable between ventrally and posteriorly notched shells of *G. demissa.* Correspondingly, field surveys reveal that 96% of all shell repairs in *M. edulis* are located near the posterior margin. Mortality before completion of shell repair was significantly greater for experimentally drilled vs. notched shells of either species. Mantle tissue was damaged by penetrative shell-drilling, but not inevitably in valve margin breakage.

OVER-WINTERING OF *CRASSOSTREA ARIAKENSIS* IN LAND-BASED SYSTEMS IN VIRGINIA. Alan J. Erskine and **Standish K. Allen, Jr.,** Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

Decimation of the *Crassostrea virginica* industry in Virginia has been well documented. Recent interest has turned to non-native *C. ariakensis* culture for experimentation. We hypothesized that it was beneficial, biosecure and cost effective for industry to over-winter *C. ariakensis* inside their hatcheries. Triploid *C. ariakensis* were deployed in raceway and upweller systems at four sites in Chesapeake Bay from November 2000 to April 2001. Three size classes, 4–6mm, 6–8mm and 8–12mm, were deployed in replicate at a maximum carrying capacity of 2000 grams total wet weight. Twenty-five random oysters were sampled monthly and shucked wet weights and hinge to lip shell height measurements were recorded. A low salinity site (10–12ppt) on the bayside of Chesapeake Bay and a mid salinity site (22–25ppt) on the seaside had the highest growth at 30 mm and 3 grams. This experiment shows that over-wintering juvenile *C. ariakensis* could be incorporated as a step in the technology of non-native oyster culture.

IRRADIATION OF OYSTER PRIMARY CELL CULTURES WITH ULTRAVIOLET-LIGHT TO ELIMINATE BACTERIAL AND PROTOZOAL CONTAMINANTS.

Chwan-Hong Foo* and **Jerome F. La Peyre,** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana Agricultural Experiment Station, Baton Rouge, LA 70803.

Microbial contamination of oyster primary cell cultures is an obstacle to cell line development. *Perkinsus marinus* and *Vibrio vulnificus* are two prevalent contaminants of oyster cell cultures. Studies have shown that ultraviolet-light (UV) effectively kills certain aquatic protozoa and bacteria. Our objective was to develop a procedure to eliminate *P. marinus* and *V. vulnificus* from primary cell cultures by UV irradiation, while retaining the viability of oyster cells. Oyster heart cells, *P. marinus* and *V. vulnificus* cultures were irradiated with 50,000, 100,000, 201,000, and 402,000 μjoules/cm^2 of UV light. Two days post-irradiation, oyster cell viability was determined by measuring their metabolic activity using the MTS/PMS assay. *Perkinsus marinus* growth, 2, 4 and 6 days after irradiation, and *V. vulnificus* growth, 3, 6, and 24 hours post-irradiation, were both assessed by measuring turbidity and metabolic activity (MTS/PMS assay). Results indicated that oyster cells viability decreased significantly ($P < 0.0001$) with increasing UV energy levels. *Perkinsus marinus* growth on days 2 and 4 were significantly inhibited by all UV levels, while growth on day 6 was inhibited with UV levels above 100,000 μjoules/cm^2. *Vibrio vulnificus* growth, 3 and 6 hours post-irradiation, was inhibited ($P < 0.05$) by all UV levels, but growth rebounded 24 hours after irradiation. This study suggests that UV irradiation has a very limited ability to eliminate *P. marinus* or *V. vulnificus* without negatively affecting oyster cell primary cultures.

IN VITRO EFFECTS OF HEAVY METALS AND ATRAZINE ON PACIFIC OYSTER, *CRASSOSTREA GIGAS*, HAEMOCYTES.

B. Gagnaire,[1,2] **H. Thomas-Guyon,**[1] and **T. Renault,**[2] [1]Université de La Rochelle, Laboratoire de Biologie et Environment Marin (LBEM), avenue Michel Crépeau, 17042 La Rochelle; [2]Ifremer La Tremblade, Laboratoire de Génetique et Pathologie (LGP), Ronce-les-Bains, 17390 La Tremblade.

In the last decades shellfish culture has developed in a significant way around the world. However, culture areas are often subjected to recurring pollutions. The recrudescent use of herbicides in agriculture, including atrazine, implies pollutant transfer towards the aquatic environment in estuarine areas. Moreover, industrial wastes are sources of heavy metal contamination. It is appropriate to consider the harmful effects of pollutants in marine species, particularly in cultured molluscs. Bivalves, including mussels and oysters, have been suggested as ideal indicator organisms because of their way of life. They filter large volumes of seawater and may therefore accumulate contaminants within their tissues. The development of techniques allowing analysis of the effects of such compounds on bivalve biology may lead to monitoring of pollutant transfer in estuarine areas. In this context, the effects of atrazine and the effects of various heavy metals on defence mechanisms were analysed in Pacific oysters, *Crassostrea gigas*. Pollutant effects were tested *in vitro* on oyster haemocytes. Cell viability and activities were monitored by flow cytometry. Enzymatic phenoloxidase-like activity was also evaluated by spectrophotometry. Atrazine induced no effect on oyster haemocytes under the conditions tested. On the contrary, mercury caused a significant mortality of haemocytes maintained *in vitro*. Aminopeptidase and phenoloxidase-like activities were also modified in the presence of this pollutant.

KEY WORDS: Pacific oyster, *Crassostrea gigas*, haemocytes, flow cytometry, heavy metals, atrazine, phenoloxidase, cellular activities, toxicity

INDUCIBLE ANTIBACTERIAL ACTIVITY IN OYSTER (*CRASSOSTREA VIRGINICA*) HEMOLYMPH.

Holly A. Gefroh, Matthew J. Jenny, and **Ryan B. Carnegie,** Program in Marine Biomedicine and Environmental Sciences; and **Kevin L. Schey,** Department of Pharmacology, Medical University of South Carolina, 171 Ashley Avenue, Charleston, SC 29425; **Robert W. Chapman,** South Carolina Department of Natural Resources, 217 Ft. Johnson Rd., P O Box 12559, Charleston, SC 29422.

Oyster (*Crassostrea virginica*) tissues resist infection by marine bacteria, but the basis of this is unclear. Bacteria invading internal spaces are quickly agglutinated and phagocytosed by hemocytes; however, areas where hemocytes are not active (e.g., epithelial surfaces) also resist heavy colonization. Oyster lysozyme kills bacteria, but is thought to be only weakly effective against the most common marine species (Gram-negatives). Soluble bacteriolytic peptides found in many organisms, including the mussel *Mytilus edulis*, may supplement phagocytosis and the activity of lysozyme in oysters as well.

Our objectives were to determine whether or not anti-Gram-negative bacterial activity could be induced in the hemolymph of *C. virginica*, and if so, to isolate and characterize its source. Lipopolysaccharide (LPS), laminarin, or dH$_2$O control was injected into the adductor muscles of wild *C. virginica* (N = 6 oysters/treatment) collected locally. Hemolymph was collected from the adductor muscles at 12 and 24 h and pooled by time interval and treatment type. Soluble protein from cell-free hemolymph plasma was desalted using a C_{18} column, eluted with 50% acetonitrile, dried down and reconstituted in dH_2O, and spotted on a plate lawn of *Escherichia coli*. Plasma protein samples from LPS-challenged (12 and 24 h post-challenge) and laminarin-challenged (24 h) oysters inhibited *E. coli* growth, while plasma protein from unchallenged oysters did not.

The induced antibacterial activity passed through a 10-kilodalton (kDa) cutoff membrane. Further separation by reversed phase high performance liquid chromatography (HPLC) and analysis by matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) revealed several peptides around 3–7 and 9.5 kDa to be candidates for its source. These candidate peptides are currently being sequenced.

CONSTRUCTING SHELLFISH REEFS IN A POLLUTED, URBAN ESTUARY: SCIENTISTS JOIN WITH THE COMMUNITY TO WORK FOR A COMMON GOAL. **Jennifer Greene,* Raymond Grizzle, David Burdick, and Larry Ward,** Jackson Estuarine Laboratory, University of New Hampshire, Durham, NH 03824; **Ann Reid,** Great Bay Coast Watch, Sea Grant Cooperative Extension, Durham, NH 03824.

South Mill Pond, a 7-hectare estuarine embayment in the City of Portsmouth, New Hampshire has been receiving combined sewer overflows since the late 1800s. A tide gate controls water flow into and out of the Pond and there is a road causeway with box culverts that separates the Pond into inner and outer sections. The City has a major sewer re-construction project underway that will, when completed, reduce inputs of sanitary sewer wastes. Scientists joined with the City, students from local schools, and local volunteers to begin ecological restoration of the Pond in 2001. Six shellfish "mini-reefs" (each 2 × 5 m in surface area) were constructed in May using mussels (*Mytilus edulis*) transplanted from a nearby natural reef. Mortalities as high as 80% occurred on the three reefs in the inner pond within the first 2 months, likely as a result of elevated temperatures caused by extended closure of the broken tide gate during June and July. Hence, three additional mussel reefs were constructed in the inner pond in October 2001. Oysters (*Crassostrea virginica*) remotely set at Jackson Estuarine Laboratory were added as 3-month old spat to the three new reefs in the inner pond and the three original reefs in the outer pond in October, resulting in six mussel/oyster reefs. Eighth grade students participated in construction of the mussel reefs and third graders participated with the oysters. Community volunteers also participated in reef construction and post-construction monitoring. Three quadrat ($0.16\ m^2$) samples per reef showed initial mean mussel densities on the six original reefs constructed in May ranged from 150 to 930 m^{-2}. After 6 months (November), mussel densities had dropped to 50 to 115 m^{-2} on the six original reefs but size-frequency plots showed an average increase in shell length of 5 mm in the largest size class of mussels over the first 3 months, indicating good individual growth rates. Recruitment into the smallest size classes also occurred on some reefs. Using the same sampling protocol, initial mussel densities on the three new reefs ranged from 430 to 1376 m^2. Future work will include continued monitoring of all nine reefs, construction of abutting saltmarsh, and environmental monitoring.

THE EASTERN OYSTER AS AN INDICATOR SPECIES TO ESTABLISH RESTORATION TARGETS IN SOUTHWEST FLORIDA ESTUARIES. **Rashel V. Grindberg,* Erin C. Rasnake, Michael Savarese, and Aswani K. Volety,** Florida Gulf Coast University, College of Arts & Sciences, 10501 FGCU Blvd South, Ft. Myers, FL 33965.

Water management practices within Southwest Florida have drastically altered natural water quality conditions within estuaries. The ecological and physiological responses of oysters, *Crassostrea virginica*, were compared among pristine (Blackwater River), semi-altered (Henderson Creek) and altered (Faka-Union canal) estuaries with historically similar hydrologic conditions. In the Faka-Union estuary, a system that receives excessive freshwater during the rainy season, the distribution of reefs, the regions of maximum living density, and the foci of maximum productivity are displaced seaward relative to pristine estuaries. Henderson Creek, an estuary receiving pulses of nutrients and freshwater due to weir design, has oyster populations with higher mean productivities and higher living densities. While upstream locations in all three estuaries have lower disease prevalence among adult oysters, juveniles experience heavy mortality due to freshwater releases. Overall growth rates are higher at upstream locations. Spat recruitment occurred between June and October in all estuaries.

Faka-Union and Henderson Creek estuaries are scheduled for restoration. The patterns of oyster distribution and physiology will help establish target restoration conditions and provide a foundation for the monitoring of restoration effectiveness in Southwest Florida estuaries. Henderson Creek is presently undergoing restoration through the retrofitting of its upstream weir to permit dynamic control of freshwater release. Sheet flow should be restored to Faka-Union in order to re-establish salinity levels favorable for maximum reef development, living density, oyster growth, recruitment, and productivity. Changes in oyster ecological and physiological conditions will be monitored over subsequent years to gauge restoration effectiveness.

LONG-TERM CHANGES IN INTERTIDAL OYSTER REEFS IN A FLORIDA LAGOON POTENTIALLY CAUSED BY BOATING ACTIVITIES: AN ANALYSIS OF AERIAL PHOTOGRAPHS FROM 1943–2000.

Raymond Grizzle* and **Jamie Adams**, Jackson Estuarine Laboratory, University of New Hampshire, Durham, NH 03824; **Linda Walters**, Department of Biology, University of Central Florida, Orlando, FL 32816.

Previous research in the late 1990s had shown that some intertidal oyster (*Crassostrea virginica*) reefs in that portion of the Mosquito Lagoon within the Canaveral National Seashore, Florida had dead margins consisting of mounded up, disarticulated shells. It was hypothesized that boating activities were the cause of the damage because all the reefs were adjacent to major boating channels. We characterized the history of the appearance of dead margins (and other reef changes) using aerial photographs taken between 1943 and 2000. Imagery analyzed included prints (black & white, color, or color infrared) from 1943, 1951, 1963, 1975, 1988, and 1995, and digital imagery from 2000 (USGS 1:12,000 digital ortho-quarterquads), at scales from 1:6,000 to 1:24,000. Prints were scanned at a resolution sufficient to yield 1-m pixels. After scanning, each set of images was referenced to the year 2000 imagery using ArcView and ArcInfo GIS software. All reefs found to have dead margins based on 1995 and 2000 aerials were visited in November 2001 to confirm the presence and extent of dead areas. This provided a general ground-truthing for the "signature" (a highly reflective, light-colored area adjacent to darker-colored live reef) to be used to detect the appearance of dead margins in the historical aerials. The earliest appearance of dead margins was in the 1975 aerials on reefs adjacent to the intracoastal waterway (ICW), a major boating channel. The total number and areal extent of dead margins increased with time. Our current preliminary estimate is that between 10 and 20% of the reefs in the Seashore have been damaged. The most dramatic changes have occurred in reefs along the ICW, some apparently migrating away from the channel as much as 50 m and with empty shells mounded up a meter above the high water line. This historical analysis provides strong (although only correlative) evidence that boating activity has had dramatically detrimental effects on some oyster reefs in the study area. Ongoing studies are aimed at further testing this hypothesis and elucidating the actual mechanisms involved.

AN OYSTER (*CRASSOSTREA VIRGINICA*) REEF RESTORATION EXPERIMENT IN NEW HAMPSHIRE INVOLVING CROSBREED STOCK AND NATIVE TRANSPLANTS.

Raymond Grizzle, Jennifer Greene, and **Stephen Jones**, Jackson Estuarine Laboratory, University of New Hampshire, Durham, NH; **Mark Luckenbach** and **Roger Mann**, Virginia Institute of Marine Science, Gloucester Point, VA.

The first documented MSX epizootic in New Hampshire occurred in 1995, resulting in dramatic declines in oyster abundances on some reefs. The present project is the first experimental scale effort in the State aimed at development of a long-term program to mitigate the effects of disease. In 1999, studies were initiated in the Salmon Falls River to: (1) characterize a disease-decimated reef, (2) restore portions of the reef using spat from CROSBreed stock (an MSX and dermo-resistant line) and transplanting of native oysters, and (3) determine the effects of the restored reef on water quality. Here we report on the first two objectives. Diver surveys, tonging, and underwater videography indicated the overall bottom area probably dominated by oysters before 1995 extended along the main channel a total distance of 350 m with an average width of 15 m. Quadrat sampling in 2000 and 2001 showed this area was numerically dominated by the ribbed mussel (*Geukensia demissa*) with a mean density of 40 m^2; oysters were 20 m^2, and the blue mussel (*Mytilus edulis*) 5 m^2. Maximum, mean horizontal free-stream flow speed measured over portions of two tidal cycles with an acoustic Doppler velocimeter was 32 cm s^{-1}. In May 2000, approximately 230 bushels of native oysters, dredged from the Piscataqua River about 1 km south of the study site, were deposited in an area measuring 10 × 30 m on the natural reef bottom. Spat from CROSBreed stock were remotely set in June of 2000, held in bags for 4 months, then transferred to a 10 × 20 m area on the natural reef. In October 2001, after 1 year of development, the CROSBreed reef area had a mean density of 226 oysters m^2, compared to 90 m^2 on the native transplant reef, and 36 m^2 on the natural reef. The CROSBreed oysters have shown good growth, increasing from a mean size of 26.8 mm shell height when put out in October 2000 to 48.6 mm in October 2001, and no measurable mortality. Natural spat set in 2000 was greatest on the CROSBreed reef, suggesting a "minimum threshold density" for successful natural recruitment to restored reef areas.

WHAT CERTAIN 19TH AND EARLY 20TH CENTURY NAVIGATIONAL AND SPECIAL PURPOSE SURVEY CHARTS REVEAL ABOUT CHANGES IN THE OYSTER REEF MORPHOLOGY OF THE LOWER CHESAPEAKE BAY.

William J. Hargis, Jr., Helen E. Woods,* Rebecca Arenson, Sharon Dewing, Arman Kaltayev, Elizabeth Mountz, Marcia R. Berman, and **Dexter S. Haven**, Center for Coastal Resources Management, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

The decline of commercial oyster production in the lower James River is reflected in the reduction of oyster-reef dimensions over time. Employing navigational hydrographic survey charts made by the U.S. Coast Survey in 1854-55, 1871-73, and 1940s and oyster survey charts made in 1878 and 1909 by the USCGS and the old U.S. Fish Commission, we examine changes in the dimensions of the natural oyster reefs of the lower James River, Chesapeake Bay, and discuss the likely cause of those changes.

MORPHOLOGY OF A CHESAPEAKE BAY OYSTER REEF SYSTEM IN 1871–1873.

William J. Hargis, Jr., Helen E. Woods,* Rebecca Arenson, Elizabeth Mountz, Marcia R. Berman, and **Sharon Dewing,** Center for Coastal Resources Management, Virginia Institute of Marine Science, Gloucester Point, VA 23062.

During research on oyster reef evolution in the Chesapeake Bay it became apparent that those once prominent benthic features must have influenced their surrounding significantly. To investigate the extent of that influence on the geomorphology, hydrodynamics, and other ecologically important features, we developed a 3 dimensional presentation of the once highly productive oyster reef system of the James River estuary. Charts of the study are drawn from soundings made by the U.S. Coast Survey in 1871–73 were employed. Soundings were digitized on a Numonics 2200 digitizing tablet interfaced with ArcInfo running in a UNIX operating environment. The coordinate grids were projected to NAD27. A 3-D TIN (Triangulated Irregular Network) model generated the picture of the bottom of the study area extant in 1871–73. The 3-D presentation, center-piece of our presentation, clearly depicts the oyster reef system of 1871–73. Extending into the intertidal and acting as a massive system of weirs and baffles, the upthrusting reefs (Hargis, In Press) must have affected deposition, scouring and erosion, not only near field but more distantly, even into the shallows and adjacent shorelines. Undoubtedly, they influenced biological processes too.

GEOGRAPHIC VARIATION IN NUCLEAR GENES OF THE EASTERN OYSTER *CRASSOSTREA VIRGINICA*.

Cindi A. Hoover* and **Patrick M. Gaffney,** Graduate College of Marine Studies, University of Delaware, Lewes, DE 19958.

Studies of genomic DNA in the eastern oyster, *Crassostrea virginica*, have uncovered genetic discontinuities in population structure. Like most benthic marine invertebrates, *C. virginica* has a planktonic larval stage, which is in principle capable of widespread dispersal. If extensive dispersal occurs, one would expect to observe genetic homogeneity across the geographic range of the species. However, studies have found geographic genetic heterogeneity in both mitochondrial DNA (mtDNA) and nuclear DNA (nDNA) of *C. virginica*. The break in mtDNA has prompted the division of the *C. virginica* into Atlantic and Gulf coast subpopulations. However, unlike mtDNA, the degree of nDNA differentiation is still poorly known. This study examines nDNA from Atlantic and Gulf coast oyster populations for genetic polymorphisms using restriction endonuclease fragment length (RFLP) analysis, denaturing gradient gel electrophoresis (DGGE), and direct sequencing. Nuclear primers are currently being screened for polymorphisms in a panel of organisms representing the geographic range from Canada to Mexico. This work will improve on previous research by examining additional nuclear markers and will help clarify the question of large-scale variation between Gulf and Atlantic coast oyster populations as well as shed light on smaller-scale regional patterns of variation.

CHARACTERIZATION AND MANIPULATION OF SEX STEROIDS AND VITELLOGENIN IN FRESHWATER MUSSELS.

Nicola J. Kernaghan* and **Eileen Monck,** University of Florida, College of Veterinary Medicine, Gainesville, FL; **Carla Wieser** and **Timothy S. Gross,** USGS/BRD/Florida Caribbean Science Center, Gainesville, FL.

The characterization and manipulation of sex steroids and vitellogenin in freshwater mussels, is critical for the development of artificial culture procedures and the evaluation of reproductive health of populations. The current study included an evaluation of reproductive cycles and vitellogenin in *Elliptio buckleyi*. In addition, female *Elliptio buckleyi* and *Lampsilis teres* were exposed to exogenous estradiol to induce spawning. Body tissues were collected from adult mussels and standard RIA procedures were utilized for androgen, and estrogen analyses. Vitellogenin, an egg yolk protein produced under the influence of sex steroids, was determined using an indirect method developed by Blaise et al. (1999). Sex steroid concentrations were found to be closely correlated to reproductive activities and spawning. Tissue concentrations of both vitellogenin and estrogen were significantly elevated following exposure to exogenous estradiol. Histological examination of gonad tissue also indicated changes in reproductive status. The development of these procedures for use with freshwater mussel species will be critical to the elucidation of potential habitat and contaminant effects on reproductive function, as well as the culture of endangered species.

A SPECIFIC ASSOCIATION OF DOCOSAHEXAENOIC FATTY ACID WITH CARDIOLIPINS OF SOME MARINE BIVALVES.

Edouard Kraffe,* Philippe Soudant, Yanic Marty, and **Nelly Kervarec,** Université de Bretagne Occidentale, UMR 6521 and UMR 6539, BP 809 29200 Brest, France; **Pierre Guenot** CRMPO, Université de Haute Bretagne, 35042 Rennes cedex, France.

A cardiolipin (CL) class, also termed diphosphatidylglycerol, was isolated by high performance liquid chromatography from lipid extracts of *Pecten maximus, Crassostrea gigas* and *Mytilus edulis*, and characterized by analytical and spectroscopic methods. The fatty acid (FA) composition of this CL represents a specific association with docosahexaenoic acid [22:6(n-3), DHA], which accounted for more than 90% w/w of the total FA of this class. The structural determination by nuclear magnetic resonance spectrometry and positive ion electrospray mass spectrometry verified a configuration having four identical 22:6(n-3) molecules. This specific composition is different from those already reported in other eukaryotes. Indeed, CL acyl chains reported in the literature are mainly composed of monounsaturated or diunsaturated chains with

16 or 18 carbon atoms. The DHA-enriched CL may reflect a specific adaptation in bivalves that enhances the structural and functional mechanisms of biomembranes in response to environmental variations (temperature, salinity, emersion).

HEMOCYTE-MEDIATED DEFENSE RESPONSES OF THE LOBSTER *HOMARUS AMERICANUS*. **Brenda S. Kraus,* Amy E. Beaven,** and **Robert S. Anderson,** Chesapeake Biological Laboratory, University of Maryland Center for Environmental Science, P. O. Box 38, Solomons, MD 20688.

Lobster hemocytes held in primary culture avidly phagocytosed untreated yeast cells labeled with fluorescein succinimidyl ester. However, serum-treated yeast cells were less readily ingested by the hemocytes. Serum agglutinins can serve to facilitate phagocytosis of certain foreign particles (opsonization). Although anti-yeast agglutinins were present in lobster serum they seemed to inhibit phagocytosis, perhaps by blocking sites involved with recognition by hemocytes. Bacterial agglutinins have also been measured in lobster sera; their role as opsonins is under study. After appropriate stimulation by phagocytosis or membrane perturbation, hemocytes can produce cytotoxic reactive oxygen species (ROS) which contribute to host defenses by destroying microorganisms. Luminol-augmented chemiluminescence (CL) was used to quantify ROS generation by lobster hemocytes. Phorbol myristate acetate (PMA), a protein kinase C activator, was shown to elicit ROS in hemocytes withdrawn from healthy lobsters, based on hemolymph protein concentration. However, phagocytosis of *Listonella anguillarum* infrequently (~25%) produced a ROS activity in PMA-responding animals. Opsonization of *L. anguillarum* with serum did not enhance CL; this was not unexpected because no anti-*L. anguillarum* agglutinin activity was detected in lobster serum. Studies related to the role of agglutinins in recognition and effector mechanisms of lobster hemocytes using other biotic and abiotic test particles are in progress.

POTENTIAL ELIMINATION OF THE PROTOZOAN PATHOGEN *PERKINSUS MARINUS* FROM EASTERN OYSTERS BY FRESHET EVENTS. **Megan K. G. La Peyre,*** U.S.G.S. Louisiana Cooperative Research Unit, School of Forestry, Wildlife and Fisheries, Louisiana State University, Baton Rouge, LA 70803; **Amy D. Nickens** and **Jerome F. La Peyre,** Cooperative Aquatic Animal Health Research Program, Department of Veterinary Science, Louisiana State University Agricultural Center, Baton Rouge, LA 70803.

Environmental conditions have long been held to be critical controls on host-parasite interactions but little attention has been paid to the effects of short-term events on host-parasite interactions. We tested the hypothesis that freshet events may be detrimental to *P. marinus* while having only minimal impacts on *C. virginica* survival. Research based predominantly on environmental averages has led to the consensus that environmental conditions such as salinity and temperature control *P. marinus* infection in *C. virginica*. In contrast, salinity records from the Gulf coast indicate that there is considerable variation in salinity, and several studies have suggested that freshet events may be related to low *P. marinus* infection intensities of oysters in certain areas. In order to determine the effects of freshets on *C. virginica* and *P. marinus*, we initiated a controlled laboratory experiment. In April, July and December, 2001, oysters collected from Grand Isle, LA were divided equally between a control system (maintained at 20 ppt) and a treatment system (salinity lowered from 20 ppt to 0-1 ppt over 48 hours). Thirty oysters were sampled weekly from each tank and infection intensities determined. Oyster mortality was monitored daily. Treatment oysters did have reduced *P. marinus* body burden, but actual success was highly dependent on the season. *Crassostrea virginica* was not adversely affected by freshet events in cool temperature, spring and winter experiments, but experienced high mortality during a summer freshet event. Since most freshet events occur in winter-spring months, the use of controlled freshwater events might present a potential management tool for reducing *P. marinus* infection in oysters.

A FIELD INVESTIGATION OF THE EFFECTS OF V-NOTCHING ON THE HEALTH AND SUSCEPTIBILITY TO INFECTION OF OVIGEROUS FEMALE AMERICAN LOBSTERS. **Jean Lavallée,*** AVC Lobster Science Centre, University of Prince Edward Island, 550 University Avenue, Charlottetown, PE, Canada, C1A 4P3; **Donald J. Rainnie,** AVC Inc., 550 University Avenue, Charlottetown, PE, Canada, C1A 4P3.

V-notching is a fishery management practice consisting of marking ovigerous lobsters by punching a V shaped notch in the tail before returning it to the seawater. This study investigated some of the possible effects of V-notching on the health of ovigerous lobsters during the 2000 fall fishing season on Prince Edward Island. One hundred and thirty ovigerous lobsters were physically examined and assigned to two treatment groups. Hemolymph samples were collected from 15 lobsters from each treatment group and analysed for total protein (TP), total hemocyte counts (THC) and for the presence of *Aerococcus viridans, Anophryoides haemophila* and *Vibrio spp.* Lobsters were housed individually in cages containing 2, 3 or 4 compartments. Lobsters from the treated group were V-notched immediately prior to returning the cages to the sea bottom. Monitoring for mortality, and vigor status was conducted at least weekly. Hemolymph was taken on 15 lobsters of both treatment groups for TP and THC at the mid-point in the study. At study termination (55 days), all lobsters were re-examined and hemolymph was sampled for determination of TP, THC and presence of *A. viridans, An. haemophila* and *Vibrio spp.* Additionally, 2 V-notched lobsters were sampled on Days 1, 3, 6, 13, 27 & 55 for presence of *A. viridans, An. haemophila* and *Vibrio spp.* and for histological assessment of the wound. Mortality during the course of the study was limited to one lobster, and reflected an act of cannibalism. There was no significant difference ($p > 0.05$) between the two treatment groups for any parameter monitored. Histological examination of the V-notch wound revealed that the wounds appeared well sealed off to the environment by the rapid infiltration of hemocytes by 24 hours.

A PRELIMINARY LINKAGE MAP FOR THE PACIFIC OYSTER *CRASSOSTREA GIGAS*, CONSTRUCTED WITH RAPD AND AFLP MARKERS.

Li Li,* Institute of Oceanology, Chinese Academy of Science, 7 Nanhai Road, Qingdao, Shandong 266071, China; **Ximing Guo,** Haskin Shellfish Research Laboratory, Institute of Coastal and Marine Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349.

The development of genetic markers and linkage maps is an important step toward the identification and potential improvement of commercially important traits in oysters. The construction of a linkage map requires a large number of molecular markers, which have been a challenge in oysters. Microsatellites are probably the best markers for linkage mapping, but they are expensive to develop and not readily available to many labs. Therefore, we developed relatively inexpensive markers such as the random amplified polymorphic DNA (RAPD) and amplified fragment length polymorphism (AFLP) markers for linkage mapping in the Pacific oyster *Crassostrea gigas* Thunberg. Selected markers were used for linkage mapping in a reference family with 75 progenies. The reference family was a backcross of an interstrain hybrid to one of the parental strain, ((Miyagi × Hiroshima) × Miyagi). In this study, 110 RAPD primers were screened with the parents and five progenies, and 25 primers with at least one reliable and segregating band were selected for mapping analysis. The 25 primers generated 259 bands, of which 102 (39%) were polymorphic in the two parents. The number of segregating RAPD markers was 41 in the mother and 17 in the father. Using ten AFLP primer combinations, 802 peaks were obtained, of which 253 (32%) are polymorphic. The number of segregating AFLP markers was 81 in the mother and 50 in the father. A preliminary female linkage map was constructed with 122 RAPD and AFLP markers covering all ten chromosomes, and details of the map will be presented at the meeting.

GONADAL MATURATION OF TRIPLOID SCALLOPS *ARGOPECTEN PURPURATUS* LAMARCK, 1819.

Karin B. Lohrmann,* Elisabeth von Brand, and **Cristian Gallardo,** Universidad Católica del Norte, Facultad de Ciencias del Mar, Cas. 117, Coquimbo, Chile.

It is expected that in triploid organisms the energy normally used for reproduction would be allocated to growth. However, not all triploid molluscs are completely sterile; and in some cases even gametes are produced. The aim of this study was to assess the gonadal development in the native scallop *Argopecten purpuratus* induced to triploidy.

A. purpuratus is a functional hermaphrodite, the male gonad being creamy-white, located proximal to the foot, and the distal female gonad is bright orange-red. They were induced to triploidy with 6-dimethylaminopurine (6-DMAP). Treated (=induced) and control scallops were processed for histology using routine methods. At the age of 11 months, when the control scallops were mature, some treated scallops had a gonad which showed a uniform brown colour. These were true triploids as evaluated through chromosomal counts. They showed the tendency of reducing the female gonad, only few pre-vitelogenic oocytes were observed, in otherwise empty acini. The male gonad was relatively more developed, but no gametes further than secondary spermatocytes or early spermatids with no flagella were detected.

DETECTION OF THE WHITE SPOT SYNDROME VIRUS (WSSV) IN CARCINOLOGIC FAUN ASSOCIATED TO SHRIMP CULTURE OF SINALOA, MEXICO, USING POLYMERASE CHAIN REACTION (PCR) AND *IN SITU* HYBRIDIZATION.
